Prakata

Akuntansi merupakan sebuah cabang ilmu dalam bidang Ekonomi yang memb ahas transaksi dan pencatatannya dalam ilmu ekonomi termasuk bisnis secara praktek. Akuntansi sebagai sebuah ilmu juga sering dikaitkan dengan aktifitas di pasar modal. Buku ajar ini mencoba memberikan gambaran mengenai akuntansi dan pasar modal dengan kumpulan jurnal dari berbagai jurnal internasional.

Seperti disebutkan bahwa buku merupakan kumpulan jurnal yang membahas tentang akuntansi dan pasarm modal dan diperuntukkan bagi mahasiswa Doktor Keuangan dan juga Doktor Akuntansi. Paper ini dimulai dengan menjelaskan tentang evaluasi dan angka akuntansi dan disambung dengan infromasi yang berkaitan akuntansi dan pasar modal. Angka akuntansi tersebut sering disebutkan pendapatan perusahaan dimana pendapatan perusahaan ini menjadi informasi yang berkaitan dengan harga saham di bursa saham. Kemudian pembahasan perubahan pendapatan perusahaan selalu berkaitan dengan perubahan harga saham di Bursa. Perubahan pendekatan akuntansi dalam perusahaan tersebut bisa juga mempengaruhi pasar modal. Keterbukaan perusahaan sangat penting bagi investor untuk bisa menganalisis harga saham dalam rangka memberi keputusan untuk membeli atau menjual saham yang dianalisis. Pengumuman perusahaan atas pendapatan juga merupakan transparansi perusahaan yang diwajibkan oleh regulator yaitu Bursa dan Otoritas Jasa Keuangan (OJK). Informasi tersebut juga bisa diperoleh melalui pihak orang dalam sehingga mengetahui bagaimana sewajarnya harga saham tersebut. Adanya perdagangan orang dalam juga menjadi topik bahasan dalam buku ajar ini. Kepemilikan saham perusahaan juga bisa mempengaruhi harga saham karena pemilik yang memiliki reputasi juga bisa membuat harga saham menjadi menarik.

Buku ini merupakan bahan bacaan para pengikut kuliah Akuntansi dan Pasar Modal di berbagai Program Doktor Ilmu Manajemen, karena buku ini merupakan kumpulan jurnal. Berbagai jurnal baik teori maupun empiris dikumpulkan dalam rangka bahan ajar untuk mahasiswa Doktor.

Buku ini masih banyak kekurangannya, sehingga kritik yang sangat membangun sangat terbuka kami terima dan kami mengharapkan kritikan tersebut. Buku ini akan terus diperbaharui dalam rangka mendapatkan informasi dan teori baru dalam bidang Akuntansi dan Pasar Modal. Kami mengucapkan terima kasih atas bantuan semua pihak sehingga terbitnya buku ini

Hormat kami,

Prof. Dr. Nera Miranda Machdar, S.E.Ak, CA, CSRA., CSP, BKP
Dr. M. Jhonni Sinaga, S.E., M.M., CIPFM, CIERM

An Empirical Evaluation of Accounting Income Numbers

RAY BALL* and PHILIP BROWN†

Accounting theorists have generally evaluated the usefulness of accounting practices by the extent of their agreement with a particular analytic model. The model may consist of only a few assertions or it may be a rigorously developed argument. In each case, the method of evaluation has been to compare existing practices with the more preferable practices implied by the model or with some standard which the model implies all practices should possess. The shortcoming of this method is that it ignores a significant source of knowledge of the world, namely, the extent to which the predictions of the model conform to observed behavior.

It is not enough to defend an analytical inquiry on the basis that its assumptions are empirically supportable, for how is one to know that a theory embraces all of the relevant supportable assumptions? And how does one explain the predictive powers of propositions which are based on unverifiable assumptions such as the maximization of utility functions? Further, how is one to resolve differences between propositions which arise from considering different aspects of the world?

The limitations of a completely analytical approach to usefulness are illustrated by the argument that income numbers cannot be defined substantively, that they lack "meaning" and are therefore of doubtful utility.[1] The argument stems in part from the patchwork development of account-

* University of Chicago. † University of Western Australia. The authors are indebted to the participants in the Workshop in Accounting Research at the University of Chicago, Professor Myron Scholes, and Messrs. Owen Hewett and Ian Watts.

[1] Versions of this particular argument appear in Canning (1929); Gilman (1939); Paton and Littleton (1940); Vatter (1947), Ch. 2; Edwards and Bell (1961), Ch. 1; Chambers (1964), pp. 267–68; Chambers (1966), pp. 4 and 102; Lim (1966), esp. pp. 645 and 649; Chambers (1967), pp. 745–55; Ijiri (1967), Ch. 6, esp. pp. 120–31; and Sterling (1967), p. 65.

ing practices to meet new situations as they arise. Accountants have had to deal with consolidations, leases, mergers, research and development, price-level changes, and taxation charges, to name just a few problem areas. Because accounting lacks an all-embracing theoretical framework, dissimilarities in practices have evolved. As a consequence, net income is an aggregate of components which are not homogeneous. It is thus alleged to be a "meaningless" figure, not unlike the difference between twenty-seven tables and eight chairs. Under this view, net income can be defined only as the result of the application of a set of procedures $\{X_1, X_2, \cdots\}$ to a set of events $\{Y_1, Y_2, \cdots\}$ with no other definitive substantive meaning at all. Canning observes:

> What is set out as a measure of net income can never be supposed to be a fact in any sense at all except that it is the figure that results when the accountant has finished applying the procedures which he adopts.[2]

The value of analytical attempts to develop measurements capable of definitive interpretation is not at issue. What is at issue is the fact that an analytical model does not itself assess the significance of departures from its implied measurements. Hence it is dangerous to conclude, in the absence of further empirical testing, that a lack of substantive meaning implies a lack of utility.

An empirical evaluation of accounting income numbers requires agreement as to what real-world outcome constitutes an appropriate test of usefulness. Because net income is a number of particular interest to investors, the outcome we use as a predictive criterion is the investment decision as it is reflected in security prices.[3] Both the content and the timing of existing annual net income numbers will be evaluated since usefulness could be impaired by deficiencies in either.

An Empirical Test

Recent developments in capital theory provide justification for selecting the behavior of security prices as an operational test of usefulness. An impressive body of theory supports the proposition that capital markets are both efficient and unbiased in that if information is useful in forming capital asset prices, then the market will adjust asset prices to that information quickly and without leaving any opportunity for further abnormal gain.[4] If, as the evidence indicates, security prices do in fact adjust rapidly to new information as it becomes available, then changes in security prices will re-

[2] Canning (1929), p. 98.

[3] Another approach pursued by Beaver (1968) is to use the investment decision, as it is reflected in transactions volume, for a predictive criterion.

[4] For example, Samuelson (1965) demonstrated that a market without bias in its evaluation of information will give rise to randomly fluctuating time series of prices. See also Cootner (ed.) (1964); Fama (1965); Fama and Blume (1966); Fama, *et al.* (1967); and Jensen (1968).

flect the flow of information to the market.[5] An observed revision of stock prices associated with the release of the income report would thus provide evidence that the information reflected in income numbers is useful.

Our method of relating accounting income to stock prices builds on this theory and evidence by focusing on the information which is unique to a particular firm.[6] Specifically, we construct two alternative models of what the market expects income to be and then investigate the market's reactions when its expectations prove false.

EXPECTED AND UNEXPECTED INCOME CHANGES

Historically, the incomes of firms have tended to move together. One study found that about half of the variability in the level of an average firm's earnings per share (EPS) could be associated with economy-wide effects.[7] In light of this evidence, at least part of the change in a firm's income from one year to the next is to be expected. If, in prior years, the income of a firm has been related to the incomes of other firms in a particular way, then knowledge of that past relation, together with a knowledge of the incomes of those other firms for the present year, yields a conditional expectation for the present income of the firm. Thus, apart from confirmation effects, the amount of new information conveyed by the present income number can be approximated by the difference between the actual change in income and its conditional expectation.

But not all of this difference is necessarily new information. Some changes in income result from financing and other policy decisions made by the firm. We assume that, to a first approximation, such changes are reflected in the average change in income through time.

Since the impacts of these two components of change—economy-wide and policy effects—are felt simultaneously, the relationship must be estimated jointly. The statistical specification we adopt is first to estimate, by Ordinary Least Squares (OLS), the coefficients (a_{1jt}, a_{2jt}) from the linear regression of the change in firm j's income ($\Delta I_{j,t-\tau}$) on the change in the average income of all firms (other than firm j) in the market ($\Delta M_{j,t-\tau}$)[8] using data up to the end of the previous year ($\tau = 1, 2, \cdots, t-1$):

$$\Delta I_{j,t-\tau} = \hat{a}_{1jt} + \hat{a}_{2jt}\Delta M_{j,t-\tau} + \hat{u}_{j,t-\tau} \qquad \tau = 1, 2, \cdots, t-1, \qquad (1)$$

[5] One well documented characteristic of the security market is that useful sources of information are acted upon and useless sources are ignored. This is hardly surprising since the market consists of a large number of competing actors who can gain from acting upon better interpretations of the future than those of their rivals. See, for example, Scholes (1967); and footnote 4 above. This evaluation of the security market differs sharply from that of Chambers (1966, pp. 272–73).

[6] More precisely, we focus on information not common to all firms, since some industry effects are not considered in this paper.

[7] Alternatively, 35 to 40 per cent could be associated with effects common to all firms when income was defined as tax-adjusted Return on Capital Employed. [Source: Ball and Brown (1967), Table 4.]

[8] We call M a "market index" of income because it is constructed only from firms traded on the New York Stock Exchange.

where the hats denote estimates. The expected income change for firm j in year t is then given by the regression prediction using the change in the average income for the market in year t:

$$\Delta \hat{I}_{jt} = \hat{a}_{1jt} + \hat{a}_{2jt}\Delta M_{jt} .$$

The unexpected income change, or forecast error ($\hat{u}_{jt}$), is the actual income change minus expected:

$$\hat{u}_{jt} = \Delta I_{jt} - \Delta \hat{I}_{jt} . \tag{2}$$

It is this forecast error which we assume to be the new information conveyed by the present income number.

THE MARKET'S REACTION

It has also been demonstrated that stock prices, and therefore rates of return from holding stocks, tend to move together. In one study,[9] it was estimated that about 30 to 40 per cent of the variability in a stock's monthly rate of return over the period March, 1944 through December, 1960 could be associated with market-wide effects. Market-wide variations in stock returns are triggered by the release of information which concerns all firms. Since we are evaluating the income report as it relates to the individual firm, its contents and timing should be assessed relative to changes in the rate of return on the firm's stocks net of market-wide effects.

The impact of market-wide information on the monthly rate of return from investing one dollar in the stock of firm j may be estimated by its predicted value from the linear regression of the monthly price relatives of firm j's common stock[10] on a market index of returns:[11]

---

[9] King (1966).

[10] The monthly price relative of security j for month m is defined as dividends (d_{jm}) + closing price ($p_{j,m+1}$), divided by opening price (p_{jm}):

$$PR_{jm} = (p_{j,m+1} + d_{jm})/p_{jm} .$$

A monthly price relative is thus equal to the discrete monthly rate of return plus unity; its natural logarithm is the monthly rate of return compounded continuously. In this paper, we assume discrete compounding since the results are easier to interpret in that form.

[11] Fama, *et al.* (1967) conclude that "regressions of security on market returns over time are a satisfactory method for abstracting from the effects of general market conditions on the monthly rates of return on individual securities." In arriving at their conclusion, they found that "scatter diagrams for the [returns on] individual securities [vis-à-vis the market return] support very well the regression assumptions of linearity, homoscedasticity, and serial independence." Fama, *et al.* studied the natural logarithmic transforms of the price relatives, as did King (1966). However, Blume (1968) worked with equation (3). We also performed tests on the alternative specification:

$$\ln_e (PR_{jm}) = b'_{1j} + b'_{2j}\ln_e (L_m) + v'_{jm} , \tag{3a}$$

where $\ln_e$ denotes the natural logarithmic function. The results correspond closely with those reported below.

$$[PR_{jm} - 1] = \hat{b}_{1j} + \hat{b}_{2j}[L_m - 1] + \hat{v}_{jm}, \tag{3}$$

where PR_{jm} is the monthly price relative for firm j and month m, L is the link relative of Fisher's "Combination Investment Performance Index" [Fisher (1966)], and v_{jm} is the stock return residual for firm j in month m. The value of $[L_m - 1]$ is an estimate of the market's monthly rate of return. The m-subscript in our sample assumes values for all months since January, 1946 for which data are available.

The residual from the OLS regression represented in equation (3) measures the extent to which the realized return differs from the expected return conditional upon the estimated regression parameters (b_{1j}, b_{2j}) and the market index $[L_m - 1]$. Thus, since the market has been found to adjust quickly and efficiently to new information, the residual must represent the impact of new information, about firm j alone, on the return from holding common stock in firm j.

SOME ECONOMETRIC ISSUES

One assumption of the OLS income regression model[12] is that M_j and u_j are uncorrelated. Correlation between them can take at least two forms, namely the inclusion of firm j in the market index of income (M_j), and the presence of industry effects. The first has been eliminated by construction (denoted by the j-subscript on M), but no adjustment has been made for the presence of industry effects. It has been estimated that industry effects probably account for only about 10 per cent of the variability in the level of a firm's income.[13] For this reason equation (1) has been adopted as the appropriate specification in the belief that any bias in the estimates a_{1jt} and a_{2jt} will not be significant. However, as a check on the statistical efficiency of the model, we also present results for an alternative, naive model which predicts that income will be the same for this year as for last. Its forecast error is simply the change in income since the previous year.

As is the case with the income regression model, the stock return model, as presented, contains several obvious violations of the assumptions of the OLS regression model. First, the market index of returns is correlated with the residual because the market index contains the return on firm j, and because of industry effects. Neither violation is serious, because Fisher's index is calculated over all stocks listed on the New York Stock Exchange (hence the return on security j is only a small part of the index), and because industry effects account for at most 10 per cent of the variability in the rate

[12] That is, an assumption necessary for OLS to be the minimum-variance, linear, unbiased estimator.

[13] The magnitude assigned to industry effects depends upon how broadly an industry is defined, which in turn depends upon the particular empirical application being considered. The estimate of 10 per cent is based on a two-digit classification scheme. There is some evidence that industry effects might account for more than 10 per cent when the association is estimated in first differences [Brealey (1968)].

of return on the average stock.[14] A second violation results from our prediction that, for certain months around the report dates, the expected values of the v_j's are nonzero. Again, any bias should have little effect on the results, inasmuch as there is a low, observed autocorrelation in the $\hat{v}_j$'s,[15] and in no case was the stock return regression fitted over less than 100 observations.[16]

SUMMARY

We assume that in the unlikely absence of useful information about a particular firm over a period, its rate of return over that period would reflect only the presence of market-wide information which pertains to all firms. By abstracting from market effects [equation (3)] we identify the effect of information pertaining to individual firms. Then, to determine if part of this effect can be associated with information contained in the firm's accounting income number, we segregate the expected and unexpected elements of income change. If the income forecast error is negative (that is, if the actual change in income is less than its conditional expectation), we define it as bad news and predict that if there is some association between accounting income numbers and stock prices, then release of the income number would result in the return on that firm's securities being less than

[14] The estimate of 10 per cent is due to King (1966). Blume (1968) has recently questioned the magnitude of industry effects, suggesting that they could be somewhat less than 10 per cent. His contention is based on the observation that the significance attached to industry effects depends on the assumptions made about the parameters of the distributions underlying stock rates of return.

[15] See Table 4, below.

[16] Fama, *et al.* (1967) faced a similar situation. The expected values of the stock return residuals were nonzero for some of the months in their study. Stock return regressions were calculated separately for both exclusion and inclusion of the months for which the stock return residuals were thought to be nonzero. They report that both sets of results support the same conclusions.

An alternative to constraining the mean v_j to be zero is to employ the Sharpe Capital Asset Pricing Model [Sharpe (1964)] to estimate (3b):

$$PR_{jm} - RF_m - 1 = b'_{1j} + b'_{2j}\,[L_m - RF_m - 1] + v'_{jm}\,, \tag{3b}$$

where RF is the risk-free ex ante rate of return for holding period m. Results from estimating (3b) (using U.S. Government Bills to measure RF and defining the abnormal return for firm j in month m now as $b'_{1j} + v'_{jm}$) are essentially the same as the results from (3).

Equation (3b) is still not entirely satisfactory, however, since the mean impact of new information is estimated over the whole history of the stock, which covers at least 100 months. If (3b) were fitted using monthly data, a vector of dummy variables could be introduced to identify the fiscal year covered by the annual report, thus permitting the mean residual to vary between fiscal years. The impact of unusual information received in month m of year t would then be estimated by the sum of the constant, the dummy for year t, and the calculated residual for month m and year t. Unfortunately, the efficiency of estimating the stock return equation in this particular form has not been investigated satisfactorily, hence our report will be confined to the results from estimating (3).

TABLE 1

would otherwise have been expected.[17] Such a result ($\hat{u} < 0$) would be evidenced by negative behavioı in the stock return residuals ($\hat{v} < 0$) around the annual report announcement date. The converse should hold for a positive forecast error.

Two basic income expectations models have been defined, a regression model and a naive model. We report in detail on two measures of income [net income and EPS, variables (1) and (2)] for the regression model, and one measure [EPS, variable (3)] for the naive model.

Data

Three classes of data are of interest: the contents of income reports; the dates of the report announcements; and the movements of security prices around the announcement dates.

INCOME NUMBERS

Income numbers for 1946 through 1966 were obtained from Standard and Poor's *Compustat* tapes.[18] The distributions of the squared coefficients of correlation[19] between the changes in the incomes of the individual firms and the changes in the market's income index[20] are summarized in Table 1. For the present sample, about one-fourth of the variability in the changes

[17] We later divide the total return into two parts: a "normal return," defined by the return which would have been expected given the normal relationship between a stock and the market index; and an "abnormal return," the difference between the actual return and the normal return. Formally, the two parts are given by: $b_{1j} + b_{2j}[L_m - 1]$; and v_{jm}.

[18] Tapes used are dated 9/28/1965 and 7/07/1967.

[19] All correlation coefficients in this paper are product-moment correlation coefficients.

[20] The market net income index was computed as the sample mean for each year. The market EPS index was computed as a weighted average over the sample members, the number of stocks outstanding (adjusted for stock splits and stock dividends) providing the weights. Note that when estimating the association between the income of a particular firm and the market, the income of that firm was excluded from the market index.

TABLE 2

*Deciles of the Distributions of the Coefficients of First-Order Autocorrelation in the Income Regression Residuals**

(2) EPS..........	−.39	−.29	−.21	−.15	−.08	−.03	.07	.17	.35

* Estimated over the 21 years, 1946–1966.

in the median firm's income can be associated with changes in the market index.

The association between the levels of the earnings of firms was examined in the forerunner article [Ball and Brown (1967)]. At that time, we referred to the existence of autocorrelation in the disturbances when the levels of net income and EPS were regressed on the appropriate indexes. In this paper, the specification has been changed from levels to first differences because our method of analyzing the stock market's reaction to income numbers presupposes the income forecast errors to be unpredictable at a minimum of 12 months prior to the announcement dates. This supposition is inappropriate when the errors are autocorrelated.

We tested the extent of autocorrelation in the residuals from the income regression model after the variables had been changed from levels to first differences. The results are presented in Table 2. They indicate that the supposition is not now unwarranted.

ANNUAL REPORT ANNOUNCEMENT DATES

The *Wall Street Journal* publishes three kinds of annual report announcements: forecasts of the year's income, as made, for example, by corporation executives shortly after the year end; preliminary reports; and the complete annual report. While forecasts are often imprecise, the preliminary report is typically a condensed preview of the annual report. Because the preliminary report usually contains the same numbers for net income and EPS as are given later with the final report, the announcement date (or, effectively, the date on which the annual income number became generally available) was assumed to be the date on which the preliminary report appeared in the *Wall Street Journal.* Table 3 reveals that the time lag between the end of the fiscal year and the release of the annual report has been declining steadily throughout the sample period.

STOCK PRICES

Stock price relatives were obtained from the tapes constructed by the Center for Research in Security Prices (CRSP) at the University of Chi-

TABLE 3

Time Distribution of Announcement Dates

Per cent of firms	Fiscal year								
	1957	1958	1959	1960	1961	1962	1963	1964	1965
25	2/07[a]	2/04	2/04	2/03	2/02	2/05	2/03	2/01	1/31

* Estimated over the 246 months, January, 1946 through June, 1966.

cago.[21] The data used are monthly closing prices on the New York Stock Exchange, adjusted for dividends and capital changes, for the period January, 1946 through June, 1966. Table 4 presents the deciles of the distributions of the squared coefficient of correlation for the stock return regression [equation (3)], and of the coefficient of first-order autocorrelation in the stock residuals.

INCLUSION CRITERIA

Firms included in the study met the following criteria:

1. earnings data available on the *Compustat* tapes for each of the years 1946–1966;
2. fiscal year ending December 31;
3. price data available on the CRSP tapes for at least 100 months; and
4. *Wall Street Journal* announcement dates available.[22]

Our analysis was limited to the nine fiscal years 1957–1965. By beginning the analysis with 1957, we were assured of at least 10 observations when

[21] The Center for Research in Security Prices at the University of Chicago is sponsored by Merrill Lynch, Pierce, Fenner and Smith Incorporated.

[22] Announcement dates were taken initially from the *Wall Street Journal Index*, then verified against the *Wall Street Journal*.

estimating the income regression equations. The upper limit (the fiscal year 1965, the results of which are announced in 1966) is imposed because the CRSP file terminated in June, 1966.

Our selection criteria may reduce the generality of the results. The subpopulation does not include young firms, those which have failed, those which do not report on December 31, and those which are not represented on *Compustat*, the CRSP tapes, and the *Wall Street Journal*. As a result, it may not be representative of all firms. However, note that (1) the 261 remaining firms[23] are significant in their own right, and (2) a replication of our study on a different sample produced results which conform closely to those reported below.[24]

Results

Define month 0 as the month of the annual report announcement, and API_M, the Abnormal Performance Index at month M, as:

$$API_M = \frac{1}{N} \sum_{n}^{N} \prod_{m=-11}^{M} (1 + v_{nm}).$$

Then API traces out the value of one dollar invested (in equal amounts) in all securities n ($n = 1, 2, \cdots, N$) at the end of month -12 (that is, 12 months prior to the month of the annual report) and held to the end of some arbitrary holding period ($M = -11, -10, \cdots, T$) after abstracting from market affects. An equivalent interpretation is as follows. Suppose two individuals A and B agree on the following proposition. B is to construct a portfolio consisting of one dollar invested in equal amounts in N securities. The securities are to be purchased at the end of month -12 and held until the end of month T. For some price, B contracts with A to take (or make up), at the end of each month M, only the normal gains (or losses) and to return to A, at the end of month T, one dollar plus or minus any abnormal gains or losses. Then API_M is the value of A's equity in the mutual portfolio at the end of each month M.[25]

Numerical results are presented in two forms. Figure 1 plots API_M first for three portfolios constructed from all firms and years in which the income forecast errors, according to each of the three variables, were positive (the top half); second, for three portfolios of firms and years in which the income forecast errors were negative (the bottom half); and third, for a single portfolio consisting of all firms and years in the sample (the line which wanders just below the line dividing the two halves). Table 5 includes the numbers on which Figure 1 is based.

---

[23] Due to known errors in the data, not all firms could be included in all years. The fiscal year most affected was 1964, when three firms were excluded.

[24] The replication investigated 75 firms with fiscal years ending on dates other than December 31, using the naive income-forecasting model, over the longer period 1947–65.

[25] That is, the value expected at the end of month T in the absence of further abnormal gains and losses.

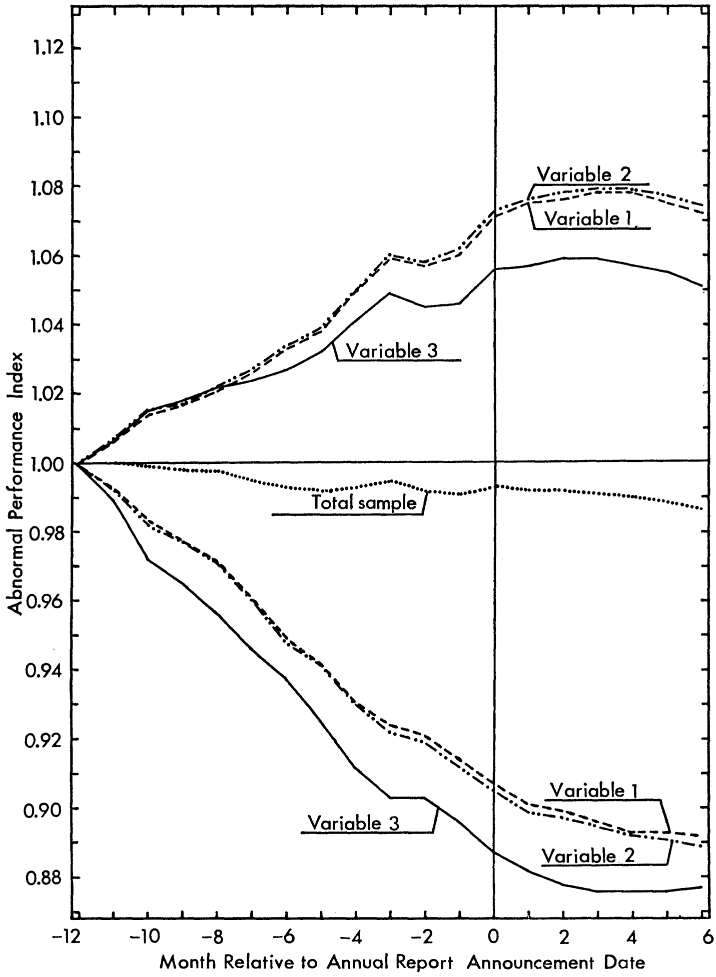

FIG. 1 Abnormal Performance Indexes for Various Portfolios

Since the first set of results may be sensitive to the distributions of the stock return disturbances,[26] a second set of results is presented. The third column under each variable heading in Table 5 gives the chi-square statistic for a two-by-two classification of firms by the sign of the income forecast error, and the sign of the stock return residual for that month.

OVERVIEW

As one would expect from a large sample, both sets of results convey essentially the same picture. They demonstrate that the information contained in the annual income number is useful in that if actual income differs

[26] The empirical distributions of the stock return residuals appear to be described well by symmetric, stable distributions that are characterized by tails longer than those of the normal distribution [Fama (1965); Fama, *et al.* (1967)].

[a] Column headings:

(1) Abnormal Performance Index—firms and years in which the income forecast error was positive.

(2) Abnormal Performance Index—firms and years in which the income forecast error was negative.

(3) Chi-square statistic for two-by-two classification by sign of income forecast error (for the fiscal year) and sign of stock return residual (for the indicated month).

Note: Probability (chi-square $\geq 3.84 \mid \chi^2 = 0) = .05$, for 1 degree of freedom.
Probability (chi-square $\geq 6.64 \mid \chi^2 = 0) = .01$, for 1 degree of freedom.

from expected income, the market typically has reacted in the same direction. This contention is supported both by Figure 1 which reveals a marked, positive association between the sign of the error in forecasting income and the Abnormal Performance Index, and by the chi-square statistic (Table 5). The latter shows it is most unlikely that there is no relationship between the sign of the income forecast error and the sign of the rate of return residual in most of the months up to that of the annual report announcement.

However, most of the information contained in reported income is anticipated by the market before the annual report is released. In fact, anticipation is so accurate that the actual income number does not appear to cause any unusual jumps in the Abnormal Performance Index in the announcement month. To illustrate, the drifts upward and downward begin at least 12 months before the report is released (when the portfolios are first

TABLE 6

Contingency Table of the Signs of the Income Forecast Errors—by Variable

Sign of income forecast error	Sign of income forecast error					
	Variable (1)		Variable (2)		Variable (3)	
	+	−	+	−	+	−
Variable (1)						
+	1231	—	1148	83	1074	157
−	—	1109	83	1026	399	710
Variable (2)						
+	1148	83	1231	—	1074	157
−	83	1026	—	1109	399	710
Variable (3)						
+	1074	399	1074	399	1473	—
−	157	710	157	710	—	867

constructed) and continue for approximately one month after. The persistence of the drifts, as indicated by the constant signs of the indexes and by their almost monotonic increases in absolute value (Figure 1), suggests not only that the market begins to anticipate forecast errors early in the 12 months preceding the report, but also that it continues to do so with increasing success throughout the year.[27]

SPECIFIC RESULTS

1. There appears to be little difference between the results for the two regression model variables. Table 6, which classifies the sign of one variable's forecast error contingent upon the signs of the errors of the other two variables, reveals the reason. For example, on the 1231 occasions on which the income forecast error was positive for variable (1), it was also positive on 1148 occasions (out of a possible 1231) for variable (2). Similarly, on the 1109 occasions on which the income forecast error was negative for variable (1), it was also negative on 1026 occasions for variable (2). The fact that the results for variable (2) strictly dominate those for variable (1) suggests, however, that when the two variables disagreed on the sign of an income forecast error, variable (2) was more often correct.

While there is little to choose between variables (1) and (2), variable (3) (the naive model) is clearly best for the portfolio made up of firms with negative forecast errors. A contributing factor is the following. The naive model gives the same forecast error as the regression model would give if

[27] Note that Figure 1 contains averages over many firms and years and is not indicative of the behavior of the securities of any particular firm in any one year. While there may be, on average, a persistent and gradual anticipation of the contents of the report throughout the year, evidence on the extent of autocorrelation in the stock return residuals would suggest that the market's reaction to information about a particular firm tends to occur rapidly.

(a) the change in market income were zero, and (b) there were no drift in the income of the firm. But historically there has been an increase in the market's income, particularly during the latter part of the sample period, due to general increase in prices and the strong influence of the protracted expansion since 1961. Thus, the naive model [variable (3)] typically identifies as firms with negative forecast errors those relatively few firms which showed a decrease in EPS when most firms showed an increase. Of the three variables, one would be most confident that the incomes of those which showed negative forecast errors for variable (3) have in fact lost ground relative to the market.

This observation has interesting implications. For example, it points to a relationship between the magnitudes of the income forecast errors and the magnitudes of the abnormal stock price adjustments. This conclusion is reinforced by Figure 1 which shows that the results for positive forecast errors are weaker for variable (3) than for the other two.

2. The drift downward in the Abnormal Performance Index computed over all firms and years in the sample reflects a computational bias.[28] The bias arises because

$$E[\prod_m (1 + v_m)] \neq \prod_m [1 + E(v_m)],$$

where E denotes the expected value. It can readily be seen that the bias over K months is at least of order $(K - 1)$ times the covariance between v_m and v_{m-1}.[29] Since this covariance is typically negative,[30] the bias is also negative.

While the bias does not affect the tenor of our results in any way, it should be kept in mind when interpreting the values of the various API's. It helps explain, for example, why the absolute changes in the indexes in the bottom panel of Figure 1 tend to be greater than those in the top panel; why the indexes in the top panel tend to turn down shortly after month 0; and finally, why the drifts in the indexes in the bottom panel tend to persist beyond the month of the report announcement.

3. We also computed results for the regression model using the additional definitions of income:

(a) cash flow, as approximated by operating income,[31] and

(b) net income before nonrecurring items.

Neither variable was as successful in predicting the signs of the stock return

[28] The expected value of the bias is of order minus one-half to minus one-quarter of one per cent per annum. The difference between the observed value of the API computed over the total sample and its expectation is a property of the particular sample (see footnote 26).

[29] In particular, the approximation neglects all permutations of the product $v_s \cdot v_t$, $s = 1, 2, \cdots, K-2$, $t = s+2, \cdots, K$, as being of a second order of smallness.

[30] See Table 4.

[31] All variable definitions are specified in Standard and Poor's *Compustat Manual* [see also Ball and Brown (1967), Appendix A].

residuals as net income and EPS. For example, by month 0, the Abnormal Performance Indexes for forecast errors which were positive were 1.068 (net income, including nonrecurring items) and 1.070 (operating income). These numbers compare with 1.071 for net income [Table 5, variable (1)]. The respective numbers for firms and years with negative forecast errors were 0.911, 0.917, and 0.907.

4. Both the API's and the chi-square test in Table 5 suggest that, at least for variable (3), the relationship between the sign of the income forecast error and that of the stock return residual may have persisted for as long as two months beyond the month of the announcement of the annual report. One explanation might be that the market's index of income was not known for sure until after several firms had announced their income numbers. The elimination of uncertainty about the market's income subsequent to some firms' announcements might tend, when averaged over all firms in the sample, to be reflected in a persistence in the drifts in the API's beyond the announcement month. This explanation can probably be ruled out, however, since when those firms which made their announcements in January of any one year were excluded from the sample for that year, there were no changes in the patterns of the overall API's as presented in Figure 1, although generally there were reductions in the χ^2 statistics.[32]

A second explanation could be random errors in the announcement dates. Drifts in the API's would persist beyond the announcement month if errors resulted in our treating some firms as if they had announced their income numbers earlier than in fact was the case. But this explanation can also probably be ruled out, since all announcement dates taken from the *Wall Street Journal Index* were verified against the *Wall Street Journal.*

A third explanation could be that preliminary reports are not perceived by the market as being final. Unfortunately this issue cannot be resolved independently of an alternative hypothesis, namely that the market does take more time to adjust to information if the value of that information is less than the transactions costs that would be incurred by an investor who wished to take advantage of the opportunity for abnormal gain. That is, even if the relationship tended to persist beyond the announcement month, it is clear that unless transactions costs were within about one per cent,[33]

---

[32] The general reduction in the χ^2 statistic is due largely to the reduction in sample size.

[33] This result is obtained as follows. The ratio API_m/API_{m-1} is equal to the marginal return in month m plus unity:

$$\frac{API_m}{API_{m-1}} = (1 + r_m).$$

Similarly,

$$\frac{API_m}{API_{m-2}} = \frac{API_m}{API_{m-1}} \cdot \frac{API_{m-1}}{API_{m-2}} = (1 + r_m)\cdot(1 + r_{m-1}),$$

there was no opportunity for abnormal profit once the income information had become generally available. Our results are thus consistent with other evidence that the market tends to react to data without bias, at least to within transactions costs.

THE VALUE OF ANNUAL NET INCOME RELATIVE TO OTHER SOURCES OF INFORMATION[34]

The results demonstrate that the information contained in the annual income number is useful in that it is related to stock prices. But annual accounting reports are only one of the many sources of information available to investors. The aim of this section is to assess the relative importance of information contained in net income, and at the same time to provide some insight into the timeliness of the income report.

It was suggested earlier that the impact of new information about an individual stock could be measured by the stock's return residual. For example, a negative residual would indicate that the actual return is less than what would have been expected had there been no bad information. Equivalently, if an investor is able to take advantage of the information either by selling or by taking a short position in advance of the market adjustment, then the residual will represent, ignoring transactions costs, the extent to which his return is greater than would normally be expected.

If the difference between the realized and expected return is accepted as also indicating the value of new information, then it is clear that the value of new, monthly information, good or bad, about an individual stock is given by the absolute value of that stock's return residual for the given month. It follows that the value of all monthly information concerning the average firm, received in the 12 months preceding the report, is given by:

$$TI_0 = \frac{1}{N} \sum_{j}^{N} \left[\prod_{m=-11}^{0} (1 + |v_{jm}|) \right] - 1.00,$$

---

and, in general,

$$\frac{API_m}{API_s} = (1 + r_{s+1}) \cdots (1 + r_m).$$

Thus, the marginal return for the two months after the announcement date on the portfolio consisting of firms for which EPS decrease would have been $0.878/0.887 - 1 \cong -.010$; similarly, the marginal return on the portfolio of firms for which EPS increased would have been $1.059/1.056 - 1 \cong .003$. After allowing for the computational bias, it would appear that transactions costs must have been within one per cent for opportunities to have existed for abnormal profit from applying some mechanical trading rule.

[34] This analysis does not consider the *marginal* contribution of information contained in the annual income number. It would be interesting to analyze dividends in a way similar to that we have used for income announcements. We expect there would be some overlap. To the extent that there is an overlap, we attribute the information to the income number and consider the dividend announcement to be the medium by which the market learns about income. This assumption is highly artificial in that historical income numbers and dividend payments might both simply be reflections of the same, more fundamental informational determinants of stock prices.

where TI denotes total information.[35] For our sample, averaged over all firms and years, this sum was 0.731.

For any one particular stock, some of the information between months will be offsetting.[36] The value of net information (received in the 12 months preceding the report) about the average stock is given by:

$$NI_0 = \frac{1}{N}\sum_{j}^{N}\left|\prod_{m=-11}^{0}(1 + v_{jm}) - 1.00\right|,$$

where NI denotes net information. This sum was 0.165.

The impact of the annual income number is also a net number in that net income is the result of both income-increasing and income-decreasing events. If one accepts the forecast error model,[37] then the value of information contained in the annual income number may be estimated by the average of the value increments from month -11 to month 0, where the increments are averaged over the two portfolios constructed from (buying or selling short) all firms and years as classified by the signs of the income forecast errors. That is,

$$II_0 = \frac{N1(API_0^{N1} - 1.00) - N2(API_0^{N2} - 1.00)}{(N1 + N2)},$$

where II denotes income information, and $N1$ and $N2$ the number of occasions on which the income forecast error was positive and negative respectively. This number was 0.081 for variable (1), 0.083 for variable (2), and 0.077 for variable (3).

From the above numbers we conclude:

(1) about 75 per cent [(.731 − .165)/.731] of the value of all information appears to be offsetting, which in turn implies that about 25 per cent persists; and

(2) of the 25 per cent which persists, about half [49 %, 50 %, and 47 %—calculated as .081/.165, .083/.165, and .077/.165—for variables (1)–(3)] can be associated with the information contained in reported income.

Two further conclusions, not directly evident, are:

(3) of the value of information contained in reported income, no more than about 10 to 15 per cent (12 %, 11 %, and 13 %) has not been anticipated by the month of the report;[38] and

[35] Note that the information is reflected in a value increment; thus, the original $1.00 is deducted from the terminal value.

[36] This assertion is supported by the observed low autocorrelation in the stock return residuals.

[37] Note that since we are interested in the "average firm," an investment strategy must be adopted on every sample member. Because there are only two relevant strategies involved, it is sufficient to know whether one is better off to buy or to sell short. Note also that the analysis assumes the strategy is first adopted 12 months prior to the announcement date.

[38] The average monthly yield from a policy of buying a portfolio consisting of all firms with positive forecast errors and adopting a short position on the rest would have resulted in an average monthly abnormal rate of return, from -11 to -1, of

(4) the value of information conveyed by the income number at the time of its release constitutes, on average, only 20 per cent (19%, 18%, and 19%) of the value of all information coming to the market in that month.[39]

The second conclusion indicates that accounting income numbers capture about half of the net effect of all information available throughout the 12 months preceding their release; yet the fourth conclusion suggests that net income contributes only about 20 per cent of the value of all information in the month of its release. The apparent paradox is presumably due to the fact that: (a) many other bits of information are usually released in the same month as reported income (for example, via dividend announcements, or perhaps other items in the financial reports); (b) 85 to 90 per cent of the net effect of information about annual income is already reflected in security prices by the month of its announcement; and (c) the period of the annual report is already one-and-one-half months into history.

Ours is perhaps the first attempt to assess empirically the relative importance of the annual income number, but it does have limitations. For example, our results are systematically biased against findings in favor of accounting reports due to:

1. the assumption that stock prices are from transactions which have taken place simultaneously at the end of the month;
2. the assumption that there are no errors in the data;
3. the discrete nature of stock price quotations;
4. the presumed validity of the "errors in forecast" model; and
5. the regression estimates of the income forecast errors being random variables, which implies that some misclassifications of the "true" earnings forecast errors are inevitable.

Concluding Remarks

The initial objective was to assess the usefulness of existing accounting income numbers by examining their information content and timeliness. The mode of analysis permitted some definite conclusions which we shall briefly restate. Of all the information about an individual firm which becomes available during a year, one-half or more is captured in that year's income number. Its content is therefore considerable. However, the annual income report does not rate highly as a timely medium, since most of its content (about 85 to 90 per cent) is captured by more prompt media which perhaps include interim reports. Since the efficiency of the capital market

0.63%, 0.66%, and 0.60% for variables (1), (2), and (3) respectively. The marginal rate of return in month 0 for that same strategy would have been 0.92%, 0.89%, and 0.94% respectively. However, relatively much more information is conveyed in the month of the report announcement than in either of the two months immediately preceding the announcement month or in the two months immediately following it. This result is consistent with those obtained by Beaver (1968).

[39] An optimum policy (that is, one which takes advantage of all information) would have yielded an abnormal rate of return of 4.9% in month 0.

is largely determined by the adequacy of its data sources, we do not find it disconcerting that the market has turned to other sources which can be acted upon more promptly than annual net income.

This study raises several issues for further investigation. For example, there remains the task of identifying the media by which the market is able to anticipate net income: of what help are interim reports and dividend announcements? For accountants, there is the problem of assessing the cost of preparing annual income reports relative to that of the more timely interim reports.

The relationship between the magnitude (and not merely the sign) of the unexpected income change and the associated stock price adjustment could also be investigated.[40] This would offer a different way of measuring the value of information about income changes, and might, in addition, furnish insight into the statistical nature of the income process, a process little understood but of considerable interest to accounting researchers.

Finally, a mechanism has been provided for an empirical approach to a restricted class of the controversial choices in external reporting.

EFFICIENT CAPITAL MARKETS AND THE INFORMATION CONTENT OF ACCOUNTING NUMBERS

*John T. Emery**

I. Introduction

The theory of efficient capital markets suggests that if the capital markets are efficient, security prices can be assumed at any time to "fully reflect" all available information. Various forms of the model have been subjected to extensive empirical testing. The results of these tests have been such that in reviewing the literature on the theory Fama [3] states, ". . . the evidence in support of the efficient markets model is extensive, and (somewhat uniquely in economics) contradictory evidence is sparse." Most of the research, however, has been addressed to the question of whether prices "fully reflect" particular subsets of available information. The validity of these results depends on the extent to which the information in the subset used for testing captures the information actually impounded in prices.

There is some evidence in support of the idea that prices may not impound all available information. Niederhoffer and Osborne [10] provide results which suggest that specialists on the New York Stock Exchange may possess and exploit monopolistic access to information. Also, in examining trading by corporate insiders Scholes [11] found significant market reactions to large trades by corporate insiders. His results support the efficient markets model when the efficiency conditions are defined relative to all *publicly* available information. If the efficiency conditions are defined relative to all available information including that possessed by corporate insiders, he finds some evidence that is inconsistent with the model. In particular, the price changes which often occur immediately after the disclosure of corporate insider trading actually suggest that insiders may be acting on information which is not publicly available.

If management may occasionally have monopolistic access to undisclosed information, i.e., insider information, to which the market would react if it were available or predictable, the question of whether there is some optimum strategy for disclosing this information arises. Perhaps the most extensive treatment of such strategies is in the accounting literature where there are numerous references to the suggestion that accountants smooth or normalize the income of firms. Most versions of the "income-smoothing" hypothesis are concerned with the extent to which managers may be able to alter a series of reported accounting numbers *via* the choice of accounting procedures. The most commonly alleged motivation for such practices is to reduce the extent to which

---

"bad times" or, conversely, "good times" are revealed by reported accounting numbers. Occasionally firms with large operating losses appear to adopt a "big bath" strategy by declaring large losses over a short period of time. The presumed effect is that once the firm has purged itself of the losses, it will be able to report a more favorable earnings pattern. The implication is that a smoothed series of accounting numbers, especially income numbers, will enhance the value of the firm--presumably by reducing the risk of the firm as perceived by the market. Essentially the same idea is presented in the functional fixation hypothesis of Ijiri, Jaedicke, and Knight [7]. In essence, this hypothesis states that two firms could be alike in all "real" economic respects and yet their securities could sell for different prices simply because of the way the accountant reported the results of operations.

For an income smoothing strategy to enhance the value of the firm, the accounting numbers must disclose or imply information that is not already impounded in current market prices. Accounting numbers, however, are not the only source of information about a firm. Competing sources include such items as statements by corporate officials, releases issued by brokerage firms or market-newsletter services, reports filed with the SEC on insider trading or for registrations with respect to security floatations, information "leakages," and the results of forecasting models.[1]

Much of the literature on the income smoothing hypothesis has attempted to test for the existence of possible income smoothing procedures without determining whether they would increase the value of the firm. If income smoothing is to increase prices above what they would be otherwise, the information content of the reported accounting numbers must be such that the market will react in a more favorable manner than if the numbers had not been transformed through accounting manipulations. In an efficient market, though, the manipulation of accounting numbers would not alter prices unless the numbers convey information which is not contained in other publicly available sources.

This paper compares the relation between reported accounting income and prices with the relation between certain adjusted (unsmoothed) income series and prices. If the market is efficient and alternative sources of information are available, a stronger relation between unsmoothed income and prices than between reported income and prices would suggest that the market can decide for itself what the correct accounting numbers should be. Alternatively, evidence that the manipulation of accounting numbers can influence prices implies the existence of optimal strategies for disclosing information. The success of such strategies has implications for both management and investors. The methodology is presented in the following section.

II. Methodology

While the efficient markets model is typically expressed in terms of rates of return, the income smoothing hypothesis has been defined in various ways including income levels, rates of change in income, and accounting rates of return on equity. It is assumed that if firms actually do engage in smoothing practices, they attempt to smooth the rate of return on the market value of equity. For purposes of this paper the

[1]Nicholas J. Gonedes, "Efficient Capital Markets and External Accounting," *Accounting Review* (January 1972), p. 16.

 22

rate of return will be expressed as the ratio of earnings per share to price per share. Earnings per share will be taken as the smoothing objective. These rates of return will be considered with respect to mean-reverting stochastic processes.

The accounting numbers presented by the firm can be viewed as the product of two processes. One is the stochastic process generating *basic* accounting numbers which with a given set of accounting procedures will reflect the influence of various events on the firm's production function. These events include changes in the firm's factor-input markets and changes in its output markets. Once the basic numbers are created, smoothing procedures may then be used to transform these numbers for the purpose of controlling the disclosure of information in the *reported* accounting numbers.

While a firm may have only limited control over changes in its input and output markets, it does have direct control over asset and financing decisions and can attempt to smooth basic accounting numbers through changes in operations. In an efficient market, however, the effect of real changes will be reflected in prices. The smoothing problem is whether accounting manipulations by themselves can alter prices successfully.

Gonedes [5] provides one of the clearest statements of the problem. His formulation is expressed as follows:

$$\text{(1)} \qquad \underset{(\alpha_t;\ 1\leq t\leq N)}{\text{Max}}\ \Psi = E\left[\sum_{t=1}^{N} \tilde{r}_t^c - \lambda(\tilde{r}_t^c - \Phi)^2\right] \quad ,$$

$$\text{(2)} \qquad \text{Subject to } \tilde{r}_t^c = \tilde{r}_t + \alpha_t \quad ,$$

$$\text{(3)} \qquad \sum_{t=1}^{N} \alpha t = 0 \quad ,$$

where

α = smoothing adjustment to basic rate of return,

$\tilde{r}$ = basic rate of return,

$\tilde{r}^c$ = reported rate of return,

λ = parameter measuring disutility of squared deviations about Φ,

Φ = parameter delineating the measure about which smoothing occurs. The hypothesis stated here minimizes deviation from reported income in the previous period, $\tilde{r}_t^c$-1.

The disutility represented by λ is a measure of the information content of a change in the reported rate of return. It can be expected to vary for different firms.

It is assumed that accounting manipulations are meant to redistribute income over time rather than alter total reported income permanently. This implies

$$\text{(4)} \qquad \sum_{t=1}^{N} \tilde{r}_t^c = \sum_{t=1}^{N} \tilde{r}_t \quad .$$

 23

Both total reported income and the resulting rate of return based on this income will present the same information when the base for calculating the rate of return is specified properly. To avoid introducing bias from improperly estimating the base, earnings per share will be taken as the smoothing objective.

When information about income is available from sources other than accounting statements, prices can be expected to reflect not only the information reported by the accounting statements but also that obtained from other publicly available sources. If attempts to smooth earnings through accounting manipulations do influence prices successfully, reported accounting numbers should be more highly correlated with the price of the stock than basic accounting numbers. The basic accounting numbers, however, are not generally available. Any attempt to transform the reported numbers back to the basic numbers from which they originated must rely on assumptions about the nature of the smoothing process employed. This paper examines one class of mean reverting procedures that might be used to smooth reported income.

It is supposed that management desires to report a rate of return that is as high as possible and acceptably close to the previous period's reported rate of return. By reducing the change in reported income as measured by $(\tilde{r}_t^c - \tilde{r}_{t-1}^c)^2$, management attempts to lower the market's perception of the amount of risk represented by the stock of the firm. If some firms actually employ this type of smoothing procedure, the reported numbers should exhibit less variance than the basic numbers.

To test for the possible effect of income smoothing on prices, it is necessary to estimate the basic, but not directly observable, numbers. The most common approach is that used by Kaplan and Roll [9] in which the accounting statements are adjusted to examine the effect on prices of different methods of reporting certain items. Due to the large number of possible accounting manipulations, simulation procedures are used to estimate what the basic numbers might have been by unsmoothing the reported numbers. This is done by rearranging the reported earnings into alternative series which have greater total variance than the reported series. The correlation between reported earnings and stock prices is then compared with the correlations between the simulated unsmoothed earnings and prices.

Whether firms attempt to smooth earnings through accounting manipulations or not, any procedure which alters the reported income series is likely to create artificially some basic earnings series that have a greater correlation with prices than the reported numbers but do not empirically represent fact. If the market has sources of information about income other than the reported numbers and can decide for itself what the basic numbers should be, the unsmoothing procedure described above should produce a greater number of earnings series with a higher correlation between the series and prices for firms that attempt to smooth earnings than for firms that do not. This approach will detect only smoothing behavior which the market does not impound in prices. No evidence of the type of smoothing described is expected if firms do not engage in smoothing practices or if those firms which do are successful in influencing prices through accounting manipulations.

To test the hypothesis a sample of 110 firms was selected from two-digit Standard Industrial Classification industries. The industries were aerospace, auto parts, building materials, chemicals, electronics and electronic components, petroleum products, and steel. A list of the firms is included in the Appendix. Annual earnings and price data for the years 1963 through 1972 were taken from the Compustat Annual and Quarterly tapes, respectively. The prices used were month-end closing prices two months after the end of the fiscal year. Both prices and earnings were adjusted for stock splits and stock dividends.

The smoothness of reported earnings was measured in two ways. One was the standard error of the autoregressive trend equation $EPS_t = \alpha + \beta\ EPS_{t-1}$ where EPS is earnings per share and t represents the time period. Since some firms exhibited low R^2's, the variance of the annual change in earnings per share was used as an alternative measure of smoothness.

Table 1 presents the results of the simulation to unsmooth earnings on an industry basis. The smoothing procedure simply transfers adjusted income on a per share basis from one period to another. Simulated series with a lower variance than the reported series are not considered. The correlation coefficients in Table 1 are those calculated between either the standard error about the earnings trend, SEE_j, or the variance of the yearly change in reported earnings, $\sigma^2(\Delta EPS_j)$, and the data generated by the simulation procedures. The columns labeled ρ_j contain the correlations between either SEE_j or $\sigma^2(\Delta EPS_j)$ and the number of transformed income series with a greater $\sum_t (EPS_t - EPS_{t-1})^2$ than the reported series, $\sigma^2(\Delta EPS_j^c)$. The ρ_j^c column is correlation between the number of these transformed series which have a higher correlation with prices than the reported series and the SEE_j or $\sigma^2(\Delta EPS_j)$. Let N_j be the number of the c unsmoothed earnings streams simulated for firm j for which $\sigma^2(\Delta EPS_j^c) > \sigma^2(\Delta EPS_j)$. Also, define N_j^* to be the number of these N_j earnings streams for which $\rho_j^c > \rho_j$. Then the ratio N_j^*/N_j is the percent of unsmoothed simulated series which have a higher correlation with prices than the reported earnings. The numbers in the table are the correlations between this ratio and the smoothing measures. The level of significance for the one-tailed t test is given in parentheses beneath the coefficient.

For the firms chosen from the seven industries in this sample the ρ_j coefficients which are statistically significant suggest an inverse relation between the smoothing measures and the number of new series created from the reported income numbers. Also, the significant ρ_j^c coefficients for the relation between the smoothing variables and the number of new earnings series with a higher correlation to prices than the reported earnings are negative. These results suggest that within the selected industries the number of alternative earnings series providing a better explanation of prices than reported earnings increases as the reported numbers become smoother.

If the market is efficient and has access to other sources of infomation than accounting numbers, there should be a negative relation between the measures of smoothness and the ratio N_j^*/N_j. The chemical industry is the only industry with a negative and statistically significant coefficient for the variance smoothness measure. The auto parts industry demonstrates the same relation at a lower level of significance for the variance. In general, the variance seems to be a better statistic with which to measure smoothness for these data.

Total	110	-.1703 (.038)	-.1279 (.092)	-.1210 (.104)	-.3658 (.001)	-.2154 (.012)	.3523 (.001)

*Level of significance in parentheses.

Table 2 presents the same analysis as Table 1 except that Spearman rank order correlation coefficients are used. When the numbers are ranked, the reported relations are somewhat stronger. Both the chemical and auto parts industry have a significant negative relation for N_j^*/N_j. While little attention has been given to the auto parts industry, Gordon, Horwitz and Meyers [6], Copeland [1], Dascher and Malcom [2], and White [12] examined income smoothing in the chemical industry. Their results, however, were not conclusive.

III. Conclusions

This paper examines the relation between reported accounting income and prices with the relation between certain adjustments to the reported income series and prices. The simulation procedures used to transform the reported accounting numbers provide evidence that some firms in the chemical and auto parts industry may have manipulated accounting numbers to report a smoother earnings trend than would have existed without such accounting adjustments. The significant negative relations, for the chemical industry in particular, suggest that enough of the information contained in accounting numbers is available through alternative sources that the market can estimate what the correct accounting numbers should be and price the stock accordingly. The methodology employed here examines only one type of income smoothing and does not exclude the possibility of short-term price effects. Since there is some evidence that the market is able to rely on sources of information other than accounting numbers, it would be desirable to expand the sample size. Recognizing these limitations, the implication here is consistent with the conclusion reached by Kaplan and Roll, "Earnings manipulation may be fun, but its profitability is doubtful."[2]

SESSION TOPIC: FINANCE AND ACCOUNTING

SESSION CHAIRPERSON: WILLIAM BEAVER*

THE CAPITAL MARKET, THE MARKET FOR INFORMATION, AND EXTERNAL ACCOUNTING

NICHOLAS J. GONEDES**

1. INTRODUCTION

EQUILIBRIUM PRICES of firms' shares depend on assessed distribution functions of returns to those shares. Such assessed distributions depend, in turn, upon available information pertaining to firms' production-investment ("operating") and financing decisions. One potential source of this type of information is the collection of accounting numbers periodically issued by firms. If accounting numbers do reflect events pertaining to firms' decisions, then they can serve as sources of information pertinent to valuing firms.

Given the relationship between the equilibrium prices of firms' shares, available information, and accounting numbers, it is probably not surpirsing that the notion of capital market efficiency—which also deals with information and equilibrium prices—has played an important role in research dealing with external accounting, such as research on the information content of numbers produced via the external accounting mechanism and research on the effects of disclosure law regulations (adopted by, for example, the Securities and Exchange Commission and the Financial Accounting Standards Board).[1] In a general sense, work of this sort is a subset of the growing literature on information-production activities and capital market equilibrium; see e.g., Fama and Laffer [1971], Gonedes [1975], Gonedes and Dopuch [1974], Jaffe [1975], Ng [1975], Kihlstrom and Mirman [1975], and Rubenstein [1973], among others. Thus, in general, the theoretical connection between information-production activities and capital market equilibrium provides some of the theoretical underpinnings to be exploited in work that deals with external accounting (e.g., information content issues and disclosure-law issues) via the notion of capital market efficiency.

The purpose of this paper is to explore several aspects of information-production and capital market efficiency that appear to have been glossed over in the available literature. Our explorations have implications for work on external accounting. In addition, they have implications for a variety of other issues that have been the subject of both theoretical and empirical work—such as the extent to which portfolio managers can earn "abnormal returns," the role of financial statement analysis, and the role of a body (e.g., the SEC or the FASB) that regulates disclosures by firms.[2]

* Stanford University.

** University of Chicago; The comments and criticisms of Nicholas Dopuch, George Foster, Eugene Fama, Merton Miller, Hans Stoll, and John Dickhaut are gratefully acknowledged.

1. A review of this kind of work is provided in Gonedes and Dopuch [1974; Sec. 8].

2. Implications for the role of bodies such as the FASB and the SEC are more thoroughly discussed by Gonedes, Dopuch, and Penman [1975; Sec. 3].

Some of our arguments are developed in an informal way. A variety of details (and topics) not considered here are considered in Gonedes [1974].

Section 1 briefly reviews the notion of capital market efficiency in a way that leads directly to the main topic of interest: the relationship between the market for information and the capital market. The conditions on the information market that are implicit in the conventional definition of an efficient capital market are identified and discussed in Section 3. Section 4 deals with a variety of issues that arise when the market for information is given explicit consideration. The discussion in Section 4 is used in Section 5 in a brief re-examination of some existing evidence on abnormal returns. This re-examination illustrates how explicit treatment of the information market can affect interpretations of empirical results. Section 6 discusses some issues and implications pertinent to external accounting. A summary of the paper is given in Section 7.

2. Capital Market Efficiency Conditions

The strongest and most conventional definition of an efficient capital market is: An efficient capital market is one wherein prices fully reflect all available information and, thus, one wherein prices adjust rapidly and unbiasedly to new information.[3] While this definition conveys some of what is involved, it is not very concrete. So, a more concrete characterization will be stated. Unless otherwise indicated, a conventional "homogeneous expectations" assumption will be used. Specifically, all capital market agents having the same information are assumed to agree on the assessed distribution functions of returns on assets. This assumption may seem overly restrictive. It does not, however, affect the major points made below, particularly those in Sections 3 and 4. Some other conventional assumptions used throughout are as follows: (1) all agents act as price-takers in a frictionless capital market and (2) equilibrium in the capital market is established via a process of tâtonnement with recontracting. Another assumption made in this section but relaxed at a later point is that all available information is costlessly available to each agent. For convenience, the standard one-period framework is used; this is not something that affects the major points made below.

Let I_t denote the set of all information available at time t.[4] Since information available at time t is also available at time $t+1$, I_t is a never-decreasing set with respect to time. That is, $I_{t-s} \subseteq I_{t-s+1} \subseteq \cdots \subseteq I_t$, for all $s>0$. In short, I_t contains all available information on the present and past of the economic system, including information on the present and past structure of the system. Thus, I_t includes realizations of random variables (e.g., firms' earnings and returns on firms' shares for periods $\tau \leqslant t$) as well as all identifiable relationships amongst such variables (e.g., joint distribution functions).

Next, let I_t^m denote the set of information used by the capital market (i.e., each

3. A review of theory and evidence pertaining to this notion of capital market efficiency is provided by Fama [1970]. See also Fama [1976].

4. The descriptions "at time t" and "at the beginning of time period t" will be used interchangeably.

agent) at time t in establishing equilibrium prices. The precise relationship between I_t^m and the equilibrium prices of assets will depend upon whatever model of equilibrium prices is appropriate. The two-parameter asset pricing model is one such model. The appropriate equilibrium model is not, however, an issue that needs to be considered now. Finally, let $\tilde{\pi}_{jt+1}$ denote the value of asset j at time $t+1$, where tilde ($\tilde{}$) denotes random variable.

By definition, an efficient capital market is one wherein:

$$I_t^m = I_t, \qquad \text{for all } t. \tag{2.1}$$

That is, in an efficient capital market, agents act as if they use all of the information available at time t in establishing equilibrium prices at time t, for all t. Condition (2.1) implies that an efficient capital market is one wherein, for all j and t,

$$F_m(\pi_{jt+1} \mid I_t^m) = F_m(\pi_{jt+1} \mid I_t) = F(\pi_{jt+1} \mid I_t), \tag{2.2}$$

where F_m is a generic symbol for a distribution function assessed by the market, conditional on the information that it uses, and F is a generic symbol for the corresponding correct distribution function, conditional upon I_t. Taken together, (2.1) and (2.2) say: (1) that the market acts as if it uses all of the information available at time t in setting equilibrium prices at time t and (2) that the market acts as if it uses that information correctly, in the sense that its assessed distribution functions of assets' values are precisely those implied by I_t.[5] When viewed in this light, expressions (2.1) and (2.2) formalize what is usually meant when stating that an efficient capital market "fully reflects" all available information. And, of course, if the capital market is to fully reflect all available information, it must adjust instantaneously to new information (i.e., changes in I_t). Moreover, these adjustments must be unbiased in the sense that condition (2.2) underlies the resulting equilibrium prices.

$F(\pi_{jt+1} \mid I_t)$ was referred to as the "correctly assessed" distribution function of $\tilde{\pi}_{jt+1}$, conditional on I_t. The perspective underlying this characterization is as follows: I_t is taken to be the set of all available information at time t and it is assumed that, conditional on I_t, there is a "true" or "underlying" distribution function of $\tilde{\pi}_{jt+1}$, a function that is an element of I_t.[6] The statement that the market "correctly" assesses the distribution function of $\tilde{\pi}_{jt+1}$, for each j, simply means that the market fully understands the implications of I_t. That implies that the market's assessed distribution function for $\tilde{\pi}_{jt+1}$, conditional on I_t, is none other than the "true" one, given I_t. If this were not the case, there would be a detectable difference between $F_m(\pi_{jt+1} \mid I_t^m)$ and $F(\pi_{jt+1} \mid I_t)$, for some j. Any such difference

5. Given homogeneous expectations, there is no disagreement over what is implied by I_t.

6. Recall that I_t contains specifications of all identifiable relationships (e.g., distribution functions) pertinent to describing the economic system.

would imply either that $I_t^m \neq I_t$ or that the market does not fully understand the implications of I_t—conditions that contradict our assumptions.

The above characterization can, of course, be easily recast in terms of one-period rates of return, $\tilde{R}_{jt+1} = (\tilde{\pi}_{jt+1}/\pi_{jt}) - 1$, for all j. Given the "perfect market" assumption, no agent affects current prices. Thus, given a set of prices at time t for all assets and given condition (2.2), all agents face the same distribution functions of one period rates of return. That is, the same gambles are confronted by each agent.

It might seem that the above characterization deals with only the capital market. Nothing was said about, for example, the nature (perfect vs. imperfect) of any market for goods or services. Upon closer examination, one should recognize, however, that our characterization of the capital market incorporates some strong assumptions about a different market, viz., the market for information. This issue is considered in the next section.

3. Implicit Conditions on the Market for Information

Condition (2.1) and—under the homogeneous expectations assumption—Condition (2.2) must hold for every capital market agent. Thus, every agent must have unrestricted access to all information available at time t. That implies that each agent has unrestricted access to all of the initially available information (i.e., the information available when agents first come to the market at time t) as well as all results of information-production activities initiated by any agent on personal account. And for both of these subsets of I_t, the terms of trade facing every agent are assumed to be identical, namely, costless access. In short, it is implicitly assumed that there is no discrimination in terms of the costs of or the opportunities for information-production.

The fact that information costs are assumed to be zero for each agent guarantees that all agents will fully exploit all available information-production opportunities. But this assumption does more: it discourages explicit recognition of collusion in the market for information. As indicated in Section 4, the public good attribute of information provides incentives for collusion in the production of costly information.

It should be clear, therefore, that the conventional notion of capital market efficiency—as developed in Section 2—really deals with both the capital market and the market for information.[7] Thus if one finds, for example, inconsistencies between available evidence and the capital market efficiency conditions, it is possible that the true source of the inconsistencies turns on the information market's nature, rather than the capital market's nature. Of course, inconsistencies between available evidence and these efficiency conditions can be due to an inadequacy of any of the jointly tested hypotheses used in empirical work on capital market efficiency (e.g., the hypothesis about the appropriate equilibrium

7. One might have expected recognition of this issue to have been induced by the popular trichotomizing of the efficient capital market notion into the so-called weak, semistrong, and strong forms; see Fama [1970]. It seems, however, that this trichotomy has been used to characterize the capital market and the results of tests dealing with that market. It has not shifted attention from the capital market to the market for information. Hence, the importance of the latter market's structure is not exposed via the trichotomy.

model, the implicit assumptions about the information market, and the efficiency conditions themselves). It is often impossible to determine, within a given study, which members of the joint hypothesis are descriptively invalid. Yet, it is important to recognize precisely what the components of that hypothesis are—to provide a basis for both future theoretical and future empirical work and to provide a basis for identifying the possible (and most likely) sources of observed inconsistencies between evidence and theory. The above discussion identifies an overlooked component of that jointly tested hypothesis—one that can alter interpretations of empirical results.

Moreover, by not giving explicit attention to the market for information, some important theoretical issues may be overlooked. For example, discrimination in the market for information can induce a capital market setting characterized by problems of "adverse selection"—of the kind discussed by Akerloff [1970]—and by problems associated with "signaling" behavior—of the kind discussed by Spence [1974]; see, for example, Gonedes, Dopuch, and Penman [1975].[8] It is with these possibilities in mind that we provide a brief discussion of the market for information in Section 4. Then, in the remaining sections, we consider some implications obtained by explicitly considering the market for information, rather than implicitly imposing conditions on it via a characterization of the capital market (as was done in Section 2).

4. Issues Specific to the Market for Information

4.1 Preliminaries

Some remarks on the mechanism through which resource allocation is affected by produced information are in order. The game-theoretic mechanism introduced by Gonedes [1975] is used as a starting point. It can be losely described as follows. The market for inputs (e.g., labor and capital) used by information-producers and the capital market are assumed to be perfect in the sense that all participants in these markets act as price-takers in frictionless markets. The production and dissemination of information are permitted to be handled via the unrestricted contracting and recontracting of groups or "coalitions."

In order to make optimal portfolio decisions, agents assess the distributions of returns on assets. Newly produced information permits the use of distributions conditional upon completely reliable signals (from Nature) on the exact distributions of returns. Thus, produced information affects the distributions used by investors in making optimal portfolio decisions and, consequently, if affects the equilibrium prices of firms' shares. Given firms' adherence to the "market value rule," such information affects, therefore, firms' production-investment decisions, or the allocation of real resources. In short, information produced for investors' use on personal account affects firms' production-investment decisions via the information's effects on the prices of firms' shares. Details are provided in Gonedes [1975].

8. A framework that allows for these problems permits a natural identification of the kinds of issues considered by Jensen and Meckling [1975].

4.2 Remarks on Produced Information

One of the basic problems faced in considering the market for the results of information-production is that, unlike, "private" goods, one person's use of produced information does not reduce the "amount," or affect the attributes, of produced information that is available for other users. Suppose, for example, that returns on assets can be characterized by the familiar two-parameter model. This model implies that the equilibrium expected return on an asset is linearly related to that asset's relative risk, which is conditional upon the portfolio held by an agent in equilibrium. Next, suppose that one provides a completely reliable signal pertaining to the true value of an asset's relative risk. That signal can be used by that person in assessing the equilibrium expected return on the asset. But the same signal can be used by any other agent who wishes to assess the equilibrium expected return on the asset. And the first person's use or nonuse of the signal does not affect the information content of the signal insofar as any other agent's assessments of equilibrium expected returns are concerned. In short, produced information is a "public good."

Information's being a public good does not imply that the market mechanism cannot be used for information-production. It does imply that special care is needed in specifying the kind of market setting that can be used. Two plausible specifications are discussed by Gonedes and Dopuch [1974; Sec. 5]. One is based upon the game-theoretic perspective used by Gonedes [1975]. The other involves a setting discussed by Demsetz [1970] regarding the private production of public goods. Using either specification, one gets a setting for information-production that leads to a competitive pricing mechanism for the results of information-production. The equilibrium induced by this mechanism will consist of a Pareto Optimal set of information-production decisions. In equilibrium, no information used solely for "trading" purposes—such as that considered by Fama and Laffer [1971], Hirshleifer [1971], Marshall [1974], and Ng [1975]—is produced if doing so requires the use of real resources. This does not imply, however, that there will be no wealth transfers, since side-payments may be needed to prevent information-production that requires the use of real resources and that simply induces wealth redistributions.

4.3 Observations and Implications

There are several noteworthy features of the scenario for information-production sketched in Section 4.1 and 4.2. First, there are obvious incentives for collusion—collusion that might involve the managements of different firms, the holders of different classes of securities (or the same class), managements and securities analysts, or managements and "institutional investors." Basically, these incentives exist because of the public good attribute of produced information and a setting wherein mutually acceptable arrangements for group action are feasible and enforceable.

Secondly, the scenario indicates that one cannot reject on theoretical grounds the characterization of the market for information implicit in the conventional notion of capital market efficiency (see Section 2). This holds even though there may be collusive actions amongst agents in the market for information and even though different agents may pay different prices for the same property rights in the information market.[9]

Thirdly, and most importantly, the information-market conditions leading to the above scenario's results identify a variety of potential inconsistencies between: (1) the nature of the market for information and (2) the nature of that market implicitly assumed in the conventional characterization of capital market efficiency. Consider, for example, the "exclusion of nonpurchasers" rule, which plays a critical role in the mechanisms that induce a Pareto Optimal competitive equilibrium in the market for information.

Suppose that the existing technology or the existing property rights system does not sustain enforcement of the exclusion of nonpurchasers rule. This may lead to a "failure" in the market for information. If it does, then the information-production results implied by the conventional notion of capital market efficiency may not be attained. To be sure, contemporary disclosure laws may alleviate the effects of this "market failure." But there are a variety of reasons for not expecting them to do so; see Gonedes, Dopuch, and Penman [1975; Sec. 3]. Moreover, disclosure laws are not intended to deal with all forms of information-production activities. For the most part, they deal with a firm's production of information about itself.

The issue of excluding nonpurchasers is related to an arrangement that has been discussed frequently: the bundling of services by market institutions. A bundling of the results of information-production activities and the results of other activities (e.g., portfolio management activities, safekeeping activities, and trade-execution activities) is equivalent to creating a so-called "tying arrangement," which has been widely discussed in the industrial organization literature. On the one hand, this kind of tying-in can be viewed as a practice that imposes restrictions on agents' latitude of choice and one whose elimination would induce an increase in agents' welfare. Mann [1975; p. 315] seems to adopt this perspective. On the other hand, such a tie-in arrangement can be viewed as an attempt to enforce the exclusion of nonpurchasers rule for a particular public good, *viz.*, the results of information-production activities. Purchases of the tied good(s) or service(s)—e.g., portfolio management activities—may serve as an effective metering device for measuring usage of that public good. Charging a price for the tied good in excess of the tied good's marginal cost would then be consistent with practicing price discrimination vis-à-vis sales of the public good.[10] That is not inconsistent with attaining Pareto Optimal results for the problem at hand; see footnote 9.

In the tying-in situation, forced unbundling of services may not increase agents' welfare. It will not do so if the tying arrangements are the most efficient means of enforcing exclusion of nonpurchasers vis-à-vis information-production activities. In

9. The existence of different equilibrium prices for different agents is not inconsistent with competitive equilibrium and Pareto Optimality when one is dealing with a public good; see, e.g., Samuelson [1954], [1955], and Demsetz [1970].

10. See, e.g., Bowman [1973]; Burstein [1960]; and Singer [1968; Ch. 16]. Of course, the possibility of re-selling information may weaken the metering power of the tied good, insofar as the original producers are concerned. Presumably, they recognize this possibility and attempt to make appropriate adjustments in their prices, contractual terms, selections of customers, etc. One can also presume that potential purchasers recognize these possibilities and bid accordingly. Note that related issues arise in, e.g., analyses of markets for new and used durable goods; see Benjamin and Kormendi [1974].

 38

the latter case, untying may lead to no change in information-production activities but the use of more resources in the enforcement of property rights. Or, if other means of enforcement are less effective, it may lead to changes in the composition and/or scale of information-production activities.[11]

Other kinds of inconsistencies can arise when there are discriminatory terms of trade in the market for information, due to differential costs of or opportunities for information-production. One kind of discriminatory setting arises when a firm (i.e., a firm's management) is a "monopolist" in the market for information about itself. Situations involving "inside" information are essentially of this type.

Another kind of discriminatory setting arises when some agent has a monopolistic position vis-à-vis some kind of human capital. Recognition of this possibility enables one to assess the forcefulness of some arguments dealing with, for example, portfolio management activities. It has often been suggested that economic rents on such activities attributable to special skills (e.g., data-analysis skills) are not to be expected in an efficient capital market. This suggestion often leads to a recommendation of "passive portfolio management."[12] But the situation of interest pertains to the market for information, not the capital market. Specifically, skills such as data-analysis skills (due, for example, to accounting, legal, or economic expertise) constitute a productive resource with respect to information-production, just as management skills constitute a productive resource with respect to producing, say, hand calculators or medical products.[13] To say that one has "special" skills presumably means that one has a monopoly over some kind of human capital at a particular point in time. One does not have to resort to mysterious arguments about capital market agents' "errors" or to challenge the descriptive validity of capital market efficiency conditions in order to explain the potential existence of such a position.[14] Indeed, such arguments fail to deal with the relevant market, *viz*, the market for information.

Whether or not the kind of monopolistic position described above can be perserved (ie., whether or not it can support systematic economic rents) depends upon the structure of the market for information (e.g., entry possibilities). Capital market efficiency is, in general, not sufficient to undo such a position. Specifically, the oft-heard argument that no "superior" type of portfolio management system can be superior for very long "because of capital market efficiency" is a seemingly misguided argument. The latter argument attempts to state the consequences of entry conditions in the capital market for results in the information market. Entry conditions in one of these markets need not, however, be the same as in the other. More generally, the structure of one of these markets need not provide any

11. Note that we are here dealing with tying arrangements per se, not the now defunct "fixed commission" regime usually associated with the bundling of services by members of organized national securities exchanges.

12. This notion is discussed by Black [1971].

13. Note that the nature of human capital affects what one can do with the information-production technology perceived to exist as well as one's perception of what the existing technology is relative to the economy as a whole (i.e., at least one agent). For example, agents with special legal or accounting skills may, at given point in time, be aware of opportunities unknown to agents without such skills.

14. See, e.g., Treynor [1974] and Bernstein [1975] for discussions that resort to these kinds of arguments.

implications on results in the other market. A recent paper in which this is ignored is Boudreaux [1975]. He correctly notes that the notion of capital market efficiency deals with the rapidity and unbiasedness of the capital market's reaction to new available information. He then proceeds to use these (and other) features of an efficient capital market to make statements about information-production activities, such as statements about the equilibrium allocation of real resources to information-production. Alas, this involves confusing two different markets. It is just as misleading as using the structure of the capital market to make statements about the structure of the input markets in which factors of production are sold to firms whose shares are traded in the capital market.

The kinds of inconsistencies mentioned above may lead to important inconsistencies between: (1) available evidence and (2) the conditions and implications of the conventional notion of capital market efficiency. Such violations may be observed even though each agent is correctly using all the information available to that agent (which is not necessarily the same as all the available information). When such departures are observed, it seems best to ascribe them to an aspect of the market for information rather than to an aspect of the capital market, even though the effects of the departures show up in attributes of the capital market.[15]

In short, it appears that the capital market efficiency conditions, as originally stated in Section 2, encompass conditions on capital market agents' behavior, the nature of the capital market (e.g., whether it is frictionless or not), and the nature of the market for information. If one is primarily interested in the descriptive validity of the conditions vis-à-vis the capital market, then it appears appropriate to restrict the efficiency conditions to situations for which one is willing to adopt (on *a priori* and/or empirical grounds) the maintained hypothesis of nondiscriminatory opportunities for information production at zero cost. Situations involving readily available public data and announcements that are specified (on *a priori* and/or empirical grounds) to have known implications are examples of such situations.[16]

At first glance, it might seem that the suggested restriction is important for only empirical work. I would argue that this is not the case. The theory of capital market efficiency is, presumably, supposed to provide insights into the allocation of resources and the effects of the capital market's structure on that allocation. If, however, the role of the market for information is not recognized, then it seems unlikely that a complete understanding (at least at a theoretical level) of resource allocation under uncertainty will be obtained. In a world of uncertainty, information and the opportunities for information-production play important roles in the allocation of resources. This has not gone unrecognized, as is indicated by the burgeoning literature on information economics; see, for example, the recent survey article by Hirshleifer [1973] and the overview paper by Arrow [1974].

15. As indicated earlier, it may not always be possible to determine the precise reason for a departure from the market efficiency conditions. In such cases, pending additional work, all that one can do is recognize the possibility of the information market's structure having induced the departure.

16. If the implications of such data and announcements are not presumed to be known by all market agents, then one must say something about the opportunities for and costs of ferreting out those implications. In this regard, one would have to consider, for example, the extent to which there is restricted access to forms of human capital (e.g., accounting, legal, or economic expertise) that are useful in ferreting out those implications.

The above discussion points to a variety of areas for research on the information market, such as: the kinds of collusive arrangements (if any) used, the extent to which there are discriminatory costs of or opportunities for information-production, entry conditions and opportunities, etc. The recent work by Herman and Safanda [1973] on allocating "investment information," the work by Stillson [1974] on financial institutions' information services, and the proposed work by Maisel [1975] on information and the regulation of financial institutions essentially deal with some issues of this sort.

The above discussion also provides a new perspective for interpreting empirical results on the "abnormal returns" earned by various types of market agents. This topic is the subject of the next section.

5. Discrimination in the Market for Information: Another Look at Some Existing Evidence

5.1 Preliminaries

Suppose we identify groups of agents who might have special information-production opportunities. And suppose their produced information is used for allocating resources to securities. If, in fact, those groups do have special information-production opportunities, then one expects to observe their earning, on average, economic rents or "abnormal returns." If no such rents are, on average, observed for the groups deemed most likely to have special information-production opportunities, then we shall have evidence inconsistent with the existence or at least the persistence of rent-producing discriminatory opportunities for information-production.[17] In this regard, several types of agents come immediately to mind, such as mutual funds, corporate insiders, and specialists on the New York and American Stock Exchanges. Empirical evidence pertaining to the first two groups is provided by Jensen [1969], Scholes [1972], and Jaffe [1974], among others. A brief review of their work is given in Section 5.2. A variety of observations and implications are given in Section 5.3, where the issues discussed in Section 4 are recognized.

As with many other aspects of capital market efficiency, dealing with the issue of special information-production opportunities requires some statements about the relationship between information and asset prices, and thus a characterization of capital market equilibrium. One such statement is provided by the equilibrium expected return/risk relationship implied by the familiar two-parameter asset pricing model. That relationship provides a specification of equilibrium expected returns conditional on available information. If the special groups considered here do have and use special information-production opportunities, then their expected returns, before deducting information-production costs, should differ systematically from the equilibrium expected returns conditional on readily available public information presumed to have known implications. In short, the two-parameter

17. Forces acting against the persistence of such opportunities are discussed below.

model provides a norm or benchmark that can be used in testing for agents' access to special information-production opportunities. A recent review of theory and evidence pertaining to this model is provided by Jensen [1972].

5.2 *A Brief Review of Some Evidence*[18]

The norm provided by the two-parameter framework was used by Jensen [1969] in his examination of 115 mutual funds. The returns on the 115 mutual fund shares were compared to the expected returns implied by the two-parameter model, holding portfolio risk constant.

Jensen assessed the funds' performance at several levels of analysis. He considered, for example, shareholders' returns net of management fees, loading charges, and other avoidable expenses and shareholders' returns measured gross of loading charges and all other identifiable expenses (conditional on the information disclosed by the funds). The crux of his results is that, on average, the funds' performance was not superior to the two-parameter model's predictions. In general, Jensen's results seem to provide no support for the funds having had persistent special information-production opportunities.[19]

The two-parameter model was also used by Jaffe [1974] in his examination of insider trading. The extent to which insiders earn systematic abnormal profits was assessed by estimating the differences between returns on insiders' transactions and the predictions of the two-parameter model.[20] His estimation results are consistent with the claim that insiders have special information-production opportunities. After recognizing transactions costs, only the results for his "intensive trading" samples are consistent with this claim.

Additional evidence on the extent to which insiders and other groups have special information-production opportunities is provided by Scholes [1972]. His analysis deals with the expected value of a departure from the two-parameter model's equilibrium expected rate of return. These expected values were estimated for the day of and several days surrounding those large-block sales called secondary distributions. On balance, his results are consistent with the "information hypothesis." This hypothesis states that a large block sale will affect a security's price if there is information implicit in the fact that some capital market agent is trying to sell a large block of shares. Shortly after the day of the secondary (on average, one to five days), there appeared to be no further price adjustments. The extent of the price adjustment appeared to depend on the initiator of the sale, with

18. Some familiarity with the studies reviewed here is assumed. A lengthy review of these and related studies is provided by Fama [1970].

19. One might argue that some of Jensen's results are consistent with the existence of special information-production opportunities and the subsequent dissipation of rents via costly rent-seeking behavior, which affects the funds' expenses. Yet, his results based upon ignoring all identifiable expenses seem inconsistent with that argument. In any event, this alternative interpretation does not affect our major points. It does, however, lead to implications not considered here. See, e.g., Posner [1975] and Krueger [1974].

20. Jaffe's technique is more complicated than this statement suggests. But his method boils down to the indicated kind of comparison.

the largest observed for corporations or corporate officers and the second largest observed for investment companies and mutual funds; see Scholes [1972; Table 6].

Scholes' results are consistent with the following. Up to the time of a secondary offering, the source of the distribution had special information and this information is "received" by the market via the selling activity (given the source) rather than before that activity (when the source of the distribution acquired the information). In short, one can view Scholes' results as being consistent with some agents'—in particular, corporations' and corporate officers'—having special information-production opportunities.

Scholes' results, which are based on returns measured gross of all expenses, seem to be somewhat consistent with investment companies' and mutual funds' occasionally having special information-production opportunities. This finding appears to be somewhat inconsistent with Jensen's [1969] results for returns measured gross of all expenses. Note, however, that Scholes' analyses deal with selected transactions (i.e., large-block secondary distributions) of funds rather than their overall performance. We shall return to this issue in Section 5.3.

5.3 Some Interpretations and Observations

Taken at face value, the evidence discussed above seems to be consistent with the statement that some groups of agents have special information-production opportunities. That is, there seems to be an inconsistency between this evidence and the conventional statement of the capital market efficiency conditions; see Section 2. In terms of the perspective adopted here (see Section 3), this inconsistency is something that can be ascribed (at least in part) to the nature of the market for information rather than the capital market.

Upon closer analysis, however, it is not even clear that there is an inconsistency to be ascribed to the nature of the market for information. With one exception, the abnormal returns found to have accrued to selected groups (e.g., corporate insiders) were measured before costs of information-production, both explicit and implicit. The one exception is Jensen's study of mutual funds, wherein the effects of the explicit expenses of the funds were (to the extent possible) recognized. It is quite possible that all of the apparent cases of abnormal expected returns would vanish if all explicit and implicit costs of information-production were recognized. Indeed, this cost factor may explain the weak inconsistency (see above) between Jensen's and Scholes' results on the extent to which mutual funds have access to special information-production opportunities. Scholes' results effectively assume zero information-production costs. Jensen's results based upon ignoring *identifiable* expenses are the most comparable to Scholes' results. But, as Jensen himself indicated, his adjustments were not very precise because of deficiencies in the data disclosed by funds.[21] And, of course, implicit costs (opportunity costs) would not be easily computed—by either Scholes or Jensen—even if there were no disclosure problems. If Jensen's adjustments were more precise—or if Scholes had made some adjustment for nonzero information-production costs—the evidence from the two

21. Adjusting returns for brokerage commissions was one of his important problems; see Jensen [1969, p. 228, fn. 89].

studies might have been more consistent, insofar as their implications for the information market are concerned.[22]

If the kinds of studies reviewed above are viewed as attempts to test for the existence of discrimination in the market for information, then the inadequate adjustments for the resources consumed by information-production activities appear to severely restrict the studies' implications. Such adjustments seem to be important for making inferences about the opportunities available to the indicated groups, but not other agents. In addition, they seem to be important in testing for differences in the opportunities available to the identified special groups. Both types of differences (if they exist) can provide insights into the market for information.

In this regard, note that completely adjusting results for information-production costs may involve adjusting the returns on benchmark portfolios. Suppose, for example, that the version of the two-parameter model used to provide benchmark results implies that agents must make inferences about various parameters' values (e.g., the values of assets' expected returns and risks) in order to select optimal portfolios.[23] This implies that selecting optimal portfolios involves at least estimation costs, which are types of information-production costs. If the returns on those portfolios are used to establish benchmarks and if those returns are not adjusted for information-production costs, then one's results will be biased against detecting special information-production opportunities. This is obviously important when there is a high probability of discrimination with respect to the costs of, but not necessarily the technology for, information-production.

Adjusting for the costs of information-production activities involves, of course, a variety of heady problems in data collection. This is illustrated by the problems encountered by Jensen [1969], because of inadequate disclosures regarding expenditures. But the problems encompass more than disclosures of explicit expenditures. Some transactions in the market for information may be barter transactions involving swaps of produced information. Others may involve tie-in sales or similar arrangements designed to enforce exclusion of nonpurchasers. It is not clear that any "real world" data are available for attacking these problems—not a very cheery thought for those interested in empirical work.

Finally, note that the various alleged forms of collusion amongst groups such as those identified above (e.g., collusion amongst analysts and managements) are not indications of "failure" in the market for information.[24] As indicated earlier (see Section 3), there are reasons for expecting collusion in a well-functioning market

22. Scholes' estimated value of the information impounded in funds' distributions is substantially reduced, but still nonnegative, after adjusting by his assumed commission rate of 1 percent; see his Table 6. The estimated value implied by Jensen's results for returns measured *gross of all costs* is essentially zero; adjusting for commissions leads to negative estimates. Thus, the slight inconsistency between Scholes' and Jensen's results exists even after recognizing the transactions costs that would be induced by attempts to exploit information.

23. Several versions of the two-parameter model are reviewed by Jensen [1972].

24. An illustrative allegation is provided in the SEC's recent proposal on forecast disclosures; see Securities and Exchange Commission [April 28, 1975; p. 3] and the analysis in Gonedes, Dopuch, and Penman [1975].

for information. Thus, taken by themselves, collusive acts in the market for information do not imply that some agents face obstacles not confronted by or induced by other agents. Dealing with this issue requires an analysis of the extent to which the opportunities for collusion are discriminatory.

6. External Accounting: Issues and Implications

6.1 *Preliminaries*

As indicated in Section 1, some of the theoretical underpinnings that can be exploited in work on external accounting and disclosure laws arise from the connection between information-production activities and capital market equilibrium. In this section, we consider some implications of our previous analysis of those activities and the capital market. Implications based upon the conventional definition of capital market efficiency are considered. Also, implications of the altered perspective developed in Section 3 are considered. We begin with a discussion of some issues that motivate some investigations of external accounting and capital market equilibrium.

6.2 *Illustrative Issues*

Consider a change in the accounting procedures used by some firm for external accounting (e.g., a switch from FIFO to LIFO for external reporting, perhaps induced by making that change for tax reporting). It is often alleged that the effect of any such change on reported earnings plays a critical role in managements' decisions about effecting the change.[25] This role is ascribed to the perceived influence of reported earnings on firms' equilibrium values. This perspective seems to involve an important assumption about the determination of firms' equilibrium values. Specifically, it seems to assume a somewhat mechanical relationship between firms' reported earnings and firms' equilibrium values. As it stands, this perspective implies, therefore, that a firm can change its equilibrium value by changing its accounting techniques, even though the firm undergoes no substantive economic changes.

The perspective just ascribed to some managements is not unlike that adopted by many in the accounting profession.[26] Thus, in addition to affecting some managements' decisions, it may motivate a variety of accounting rules and regulations. A glance at some official pronouncements—e.g., Opinions of the Accounting Principles Board, Statements of the Financial Accounting Standards Board, and the SEC's Accounting Series Releases—will probably suffice to indicate that it has motivated some policy decisions made by the accounting profession and the SEC. The announced or proposed decisions on the following topics are among those for which support or opposition involves this perspective to some extent: (1) accounting for leases (see FASB [1975] and Hawkins [1975]), (2) income accounting for insurance companies (see Foster [1975]), (3) accounting for "extraordinary items" (see Gonedes [1975a]), and (4) the inclusion of interim results in footnotes to annual reports (see Coopers and Lybrand [1975]). If the indicated perspective is not

25. See, for example, Wallich and Wallich [1974], which deals with changes from FIFO to LIFO.

26. See, for example, Spacek [1959] and Chambers [1974].

descriptively valid, then perhaps attention and resources are being diverted from more important issues—ones that might enhance the information content of accounting numbers.

Issues such as the above are among those motivating work on external accounting and capital market equilibrium.[27] In this work, the notion of capital market efficiency has played a critical role—in the design of empirical studies and in the development of relevant theoretical propositions. Some of these propostions are considered below. Initially, we use the conventional capital market efficiency conditions, as given in expressions (2.1) and (2.2).

6.3 *Implications for External Accounting: First Pass*

Begin by considering some of the elements of I_t—the set of all available information as of time t. In particular, consider the types of events represented by accounting numbers available at time t, which consititute a subset of I_t.

Presumably, the accounting numbers issued by any firm reflect (to some extent) events that impinged upon a firm's operations and thus affected its performance, as measured by accounting numbers. Such events include: (1) those that occur within the factor-input markets in which the firm transacts and (2) those that occur within the firm's output markets. These kinds of events may be specific to a particular industry or they may be economy-wide events. Also, some of the events that influence a firm's operations may be specific to that firm.

The set of information available at time t also contains other sources of information on economy-wide and industry-wide events, as well as on firm-specific events. Some alternative sources on economy- and industry-wide events include: industrial production reports, reports on industrial prices, reports on stabilization policies (e.g., reports on the policies of the Federal Reserve Board), and forecasts issued by trade associations, among other things. All of these kinds of items are competitive sources of information vis-à-vis accounting numbers because both they and accounting numbers reflect the same kinds of events, e.g., economy-wide and industry-wide events.

Additional potentially competing sources of information, vis-à-vis accounting numbers, include statements made by corporate officials regarding their firms' operations, releases issued by brokerage firms, releases issued by market-newsletter services, the contents of filings with the Securities and Exchange Commission (which do not include only accounting numbers) and, more generally, all results of information-production undertaken by capital market agents on personal account. In general, if these—or any other—sources reflect something that, *ex ante*, is pertinent to evaluating a firm, then their information content will, in an efficient market, be fully reflected in equilibrium prices.

Asserting that there are competing sources of information vis-à-vis accounting numbers implies something about the market for information. Specifically, it implies that there are substitute sources of information. As in any other market, the existence of substitutes weakens or eliminates any potential for a monopolistic position by one source.

One implication of the preceding remarks is that—in a conventionally defined

27. A detailed review of this kind of work is provided in Gonedes and Dopuch [1974].

efficient capital market—agents will not blindly accept and use only accounting numbers in establishing firms' values. In other words, there are alternatives to accounting numbers, viewed as sources of information. Hence, the market is not constrained to using accounting numbers. If the alternative sources of information suggest that accounting numbers are "deficient" indicators of events pertinent to assessing firms' values, then the accounting numbers will not be blindly used by capital market agents. In short, in a conventionally defined efficient capital market, there appears to be no basis for expecting a mechanical relationship between reported accounting numbers and firms' equilibrium values. In such a capital market, those numbers will affect equilibrium prices and adjustments thereof only to the extent that they convey information pertinent to assessing firms' values.

6.4 *Implications for External Accounting of the Information Market's Structure*

The above discussion is conditional upon the conventional statement of the capital market efficiency conditions, as given in expressions (2.1) and (2.2). But we argued that those conditions incorporate conditions on the market for information as well as the capital market. With an explicit treatment of the market for information, one can think of various plausible counterarguments vis-à-vis our previous conclusions. Not unexpectedly, these counterarguments turn on some sort of friction or imperfection in the market for information.

For example, one might argue: (1) that reported accounting numbers are, in some sense, "deficient" as sources of information for assessing firms' values and (2) that only a restricted group of persons (e.g., those trained in accounting, firms' managements, etc.) have the opportunities for detecting those deficiencies. The deficiencies may exist because of outright attempts to produce distorted information or simply because of the accepted rules and regulations of external accounting.[28] In effect, this situation involves discriminatory opportunities for information-production. It is one in which there are no adequate substitute sources of information, because of the discriminatory opportunities. Depending upon the structure of the market for information, such situations may arise. And they cannot be undone because of capital market efficiency; see Section 4.

It is important to recognize, however, that monopolistic situations such as the above may not persist. If one is to persist, then the select group(s) of persons capable of producing the information supportive of accounting numbers' deficiencies must be able to retain a monopoly position in the market for information. That implies that there will never be opportunities to produce substitute sources of information, due to agents' actions on personal account or public regulatory actions. In short, the persistence of such situations seems to require an extreme form of monopoly in the market for information. This appears to be one of the implicit assumptions made in some arguments about the effects of accounting numbers. For example, Chambers [1974; p 49] states:

> An efficient market, in the fullest sense, would, by the prices established in it, secure the support of enterprises or projects of companies which have demonstrated earning capacity superior to that of other

28. Some incentives for producing distorted information—capital market efficiency notwithstanding—are discussed in Gonedes, Dopuch, and Penman [1975].

companies. But if earnings reports are differentially distorted by the asset valuation and the income calculation rules adopted by different companies... the stock market *cannot discriminate between the more and the less efficient companies.* [emphasis added]

Clearly, this argument assumes that there are no substitute sources of information vis-à-vis accounting numbers.

When viewed in this light, it is easy to envisage factors acting against the existence or at least the persistence of such a situation. For example, the availability of the substitute sources of information mentioned above may work against some situations of the type described. Also, if training in accounting is really the critical issue, then there will be incentives for agents to acquire the requisite human capital—which is an input for information-production in the present scenario. This too works against the kind of monopoly position described above. Thirdly, the "nonmonopolistic" agents may themselves engage in collusive acts, on private account or via governmental bodies, that weaken or destroy the monopolistic position(s). The proposals for more disclosures about banks' portfolios (see SEC [October 1, 1974] and Coldwell [1975]) and about the financial affairs of municipalities that make public offerings (see Sommer [1975]) can be viewed as results of such collusive acts via governmental bodies. In short, the existence of a monopoly leads to economic rents. Therefore, it induces rent-seeking behavior, which works against preservation of a monopolistic position and, thus, towards the dissipation of rents.[29]

Another counterargument challenging our original conclusions turns on the extent to which capital market agents are "conditioned." A concise statement of this argument was provided by Sterling [1970; p. 453]:

Accounting reports have been issued for a long time, and their issuance has been accompanied by a rather impressive ceremony performed by the managers and accountants who issue them. The receivers are likely to have gained the impression that they ought to react, and have noted that others react, and thereby have become conditioned to react.

Clearly, if this argument is to make any sense, there must be at least one agent who can recognize that one or more other agents are "conditioned." That implies that at least one agent has information-production opportunities not available—on the same terms of trade—to other agents. That is, it implies a monopolistic position in the market for information. Consequently, the preceding discussion on such monopolistic positions applies here as well; depending upon the structure of the market for information, the indicated situation may arise. But, taken as it stands, this second counterargument is also inadequate because it does not recognize the effects of counter-vailing forces in the market for information. In other words, it fails to explain how such a position can be preserved. Indeed, it does not even explain how it could ever arise. Some agents are said to react because they observe other agents reacting to accounting numbers. The counterargument never explains how those other agents came to react in the first place.

The point of the above discussion is two-fold and simple: (1) an efficient capital market will not suffice to eliminate discriminatory costs of or opportunities for

29. Recent analyses of rent-seeking behavior, including its implications for private and social costs, are provided by Krueger [1974] and Posner [1975].

information-production and (2) asserting that such instances of discrimination may or do arise is, by itself, inadequate because it ignores all of the forces that work against the existence or preservation of that discrimination. In short, it appears that a complete understanding of the connection between external accounting and capital market equilibrium requires theoretical and empirical analyses dealing with the market for information and the capital market, rather than with only the latter. In this regard, a substantial amount of work remains to be done.

7. Summary

This paper explored several aspects of information-production and capital market equilibrium that seem to have been ignored in the available literature. It was argued that the prevalent use of a definition of capital market efficiency imposing strong conditions on the information market seems to have disguised the importance of explicitly analyzing the market for information. One consequence is that many assertions about what capital market efficiency implies—about, e.g., "superior" portfolio performance and the allocation of resources to information-production—appear to be misleading, because they do not deal with the relevant market. Moreover, it is usually not recognized that some evidence interpreted as being inconsistent with capital market efficiency is best viewed as pertaining to the market for information rather than the capital market. More generally, failure to explicitly consider the market for information may induce unwarranted inferences about the capital market. Finally, it was argued that, in general, the notion of capital market efficiency does not, taken by itself, provide a basis for fully understanding the connection between external accounting and capital market equilibrium, or any other potential source of information and capital market equilibrium.

Post-Earnings-Announcement Drift: Delayed Price Response or Risk Premium?

VICTOR L. BERNARD* AND JACOB K. THOMAS†

1. Introduction

This study seeks to discriminate between competing explanations of "post-earnings-announcement drift." Ball and Brown [1968] were the first to note that even after earnings are announced, estimated cumulative "abnormal" returns continue to drift up for "good news" firms and down for "bad news" firms. Foster, Olsen, and Shevlin [1984] (henceforth FOS) are among the many who have replicated the phenomenon.[1] FOS estimate that over the 60 trading days subsequent to an earnings announcement, a long position in stocks with unexpected earnings in the highest decile, combined with a short position in stocks in the lowest decile, yields an annualized "abnormal" return of about 25%, before transactions costs.

Competing explanations for post-earnings-announcement drift fall into two categories. One class of explanations suggests that at least a portion of the price response to new information is delayed. The delay

52

might occur either because traders fail to assimilate available information, or because certain costs (such as the costs of transacting or the opportunity costs of implementing and monitoring a trading strategy) exceed gains from immediate exploitation of information for a sufficiently large number of traders. A second class of explanations suggests that, because the capital-asset-pricing model (*CAPM*) used to calculate abnormal returns is either incomplete or misestimated, researchers fail to adjust raw returns fully for risk. As a result, the so-called abnormal returns are nothing more than fair compensation for bearing risk that is priced but not captured by the *CAPM* estimated by researchers. In the case of post-earnings-announcement drift, this explanation requires that firms with unexpectedly high (low) earnings become more (less) risky on some unrecognized dimension.[2]

Several of the results in this paper are difficult to reconcile with plausible explanations based on incomplete risk adjustment. However, they are consistent with a delayed response to information.

What is less clear is why a delayed price response would occur. While abnormal returns to trading on postannouncement drift may be within the transactions costs for small individual investors, a transactions-cost-based explanation raises several difficult unanswered questions. Moreover, one of our tests suggests an alternative explanation for a delay: that prices are affected by investors who fail to recognize fully the implications of current earnings for future earnings.

Section 2 summarizes the current state of understanding of post-earnings-announcement drift and presents arguments for delayed price response and *CAPM* misspecification as explanations for the drift. Section 3 describes the sample and some of the methods used in our empirical tests. The tests themselves are summarized in section 4. A discussion of the evidence and some conclusions are presented in section 5.

2. *Post-Earnings-Announcement Drift: The Nature of the Phenomenon*

The postannouncement drift documented by FOS is duplicated in our figure 1. The figure shows the cumulative abnormal returns (*CARs*) for ten portfolios with different earnings news. To generate the *CAR* plots, FOS used a statistical earnings forecast to estimate unexpected earnings for a sample of NYSE and AMEX firms. The unexpected earnings, scaled by the standard deviation of prior forecast errors, were then compared to the cross-sectional distribution of scaled unexpected earnings for the prior quarter. Based on their standing relative to that distribution, firms were assigned to one of ten portfolios. Finally, the abnormal (size-

[2] Finally, a third explanation—bias resulting from research design problems other than *CAPM* misspecification—is always possible. However, FOS do much to dismiss this possibility. Our study also dismisses some research design problems as potential explanations for the drift.

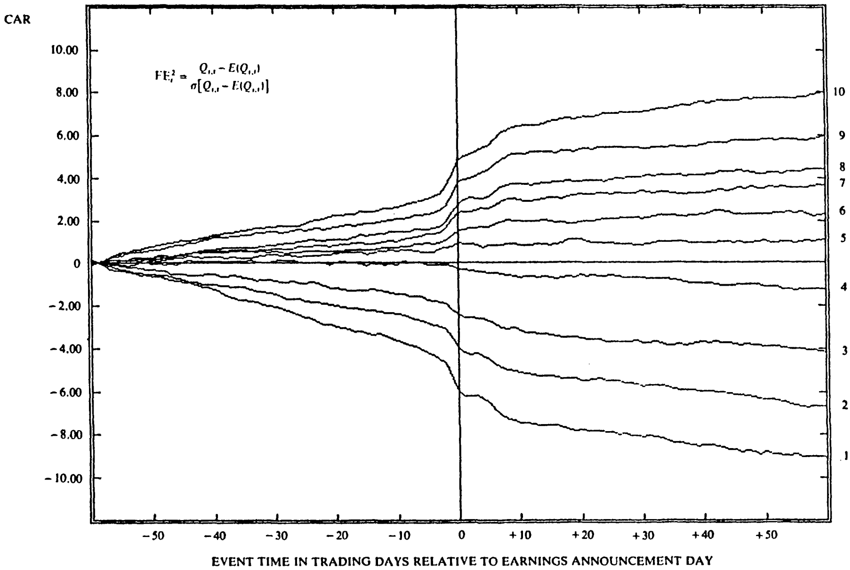

FIG. 1.—Cumulative abnormal returns for FOS earnings-based model (*EBM*) tests. Earnings announcements are assigned to deciles based on standing of standardized unexpected earnings (*SUE*) relative to prior-quarter *SUE* distribution. Portfolio 10 includes firms with the highest *SUE* ranking. Based on data from 1974–81. Cumulative abnormal returns are the sums over 120 trading days surrounding the earnings announcement, of the difference between daily returns and returns for NYSE firms in the same size decile. *SUE* represents forecast error from a first-order autoregressive earnings expectations model (in seasonal differences) scaled by its estimation-period standard deviation. (Reprinted, by permission of the publisher, from G. Foster, C. Olsen, and T. Shevlin, "Earnings Releases, Anomolies, and the Behavior of Security Returns," *The Accounting Review* [October 1984]: 589.)

adjusted) returns on those ten portfolios were plotted over the 120 trading days surrounding the earnings announcement date.

In figure 1, the estimated post-earnings-announcement abnormal returns vary monotonically with the *SUE* deciles. A long position in portfolio 10 (that with the highest unexpected earnings), combined with a short position in portfolio 1 (that with the lowest), yields an estimated abnormal return of 6.31% over the 60 trading days after the earnings announcement, or about 25% on an annualized basis. The issue we now address is whether this estimated abnormal return reflects an incomplete adjustment for risk or a delayed price response.

2.1 THE CASE FOR CAPM MISSPECIFICATION

Ball [1988] argues that there is good reason to believe stock markets to be efficient on a priori grounds, because such markets are "paradigm examples of competition." Some years earlier Ball [1978] argued that even in an efficient market, trading strategies based on earnings numbers might *appear* to generate abnormal returns, because of misspecifications in the *CAPM* used to measure the abnormal returns. There is some evidence consistent with this explanation in Ball, Kothari, and Watts [1988] (henceforth BKW) and FOS [1984].

BKW suggest that betas shift upward (downward) for firms with high (low) unexpected earnings. Since some prior studies assumed for purposes of estimation that betas were stationary, this caused an upward (downward) bias in estimated abnormal returns. To overcome this bias, BKW use an estimation approach that permits betas to shift annually. In so doing BKW find that the postannouncement drift is no longer significant.

The question is whether BKW's failure to detect a significant drift in the year after annual earnings announcement extends to other sample firms and shorter postannouncement periods. Since (as will be shown later) most of the drift occurs within three months of the earnings announcement, quarterly return periods should provide a more powerful test. In addition, BKW's sample includes primarily large firms, and FOS [1984] have shown that the absolute magnitude of the drift is inversely related to firm size. We examine whether beta shifts can explain much of postannouncement drift in a design that uses quarterly data and a sample that is not dominated by large firms.[3]

A second source of evidence consistent with *CAPM* misspecification is the major result in FOS [1984]. FOS contrast two alternative approaches to analyzing the postannouncement behavior of stock returns. The first is that used to generate figure 1: the earnings-based model (*EBM*) approach. The second approach assigns firms to portfolios on the basis of firms' estimated abnormal stock returns over the 60 days prior to and including the earnings announcement day.[4] This is labeled the *SRM* (security-return model) approach. The essential result of the *SRM* tests is that there is no indication of post-earnings-announcement drift. Thus, postannouncement drift was observed only under the first (*EBM*) approach.

The results of the *SRM* tests in FOS have been interpreted by some as indicating that postannouncement drift reflects some problem in risk measurement. For example: "Using the (SRM) method of forming portfolios yields no unusual return behavior following the earnings announce-

[3] We have learned in private conversations with BKW that our results motivated them to extend their tests to quarterly data. In contrast to their earlier results, their tests based on quarterly data indicate significant postannouncement drift, even after adjusting for beta shifts.

[4] FOS also examined tests based on abnormal returns over the two-day window ending on the earnings announcement day and obtained similar results. We do not focus on these short-window tests, however, because in addition to the issues discussed below, they are affected by a bias that would tend to obscure part of the drift. Specifically, when stock returns are ranked over an interval as short as two days, good (bad) news stocks tend to be those that closed on the second day at the ask (bid). Subsequent movement to an average price between the ask and the bid causes an artificial "return reversal" that offsets a portion of any drift.

ment and suggests again that the results of previous studies are caused by a misspecified pricing model" (Dyckman and Morse [1986, p. 58]).

Although the same conclusion was not drawn by FOS, it is understandable that readers of FOS could draw such an inference. FOS explain that the *EBM* tests are vulnerable to certain problems in risk adjustment discussed by Ball [1978]; the *SRM* tests were motivated as one approach to mitigate these problems. Given that the drift vanishes in the *SRM* tests, the results could suggest that the drift in the *EBM* tests reflects a premium for some unidentified risk.

However, Bernard and Thomas [1989] suggest that any such inference is unwarranted. The reason is that the FOS results are consistent not only with certain explanations under which the drift represents a risk premium but also with certain other explanations where the drift is a delayed price response. Specifically, they show that if (1) there exists some delay in the response to earnings news, and (2) the fraction of the *total* response that is *delayed* varies sufficiently across firms, then it is possible simultaneously to detect a drift in the *EBM* tests but not detect a drift in the *SRM* tests.[5] As a result, Bernard and Thomas suggest that a more appropriate interpretation of FOS's *SRM* test is that, rather than discriminating between *CAPM* misspecification and delayed price response, it imposes restrictions on the nature of *CAPM* misspecifications, and on the delayed price response, that could explain the drift. Hence the overall results from FOS still leave open the question of what causes postannouncement drift.

2.2 THE CASE FOR A DELAYED PRICE RESPONSE

That post-earnings-announcement drift could represent a delayed response to information has been viewed as plausible by some academics. For example, Lev and Ohlson [1982, p. 284] describe the evidence of post-earnings-announcement drift as the "most damaging to the naive and unwavering belief in market efficiency." However, it is difficult to explain why the market would fail to respond immediately to earnings information.

One possibility is that transactions costs inhibit a complete and immediate response to earnings news. Examples of such costs include the bid–ask spread, commissions (for some investors), the costs of selling short, and the costs of implementing and monitoring a strategy (including opportunity costs). We turn to a detailed discussion of this possibility later in the paper.

A second possibility is that market prices are influenced by investors who fail to appreciate the full implications of earnings information. That is, some investors may fail to form an unbiased expectation of future

[5] The analysis also requires a third (mild) assumption, that there is no positive serial correlation in the component of stock returns not associated with earnings news.

earnings immediately upon revelation of current earnings, with some portion of the response not occurring until analysts' forecasts are revised or future earnings are realized.[6] Although this possibility departs dramatically from most academics' view of market efficiency, there presently is little evidence on this specific issue. Kormendi and Lipe [1987] and Freeman and Tse [1989] indicate that responses to current earnings reflect at least *some* of the implications for future earnings, but that does not necessarily imply that the immediate response is *complete*. This and other competing explanations are the focus of our empirical tests in section 4.

3. *Sample and Estimation Procedures*

3.1 SAMPLE SELECTION

Our sample includes 84,792 firm-quarters of data for NYSE/AMEX firms for 1974–86. We also conduct some supplementary tests based on 15,457 firm-quarters of data for over-the-counter stocks on the NASDAQ system for 1974–85. Criteria for inclusion in the sample are the same as those used by FOS, who studied NYSE/AMEX firms for the period 1974–81. We require that the firm be listed on the *CRSP* daily files, and that the firm's earnings before extraordinary items and discontinued operations be available for at least ten consecutive quarters on *Compustat*. Our NYSE/AMEX sample includes only firms that appeared on any of the *Compustat* files released from 1982 through 1987.[7] Since firms included in earlier files but dropped from *Compustat* before 1982 are excluded from the sample, there is a potential for a survivorship bias in the first half of our data set. However, FOS conducted tests which indicated that postannouncement drift is not sensitive to this form of bias. Moreover, our conclusions are insensitive to whether we include or exclude "nonsurvivors" dropped from the *Compustat* files between 1982 and 1987.

3.2 ESTIMATION PROCEDURES

3.2.1. Estimation of abnormal returns. For the NYSE/AMEX sample, cumulative abnormal returns are calculated using an approach like that of FOS. FOS use a companion portfolio approach designed to control for

---

[6] Clearly, an efficient market may resolve uncertainty about the implications of a previously released earnings number when future earnings are released (Freeman and Tse [1989]). Nevertheless, regardless of how much uncertainty surrounds current earnings, stock prices in an efficient market should immediately reflect an unbiased expectation of future earnings. If information uncertainty is not "priced out," this implies no predictable postannouncement drift. If information uncertainty is priced out, this implies positive postannouncement drift for both good and bad earnings news, which is inconsistent with the data.

[7] The NASDAQ sample was selected from the 1987 *Compustat* file only.

the Banz-Reinganum size effect.[8] Under this approach, abnormal returns are calculated as follows:

$$AR_{jt} = R_{jt} - R_{pt} \tag{1}$$

where AR_{jt} = abnormal return for firm j, day t;
R_{jt} = raw return for firm j, day t;
R_{pt} = equally weighted mean return for day t on the NYSE/AMEX firm size decile that firm j is a member of at the beginning of the calendar year. Firm size is measured by the market value of common equity.

In our tests based on abnormal returns, we preserve comparability with FOS and sum abnormal returns over time to obtain cumulative abnormal returns (*CARs*). One problem with summing abnormal returns over time is that it implicitly assumes daily rebalancing and leads to an upward bias in the returns cumulated over long periods (Blume and Stambaugh [1983] and Roll [1983]). However, since this bias affects both the primary and the companion portfolios, there may be no bias in our estimated abnormal returns. In fact, we have conducted analyses that indicate that the difference between abnormal returns on extreme good news and bad news firms is similar, whether the returns are summed or compounded.[9] In addition, we describe in section 3.2.4 an alternative abnormal return calculation that is free from the bias described by Blume and Stambaugh [1983].

Observations were excluded from the analysis if the return for the earnings announcement day was missing on *CRSP*, or if the *CRSP* returns series did not encompass the 160 trading days surrounding the earnings announcement.

3.2.2. Estimation of standardized unexpected earnings (SUE). Procedures for estimating unexpected earnings were patterned after those used by FOS for the *EBM* Model 2. That is, earnings were forecasted by estimating the Foster [1977] model with historical data.[10] The difference

[8] This approach to measuring abnormal returns makes no attempt to control for systematic risk. Since our conclusions are based on comparisons of abnormal returns on high and low unexpected earnings portfolios, this introduces a bias if systematic risk differs between those two. We test for such a possibility in section 4.2.1.

[9] If anything, our use of summed returns may understate the extent of postannouncement drift. The indicated abnormal returns are about 10% larger when we employ the FOS approach but compound returns over time (using portfolios that are initially equal-weighted). Details are available upon request.

[10] The Foster model assumes that earnings follow a first-order autoregressive process in seasonal differences. FOS indicate [1984, p. 582] that they used a maximum of 20 observations to estimate the Foster model. We used a maximum of 24 observations. FOS indicate [1984, p. 581] that firms were included in the sample even if only ten consecutive quarters of data were available. We retained such firms also, but where fewer than 16 observations were available, we assumed that earnings followed a seasonal random walk. FOS indicate [1984, p. 582] that they obtained essentially the same results when this model was substituted for the Foster model.

between actual and forecasted earnings was then scaled by the standard deviation of forecast errors over the estimation period to obtain standardized unexpected earnings or *SUE*.

3.2.3. Portfolio assignment. Holthausen [1983] and FOS describe a bias that is introduced when firms are assigned to portfolios. When those assignments are based on rankings of unexpected earnings within the distribution for *all* firms, including some that have *not yet announced* earnings for the quarter, there is a hindsight bias that tends to magnify the drift. Like FOS, we overcome that bias by assigning firms to portfolios on the basis of their standings relative to the distribution of unexpected earnings in the *prior* quarter.

3.2.4. Alternative abnormal return calculation: continuously balanced SUE strategy. Abnormal returns are typically viewed as returns in excess of some benchmark, such as the market model. The FOS size-control portfolio approach yields abnormal returns that can be interpreted in this way. However, in the case of the FOS approach, an alternative interpretation is also possible. Because FOS always offset a position in a given firm with the position in a size-control portfolio, the resulting abnormal returns represent the return on a zero-investment trading strategy. The advantage of this interpretation is that, if the offsetting positions are of equivalent risk, any nonzero expected return on the zero-investment portfolio contradicts the implications of market efficiency (at least before considering transactions or other costs).

The difficulty with this interpretation is that the FOS strategy may be difficult to implement as it stands. The strategy requires an investor to take new positions in size-control portfolios every day, with each control portfolio containing hundreds of stocks. Thus, results based on this approach leave open the question of whether similar returns could be generated by an easily implemented, zero-investment strategy.

To assess the sensitivity of our results to this issue, we replicated some of our tests based on a zero-investment strategy that would be easier to implement. Since it involves having the same amount invested in good news and bad news firms at all points in time, we label this strategy the "continuously balanced" *SUE* strategy. (To differentiate it, we sometimes label the FOS approach the "FOS control portfolio" *SUE* strategy.)

The continuously balanced *SUE* strategy works as follows. On a given trading day, we identify any firms that announced earnings, and where standardized unexpected earnings fall in the upper quintile (good news) or lower quintile (bad news) of the prior-quarter distribution. If both good news and bad news firms exist for that day, we assume a long position in the former and a short position in the latter. The long (short) positions are initially equally weighted across the available good (bad) news firms, with the total amount of the long position exactly offsetting the total amount of the short position. We then compute buy-and-hold (i.e., continuously compounded) returns on each of the stocks in the long and short position, over the 60 trading days subsequent to the earnings announcement.

On 14% of trading days, there were either no new good news or no bad news firms available, and so no match could be created. In such cases, we "wait" until a match becomes available. For example, if two good news firms announced earnings on day 1, but no bad news firms announced, we would wait until at least one bad news firm announced earnings. If the first available bad news firm announced on day 4, it would be matched with all good news firms announcing from days 1 through 4, and we would then compound returns from day 5 through day 64. In 97% of all cases, a match became available within two days.

To provide some control for the Banz-Reinganum size effect, this matching process was always conducted within groups of small, medium, and large firms. Small firms are those whose January 1 market value of equity was among the lowest four deciles of the NYSE/AMEX, whereas large firms are those among the highest three deciles. Using only three size groups increased the probability of finding matches of good news and bad news firms within a short period of time. Since we used only three size groups (versus ten in the FOS control portfolio approach), our control for size is not as precise. However, if we assume that smaller firms are as likely to announce bad news as good news, this introduces no bias in the results.[11]

The continuously balanced *SUE* strategy is much easier to implement than that used by FOS but would still be costly to the extent that short selling must be used. There would be no significant difficulty, however, for investors who already own the stocks that announce bad news.

4. *Empirical Results*

4.1 DESCRIPTIVE RESULTS

4.1.1. Magnitude of the drift. FOS [1984] provide estimates of the magnitude of post-earnings-announcement drift and show that the drift varies inversely with firm size. In this and the following section, we replicate those results and demonstrate that they persist over a longer time period. Unless otherwise specified, the results in this section are based on the procedures used by FOS, to maintain comparability; results based on the continuously balanced *SUE* strategy are reported only as supplement information.

Figure 2 presents *CAR* plots for the sample, after assigning firms to portfolios on the basis of standardized unexpected earnings. In contrast to the format used by FOS in figure 1, figure 2 separates *CAR* plots for

[11] If bad news firms are more likely to be small, due to price declines in anticipation of the earnings announcement (and vice versa for good news firms), then the Banz-Reinganum size effect would impart a *downward* bias in our estimated abnormal returns. That is, the bias would tend to offset any postannouncement drift.

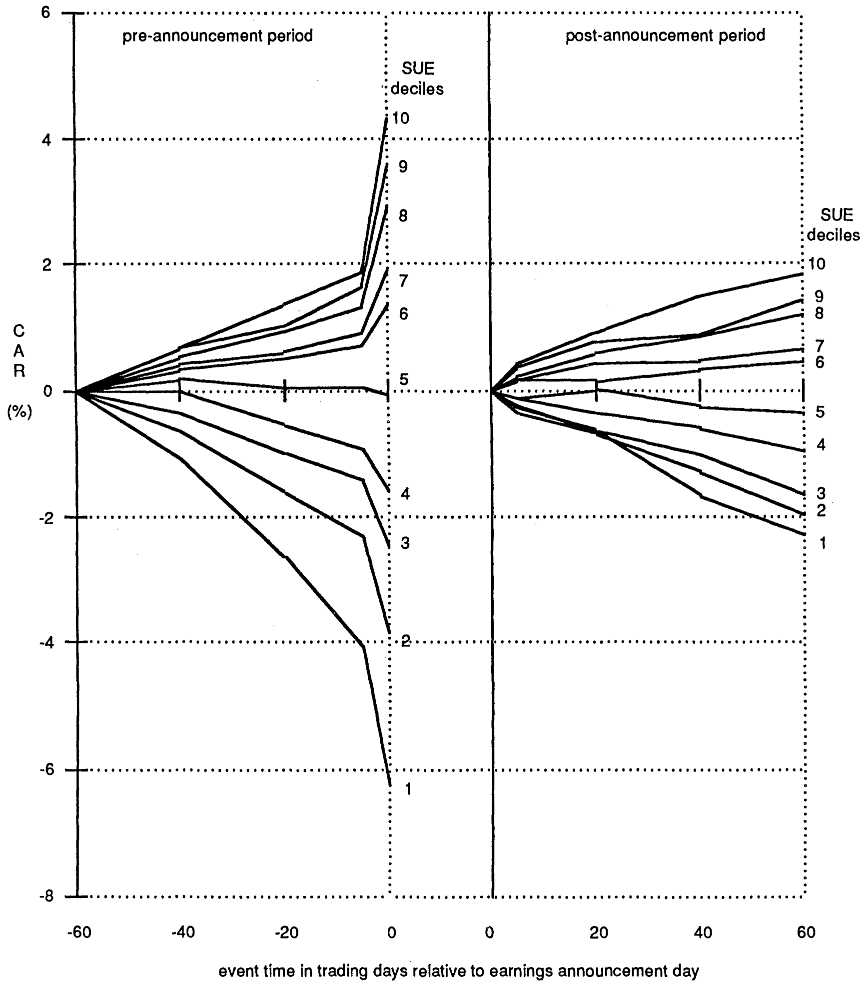

FIG. 2.—Cumulative abnormal returns (*CARs*) for *SUE* portfolios: all announcements. Earnings announcements are assigned to deciles based on standing of standardized unexpected earnings (*SUE*) relative to prior-quarter *SUE* distribution. Based on 84,792 announcements from 1974 to 1986. *CARs* are the sums over pre- and postannouncement holding periods (beginning day −59 and day 1, respectively) of the difference between daily returns and returns for NYSE/AMEX firms of the same size decile. *SUE* represents forecast errors from a first-order autoregressive earnings expectation model (in seasonal differences) scaled by its estimation-period standard deviation (see section 3.2 for details).

the pre- and postannouncement periods, to make the postannouncement abnormal returns easier to gauge. Our results for 1974–86 are similar to those obtained by FOS for 1974–81. That is, there is a pronounced post-earnings-announcement drift, increasing monotonically in unexpected earnings. A long position in the highest unexpected earnings decile and a short position in the lowest decile would have yielded an estimated abnormal return of approximately 4.2% over the 60 days subsequent to the earnings announcement, or about 18% on an annualized basis. (The annualized abnormal return on the continuously balanced *SUE* strategy is 17%.) For the 1974–81 period studied by FOS, we obtain an annualized return of 19%, which is less than the 25% implied by their results.[12]

4.1.2. Relation of drift to firm size. Figures 3 and 4 indicate how the drift varies by firm size, by presenting results for large and small firms.[13] As noted by FOS, the postannouncement drift is larger for smaller firms. Among small firms, a long position in the highest unexpected earnings decile and a short position in the lowest decile yielded an abnormal return of approximately 5.3% over the 60 days subsequent to the earnings announcement. Comparable abnormal returns for medium-sized firms (not shown) and large firms are 4.5% and 2.8%, respectively.

Results based on the continuously balanced *SUE* strategy are similar. For 60-day holding periods, mean abnormal returns for small, medium, and large firms are 5.1%, 4.3%, and 2.8%.

In regressions not reported here, we use the approach of FOS [1984, p. 595] to test the statistical significance of the postannouncement drift and the effect of firm size. Our results confirm that the magnitude of the drift is related to the magnitude of unexpected earnings, and that the absolute magnitude of the drift is inversely related to firm size, both at significance levels less than .01.

We do not present comparable plots of NASDAQ firms. However, the same phenomenon observed for NYSE/AMEX firms was observed for that sample. The magnitude of the drift for NASDAQ firms lies between that observed for small and medium-sized firms on the NYSE/AMEX. This is as expected, given that approximately 70% of our NASDAQ firms would be classified as small (relative to the NYSE/AMEX firms), 20% would be classified as medium, and 5% would be classified as large.

4.1.3. Longevity of the drift. Table 1 provides information about the longevity of the postannouncement drift for stocks ranked in the lowest and highest *SUE* decile, broken down by size and by subperiods extending two years beyond the earnings announcement date.

Most of the drift occurs during the first 60 trading days (about three months) subsequent to the earnings announcement, and there is little evidence of statistically significant drift beyond 180 trading days. If we assume all of the drift occurs within 480 days, then the fraction of the

[12] Differences between our results and those of FOS are most pronounced for small, good news firms. A possible explanation for the difference involves how control portfolios were constructed. It appears that FOS included only NYSE firms in their control portfolios [1984, p. 585], whereas we included both NYSE and AMEX firms.

[13] Firms were assigned to *SUE* deciles before segregation by size. The large firms are more heavily represented in the extreme deciles; in figure 3, *SUE* deciles 5 and 6 contain approximately 2,400 observations each, while *SUE* deciles 1 and 10 contain approximately 3,100 observations each. For small firms, the reverse relation holds; in figure 4, *SUE* deciles 5 and 6 contain approximately 3,400 observations each, while *SUE* deciles 1 and 10 contain approximately 2,700 observations each.

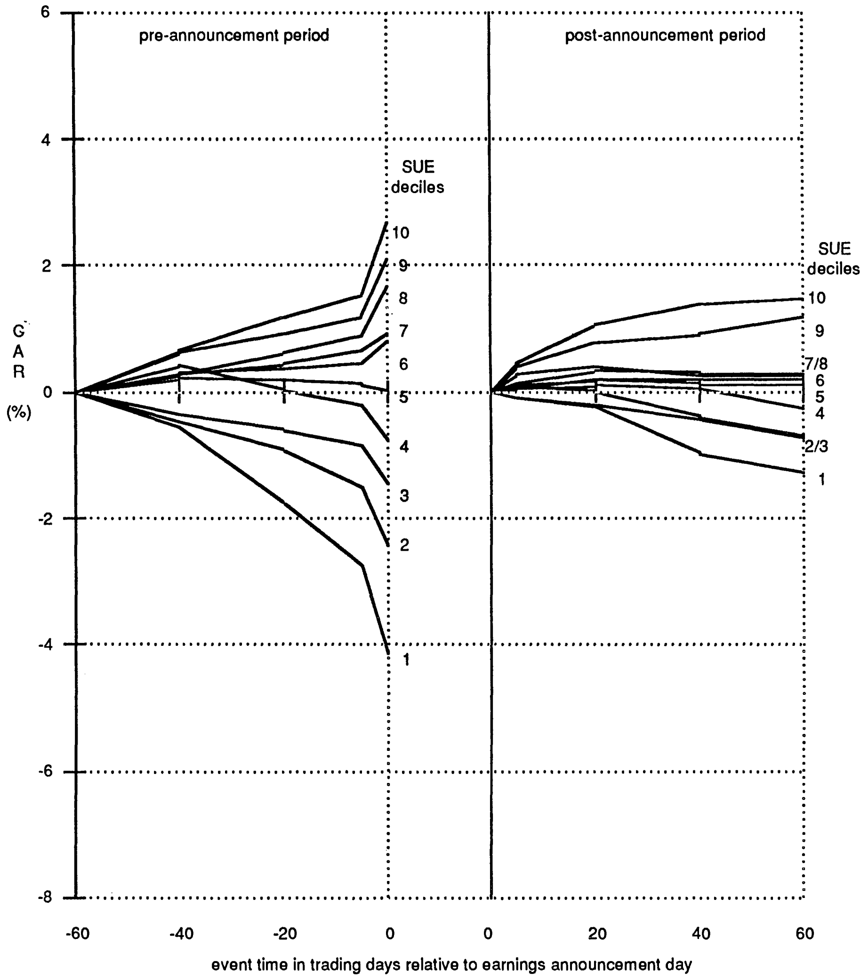

FIG. 3.—Cumulative abnormal returns (*CARs*) for *SUE* portfolios: large firms only. Earnings announcements are assigned to deciles based on standing of standardized unexpected earnings (*SUE*) relative to prior-quarter *SUE* distribution. Based on 27,584 announcements from 1974 to 1986. Large firms are in size deciles 8 to 10, based on January 1 market values of equity for all NYSE and AMEX firms. *CARs* are the sums over pre- and postannouncement holding periods (beginning day −59 and day 1, respectively) of the difference between daily returns and returns for NYSE-AMEX firms of the same size decile. *SUE* represents forecast errors from a first-order autoregressive earnings expectation model (in seasonal differences) scaled by its estimation-period standard deviation (see section 3.2 for details).

drift experienced within 60 days is 53%, 58%, and 76% for small, medium, and large firms, respectively. Approximately 100% of the drift occurs within nine months for small firms and within six months for large firms. This result is consistent with the findings of Watts [1978], who found a

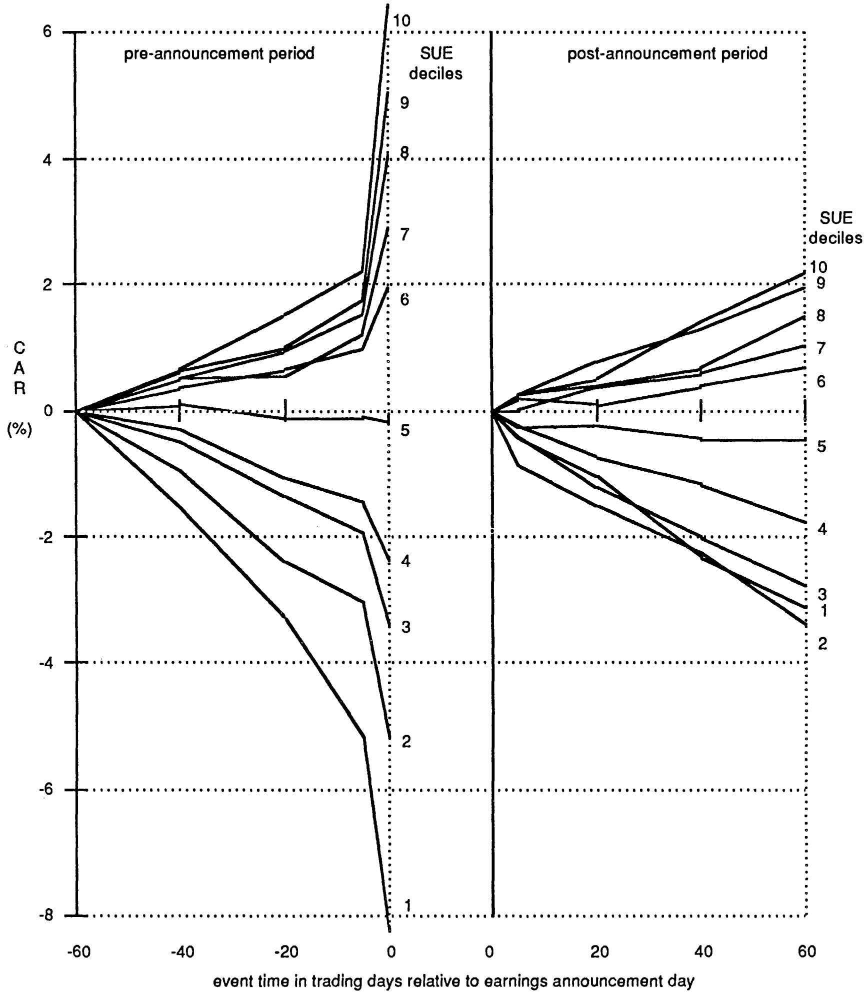

FIG. 4.—Cumulative abnormal returns (*CARs*) for *SUE* portfolios: small firms only. Earnings announcements are assigned to deciles based on standing of standardized unexpected earnings (*SUE*) relative to prior-quarter *SUE* distribution. Based on 29,796 announcements from 1974 to 1986. Small firms are in size deciles 1 to 4, based on January 1 market values of equity for all NYSE and AMEX firms. *CARs* are the sums over pre- and postannouncement holding periods (beginning day −59 and day 1, respectively) of the difference between daily returns and returns for NYSE-AMEX firms of the same size decile. *SUE* represents forecast errors from a first-order autoregressive earnings expectation model (in seasonal differences) scaled by its estimation-period standard deviation (see section 3.2 for details).

significant drift lasting six months in his sample consisting primarily of large firms.

A disproportionately large amount of the 60-day drift occurs within 5 days of the earnings announcement. If the drift were constant over the

[1] *CARs* are the sums over specified holding periods of the difference between daily returns and returns for NYSE-AMEX firms of the same size decile. *SUE* represents forecast errors from a first-order autoregressive earnings expectation model (in seasonal differences) scaled by its estimation-period standard deviation (see section 3.2 for details). Small, medium, and large firms are in size deciles 1 to 4, 5 to 7, and 8 to 10, respectively, based on January 1 market value of equity for all NYSE and AMEX firms.
Significance levels for two-tailed tests of the hypotheses that abnormal returns equal zero are coded as follows:
* Significant at the 1% level.
** Significant at the 5% level.
*** Significant at the 10% level.

60-day interval, we would expect 8% of the drift to arise within 5 days. However, the actual percentage of the 60-day drift that occurs within 5 days (not shown in table 1) is 13%, 18%, and 20% of the 60-day drift for small, medium, and large firms, respectively.

Table 1 suggests that, if the drift is explained by an incomplete adjustment for risk, the risk must exist only temporarily and must persist longer for small firms than for large firms.

4.2 TESTS OF RISK PREMIUMS AS EXPLANATION FOR THE DRIFT

4.2.1. Shifts in betas as a potential explanation. We now present results from a battery of tests designed to assess the plausibility of incomplete risk adjustment as an explanation for postannouncement drift. We first consider BKW's [1988] suggestion that betas increase for firms with high unexpected earnings and decrease for firms with low unexpected earnings.

Beta shifts are obviously a concern in a design that estimates betas in one period and then uses those estimates in a different period. Such was the case in much of the early research on postannouncement drift. However, that is not a concern in the FOS design that we adopt, since this design does not rely on estimates of betas. Instead, we *assume* that betas for our long and short positions are equal during the postannouncement period. Under this assumption, the combined long and short positions have zero systematic risk. Thus, while we examine the BKW hypothesis that betas *shift* around the time of earnings announcements, our ultimate concern is with any differences in the *levels* of betas for high- and low-*SUE* firms in the postannouncement period.

Before turning to the tests, we should note that there are indications that failure to account for beta is unlikely to explain postannouncement drift. If mismeasured betas are the explanation, then the sign of the drift should vary according to whether the excess return on the market is positive or negative. Specifically, good news stocks, which would have to be riskier than assumed, should have positive estimated abnormal returns in up markets but negative estimated abnormal returns in down markets. The opposite should hold for bad news stocks. In contrast to this prediction, however, the postannouncement estimated abnormal returns for good news (highest *SUE* decile) stocks are actually positive in both up and down markets. Similarly, estimated abnormal returns for bad news stocks (lowest *SUE* decile) are actually negative in both up and down markets.[14]

Our tests are presented in table 2. Beta estimates were derived using

[14] For good news stocks, the estimated abnormal returns over days (1, 60) are 2.5% (1.1%) when the value-weighted market return is greater (less) than the risk-free rate. For bad news stocks, the estimated abnormal returns are −2.3% (−2.4%) when the value-weighted market return is greater (less) than the risk-free rate. We thank George Foster for suggesting this test.

TABLE 2

Beta Estimates by SUE Category, in Periods Surrounding Earnings Announcement[1]

[1] For each 60-day window, we calculate compounded daily returns for individual stocks, the value-weighted *CRSP* index, and the treasury-bill rate. These data constitute a single observation in a regression of individual stock returns against market returns, both expressed in terms of differences from the treasury-bill rate. Such regressions are estimated within each *SUE* category. There are approximately 8,500 (overlapping and thus nonindependent) observations underlying estimates for the (−59, 0) and (1, 60) windows, and slightly fewer for other windows. The standard error for each estimate in the table is approximately 0.02. Cross-sectional dependence in the data may cause downward bias in the estimated standard error (Bernard [1987]).

* Significantly different from zero, .05 level (two-tailed test).

the BKW methodology for permitting betas to shift through time. For each of several 60-day windows surrounding the earnings announcement, we compounded total returns on individual stock (R_{jt}), treasury bills (R_{ft}),[15] and the valued-weighted *CRSP* index (R_{mt}). These three data points constitute a single observation for a regression based on the Sharpe-Lintner-Mossin *CAPM*:

$$R_{jt} - R_{ft} = a + b\ (R_{mt} - R_{ft}) + e_{jt}. \tag{2}$$

The regression was estimated by pooling all observations for a given *SUE* decile, within six 60-trading-day windows surrounding the earnings announcement date. This approach permits the betas to shift from one window to the next and to vary across *SUE* categories.

The estimates in table 2 show distinct evidence of the positive relation between *SUEs* and betas predicted by BKW [1988]. The rank correlation between beta and *SUE* is .83 in the (−119, −60) window, .84 in the (−59,

[15] The treasury-bill returns are derived on a daily basis from weekly returns calculated by Gautam Kaul for bills in their final week before maturity. Kaul's weekly returns were allocated to days assuming the same return for each day within the week.

0) window, .90 in the (1, 60) window, and .77 in the (61, 120) window. Also consistent with BKW, the relation first appears during the fiscal period in which the earnings are generated. That fiscal quarter would typically bridge the (−119, −60) window and the (−59, 0) window; there is no significant relation between *SUE* and beta in windows prior to day −119. Finally, and again consistent with BKW, the relation is temporary (it becomes insignificant beyond day 180).

Even though we find evidence of a positive relation between *SUE* and betas, it is much smaller than would be necessary to explain fully the magnitude of the drift. The difference between the excess returns ($R_{jt} - R_{ft}$) on *SUE* 10 firms and *SUE* 1 firms over days (1, 60) is 4.3%. (This is slightly larger than the 4.2% abnormal return reported in section 4.1.1, which was size-adjusted.) The corresponding mean excess market return ($R_{mt} - R_{ft}$) is 1.65%. Thus, if betas are to explain postannouncement drift, the difference between betas for the *SUE* 10 firms and *SUE* 1 firms would have to be 2.6 (= 4.3/1.65). In fact, the difference is only 0.21, or less than 10% as large as required.

The failure of betas to explain the magnitude of the drift can be confirmed by examining the "Jensen's alpha" in equation (2). If beta risk could fully explain the drift, then Jensen's alpha should be zero. However, in the 60-day postannouncement period, alpha is −1.6% for *SUE* portfolio 1, 3.0% for *SUE* portfolio 10, and 4.6% for a combined position (significant at the .0001 level). On an annualized basis, this represents an abnormal return of approximately 18%.[16]

We conclude that while there is some merit to the BKW claim that betas shift around earnings announcements, the magnitude of the shifts falls far short of the amounts necessary to explain the magnitude of the drift.[17]

4.2.2. Other commonly discussed asset-pricing factors as potential explanations: APT risk factors as potential explanations. In this section, we test for the possibility that trading strategies based on *SUEs* are risky on dimensions not captured by beta. The risk factors we consider are those found in the literature on arbitrage-pricing theory. Chen, Roll, and Ross [1986] provide evidence that risks associated with industrial production, changes in default risk premiums, and changes in term structure appeared to be priced. They found weaker evidence that risks associated with unanticipated inflation and changes in expected inflation also affected asset prices.

---

[16] Results based on the equally weighted market index yield similar conclusions. The rank correlation between beta and *SUE* decile is weaker but still significant at the .05 level in the (−119, −60) window, the (−59, 0) window, and the (1, 60) window. The difference between betas for *SUE* 10 firms and *SUE* 1 firms in the (1, 60) window is 13% as large as required to explain the drift; Jensen's alpha indicates an annualized abnormal return of 16%.

[17] Subsequent to conducting these tests, we became aware of similar evidence in Mendenhall [1986].

In table 3, we regress calendar-quarter returns[18] on the FOS control portfolio *SUE* strategy (*CAR* for *SUE* decile 10 minus *CAR* for *SUE* decile 1) against quarterly measures of the five risk factors studied by Chen, Roll, and Ross.[19] In addition, we consider a regression that also includes the return on the NYSE index (net of the treasury-bill rate). Table 3 indicates whether a positive or negative correlation with a particular factor would indicate that the portfolio is "risky," as opposed to offering a "hedge" against risk. The evidence from Chen, Roll, and Ross suggests that assets with returns that are *positively* correlated with unanticipated growth in industrial production (*QP*) and unanticipated changes in the default risk premium (*UPR*) are risky and have correspondingly higher required returns, as do assets with returns that are *negatively* correlated with changes in expected inflation (*DEI*), unanticipated inflation (*UI*), and unanticipated changes in the term structure (*UTS*).

Table 3 provides no evidence that the returns on the *SUE* strategy are significantly correlated with any of the five risk factors proposed by Chen, Roll, and Ross. (Three of the five coefficients are both insignificant and have the "wrong" sign.) Moreover, the five factors as a group do not explain a significant fraction of the variance in the strategy's return.

If the right-hand-side variables in table 3 accurately measure ex post premiums on all risk factors that are priced, then the intercept in the regression provides a test of market efficiency. Given that the dependent variable is the return on a zero-investment portfolio, the intercept should be zero under the efficient markets hypothesis. However, the estimated intercepts indicate an abnormal return of 4% per quarter, with *t*-values of 8.63 and 8.70.

Results from the same tests based on the continuously balanced *SUE* strategy are similar to those in table 3.

Dividend yield as a potential explanation. We also examined changes in dividend yields on good news and bad news portfolios. If dividend yields affect asset pricing, as predicted by the Brennan [1970] "after-tax" *CAPM*, then they could conceivably explain post-earnings-announcement drift. But this would require a sufficiently large increase in the difference between dividend yields on good news and bad news stocks. Although we detect such a change, the magnitude (4/10 of 1% of price)

---

[18] Generally, a position held for 60 trading days spans two calendar quarters. Thus, calculation of calendar-quarter returns requires determination of how much of the 60-day return was generated in each of the two quarters.

[19] The variables were measured using the procedures of Chen, Roll, and Ross [1986] as they would be applied to quarterly data, with the following exceptions. First, for convenience, we used the GNP deflator as our measure of inflation rather than the Consumer Price Index and used ASA-NBER forecasts as our measure of expected inflation. (Chen, Roll, and Ross used the Fama-Gibbons inflation forecasting model.) Second, our measure of the unanticipated default risk premium was the difference between the return on low-grade and high-grade corporate bonds rather than the difference between low-grade corporate and government bonds. See table 3 for further information.

[1] Dependent variable is the calendar-quarter return on a zero-investment portfolio, where long (short) positions in extreme good news stocks (extreme bad news stocks) are offset by positions in a portfolio of NYSE-AMEX firms in the same size decile. The returns are regressed against the return on the value-weighted NYSE index (in risk premium form) and five factors identified by Chen, Roll, and Ross [1986] as potentially influencing asset prices.

Extreme good (bad) news is defined in terms of standardized unexpected earnings (*SUE*), relative to prior-quarter *SUE* distribution. Firms ranked in the highest (lowest) decile are considered extreme good (bad) news firms.

Independent variables are defined as follows:

$R_{mt} - R_{ft}$ = return on value-weighted NYSE index, less 90-day treasury-bill rate;
QP = quarterly growth rate in industrial production, lagged ahead one period;
DEI = change in expected inflation;
UI = unanticipated inflation;
UPR = unanticipated change in the default risk premium (return on high-yield bonds [under BBB], less return on AAA bonds);
UTS = unanticipated change in the term structure (return on long-term government bonds, less treasury-bill rate).

[2] $F(5, 43)$ is significant at the .05 level for values in excess of 2.44.

would imply a trivial impact on expected returns, given economically plausible dividend yield effects.

Our conclusion, then, is that the observed postannouncement drift cannot be explained as a risk premium needed to compensate investors for risk factors commonly discussed in the asset-pricing literature. In the following sections, we examine whether some other unidentified risk factor could plausibly explain the drift.

4.2.3. Consistent profitability of the strategy. In this section, we examine how frequently a zero-investment *SUE* trading strategy generates a negative return. If a zero-investment strategy yields a positive *mean* return because it is risky, that risk must periodically reveal itself in the form of losses.

Panels A and B of figure 5 present the abnormal returns on the two *SUE* strategies for each calendar quarter from 1974:III through 1986:IV. In panel A the returns are to the FOS control portfolio strategy, where we assume a long (short) position in the firms whose unexpected earnings are ranked in the highest (lowest) quintile.[20] The returns to the continuously balanced *SUE* strategy appear in panel B. In both panels, we began by calculating abnormal returns over 60-trading-day postannouncement windows and then determined how much of the 60-day return was generated within the two calendar quarters spanned by those 60 days.

The interesting feature of figure 5 is the consistency with which the zero-investment portfolios generate positive returns. The returns in panel A are positive in 46 of 50 quarters and in 13 of 13 years. In panel B, the returns are positive in 44 of 50 quarters and in 13 of 13 years. FOS present similar evidence in their figure 2 [1984, p. 594], which shows a positive abnormal return in 31 of 32 quarters.[21]

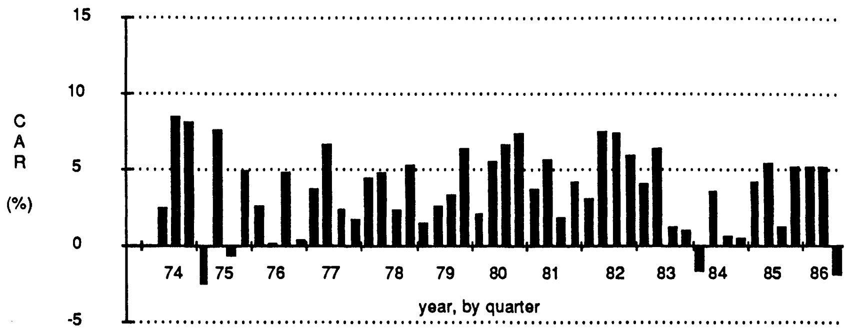
If the returns on a zero-investment portfolio represent compensation for risk, then losses should occur with an expected cost (in terms of utility) that is equal to the expected value of the risk premium. However, for the overall sample, returns of nearly 200% (before compounding) have been generated over the 50 quarters, with negative returns in only 4 or 6 quarters. These negative returns sum to less than 7%.

To better appreciate how surprising the consistency is, consider the behavior of the ex post risk premium for beta. Fama and MacBeth [1973] present returns on zero-investment, unit-beta portfolios for the period 1935–68. That portfolio generated a mean annualized return of about 10%. But among the 134 quarters represented there, returns on this portfolio were negative 39% of the time. In contrast, the mean annualized

[20] Although deciles are used elsewhere when results are presented for the FOS strategy, we use quintiles here to make panel A (based on the FOS strategy) and panel B (based on the continuously balanced *SUE* strategy) more comparable. Results for panel A are similar when deciles are used.

[21] However, FOS do not discuss the implications of this result for distinguishing among alternative explanations for the drift.

Panel A: FOS control portfolio SUE strategy



Panel B: Continuously balanced SUE strategy

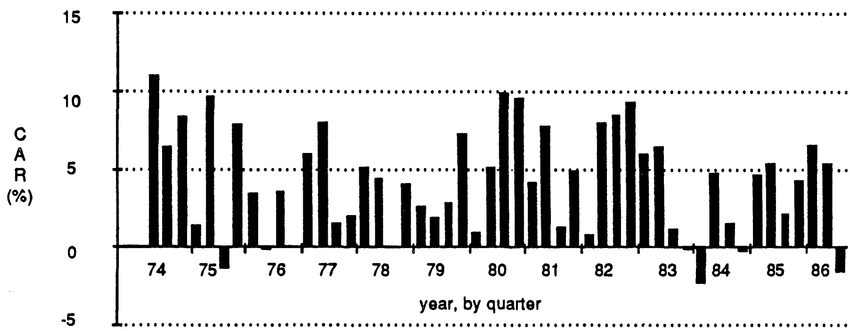


FIG. 5.—Cumulative abnormal returns (*CARs*) from *SUE* strategies, by calendar quarter. In both panels, long (short) positions are assumed in the highest (lowest) quintiles of standardized unexpected earnings (*SUE*) and held for 60 trading days. *CARs* are assigned to calendar quarters based on the portion of the 60-day *CAR* generated within that calendar quarter. *SUE* represents forecast errors from a first-order autoregressive earnings expectation model (in seasonal differences) scaled by its estimation-period standard deviation (see section 3.2 for details). In panel A, *CARs* are the combined abnormal returns from a long position in the highest *SUE* quintile and a short position in the lowest *SUE* quintile. Abnormal returns are the sums over the 60 trading days after the announcement of the difference between daily returns and returns for NYSE-AMEX firms of the same size decile. In panel B, continuous balancing requires that each $1 long position in the highest *SUE* quintile is always offset by a short position in similar-sized stocks (small, medium, or large) in the lowest *SUE* quintile. Balancing in this way sometimes requires waiting after earnings announcements until an offsetting "match" is available. *CARs*, computed over the 60 trading days after matching, are a combination of the compounded (buy and hold) returns for the long and short positions.

return on the zero-investment portfolio described in figure 5 is higher (18%) and yet is negative only 8% or 12% of the time.

Some readers of prior drafts have questioned whether the consistent profitability depicted in figure 5 could reflect some problem in the benchmark we use to measure abnormal returns. But if our benchmark fails to control for some risk that is priced in the market, then the results are even more surprising.[22] For example, if we have failed to control for systematic risk and our combined long and short position has a positive beta, the abnormal return on the strategy should be negative when the overall market return is negative. Over the 50-quarter horizon, the equally weighted NYSE index declined 16 times, and yet the abnormal return on the strategy in panel A was positive in 13 of those 16 quarters (11 of 16 quarters for panel B).

In summary, we are able to reconcile our evidence with *CAPM* misspecification (i.e., failure to control fully for risk) only if at least one of the following conditions hold: (1) the infrequency of losses in the 1974–86 period is extremely unusual, relative to what would be observed in a longer time period; (2) the risk premium earned on the *SUE* strategies represents compensation for the risk of infrequent but catastrophic losses, none of which was observed within this 13-year time span; (3) the disutility of the losses we observe is commensurate with the utility of the gains, because the losses occur during periods when a $1 decline in wealth is 28 times more important than the average $1 increase in wealth. (Cumulative gains are 28 times larger than cumulative losses.)

We find conditions (1) and (3) implausible and note that there is no evidence to support condition (2).

4.2.4. Raw returns on bad news firms. The large estimated negative *abnormal* postannouncement returns for firms with extreme negative unexpected earnings suggests that the *total* (*raw*) postannouncement returns for those firms could be less than the risk-free rate or even negative. Although such predictably low raw returns on risky assets are not ruled out by most modern capital-asset-pricing models, they are expected only under special conditions that many would find implausible as applied to a broad cross-section of stocks. Essentially, the stocks would have to offer some hedge, the value of which exceeds the cost of any other risk to which the asset is exposed.

Table 4 summarizes the total returns, compounded over various periods, for bad news stocks which ranked in the lowest decile of the unexpected earnings distribution. The bottom panel shows that the total annualized returns on the bad news stocks (averaged over firms of all sizes) were 1.5%, 12.6%, and 10.4% for periods ending 5, 20, and 40

---

[22] The results could conceivably be explained by a failure to control for some factor that causes returns to increase (decrease) for good (bad) news firms in *all* periods, regardless of macroeconomic conditions. However, the only asset-pricing models we know of that could possibly include such a factor are the Brennan [1970] "after-tax" *CAPM* (which includes a dividend yield effect) and the Amihud and Mendelson [1986] *CAPM*, which includes a term linked to the bid–ask spread. Earlier (section 4.2.2) we dismissed Brennan's dividend yield effect as an explanation. The Amihud-Mendelson *CAPM* could explain the result only if an announcement of good news (bad news) caused a long-run increase (decrease) in the proportional bid–ask spread. But one would expect the opposite given that the proportional bid–ask spread varies inversely with price, and that good news (bad news) firms tend to experience price increases (decreases).

TABLE 4

Total (Raw) Returns on "Bad News" (Lowest SUE decile) Portfolios[1]

Holding Period (Trading Days, Relative to Announcement)	Small Firms		Medium Firms		Large Firms

(1, 60)		15.4*		27.4*		
(1, 80)		14.8*		26.1*		

[1] *SUE* represents forecast error from a first-order autoregressive earnings expectations model (in seasonal differences) scaled by its estimation-period standard deviation. Firms are assigned to *SUE* deciles based on the standing of their *SUE* relative to the prior-quarter *SUE* distribution.

* Significantly different from zero, .05 level (two-tailed test).

trading days subsequent to the earnings announcement.[23] Total annualized returns for good news firms were 36.5%, 29.3%, and 26.7% for the same periods. These returns were generated during 1974–86, when the average annualized return on treasury bills one week from maturity was

[23] The standard errors of the mean annualized raw returns over the intervals (1, 5), (1, 20), and (1, 40) are all less than 1%, across all categories in table 4. These standard errors

8.5% and the return on the equally weighted NYSE index was approximately 22% (13% for the value-weighted index).

The total annualized returns for *small* bad news stocks over the 5 days after the earnings announcement were not only less than the average treasury-bill rate, they were actually negative (although not significantly different from zero). The total returns for medium firms over the same 5-day window were zero and remained less than the average T-bill rate over the 40 days subsequent to the announcement. All other total returns are in excess of the average T-bill rate. However, for two months following the announcement, the difference was small. For the overall sample, the 40-trading-day return was only 10.4%, or 1.9% higher than the average T-bill rate.[24] In contrast, the 26.7% postannouncement return for the good news firms exceeded the average T-bill rate by 18.2%.

In order to reconcile this evidence with *CAPM* misspecification, one must believe either (1) that betas on the bad news stocks are near zero (and negative for small and medium stocks shortly after the announcement), or (2) that the value of these stocks as hedges against some unidentified risk causes their cash flows to be discounted at rates less than treasury-bill rates during the 5-day postannouncement period, and at rates nearly that low for two months thereafter. Condition (1) is inconsistent with evidence in table 2, and we find it implausible that condition (2) could apply to as broad a spectrum of stocks as those in the bad news portfolios.

4.3 TESTS OF TRANSACTIONS COSTS AS EXPLANATION FOR DRIFT

Since much of the above evidence is inconsistent with explanations based on incomplete adjustment for risk, we now turn to the possibility that the drift could represent a delayed price response. One possibility is that the drift occurs because transactions costs create sufficient impediments to trading to prevent a complete and immediate response to earnings announcements.

The abnormal returns reported in this paper appear to be within round-trip transactions costs for the small individual investor. When transactions costs are defined to include both bid–ask spreads and commissions, they are about 4% and 2% for small and large stocks,

---

were calculated by scaling the standard deviation of raw returns underlying the mean (before annualizing) by the square root of the sample size, and then multiplying by the square root of the factor used to annualize the returns. To the extent the data overlap in calendar time and are cross-sectionally dependent, the standard errors are understated.

[24] A comparison of raw returns to the average treasury-bill rate is imprecise, in that it assumes the event periods are evenly distributed in calendar time. We also calculated the difference between raw returns and contemporaneous returns on treasury bills. For the overall sample, the difference was negative for the first 5 days of the postannouncement period (−7.0%) and positive for the first 40 days (2.1%).

respectively (Stoll and Whaley [1983]).[25] To calculate the cost of the *SUE* strategy, one must double these amounts to reflect the costs of a combined long and short position. Then, taking into account that the *SUE* strategy involves (on average) a 78% turnover in portfolio content each quarter, the implied cost would be about 6% (3%) per quarter for small and large stocks, respectively. These amounts are approximately equal to that 60-day abnormal returns in table 1.

In this section, we consider how the data might behave if transactions costs explain postannouncement drift, and then test for the existence of that behavior.

4.3.1. Is the drift "constrained" by an upper bound? Our first test was inspired by Ball [1978, p. 110], who argued that, ". . .if the 'slow' market reaction is explained in terms of transactions costs (or costs of 'professionals' operating in the market), then *small* deviations from expectations are those which imply market disequilibrium. Large deviations presumably attract more investors and are promptly incorporated in prices because (under this hypothesis) the net gain, after costs, is higher. The consistent interpretation of this hypothesis is that the excess returns persist up to, but not beyond, the level of marginal transactions and information processing costs."

Under Ball's depiction, a postannouncement drift would be observed only when the implied excess returns are small. Alternatively, the drift may be observed for all levels of implied excess returns but would never exceed a threshold (equal to the cost of exploiting the information), regardless of the magnitude of unexpected earnings.[26] That is, regardless of whether the *total* stock price response implied by an earnings announcement is 2%, 5%, or 20%, the price might move immediately to within (say) 2% of the implied level. At that point, incentives to exploit the earnings information would be eliminated for many traders, and the remainder of the response would occur only with some delay. In such a market, the postannouncement drift would increase as unexpected earnings increase, but only to some upper bound; beyond that bound, the drift would remain constant, regardless of the magnitude of unexpected earnings.

Ball [1978, p. 110] notes that existing evidence does not appear consistent with this characterization: ". . .the evidence. . .is that extreme-rank earnings and dividend changes are associated with *larger* estimated abnormal returns, contrary to the 'transactions cost' and 'private cost' explanations." However, we consider here whether we (and prior re-

[25] These amounts are based on data from the post-1975 era of negotiated commissions and are calculated by grouping Stoll and Whaley's deciles into three categories to conform to our definitions of small, medium, and large.

[26] Although we initially inferred that Ball's depiction was consistent with the second alternative, he has indicated to us that he intended to imply the first.

searchers) have failed to observe an upper bound because we have not yet examined sufficiently extreme values of unexpected earnings.[27] Our approach is to divide our sample into progressively smaller portfolios, based on rankings of unexpected earnings. That is, we first divide the sample into halves, then thirds, quintiles, deciles, and so on, until finally we divide the sample into 100 portfolios, based on rankings of unexpected earnings. At each of these steps, we calculate the abnormal return from a long position in the portfolio with the highest unexpected earnings, and a short position in the portfolio with the lowest unexpected earnings. Thus, at each step, the values of unexpected earnings in our portfolios become more extreme. If postannouncement drift is caused by a cost that impedes trading, we should observe that, at a point bounded by that cost, the drift should cease to increase, even though unexpected earnings continue to increase.

The results are presented in panel A of figure 6. We find that the drift (over 60 days) grows larger, up to the point where the difference between *SUEs* for extreme portfolios is equal to six. (This is the point at which the sample is split into deciles, which is as fine a decomposition as any prior study has used.) Beyond that point, the drift does not increase. Note that the upper bound for the drift is about 4%, or 2% per position. That amount is within the bounds of transactions costs for the average firm (based on Stoll and Whaley [1983]), where such costs include both commissions and the bid–ask spread. Figure 6, panel B shows that the drift is bounded at approximately 5%, 4.3%, and 3% for small, medium, and large firms, respectively. This is consistent with Stoll and Whaley's [1983] evidence that transactions costs vary inversely with firm size; when their sample is segregated into thirds, transactions costs are 3.9%, 2.6%, and 2.0% for small, medium, and large firms. When these amounts are doubled to account for a combined long and short position, they exceed the bounds implied by figure 6, panel B.

One potential alternative explanation for the result is that the more extreme values of unexpected earnings simply reflect estimation error. That is, beyond some upper bound, any additional increases in our measures of unexpected earnings represent nothing more than noise. However, the data indicate that this is not the case. Figure 6, panel A also presents the preannouncement abnormal returns for portfolios with varying levels of unexpected earnings. Note that even though the postannouncement drift reaches a maximum when *SUE* difference equals 6, the preannouncement drift continues to increase to the point where *SUE* difference equals 14. Thus, increases in unexpected earnings (at least to that point) have stock price impacts and are not purely the result of noise.

Note also that the results of this test cast additional doubt on arguments based on *CAPM* misspecification. In order to accommodate these

---

[27] We are grateful to Jim Noel, who suggested the tests in this section.

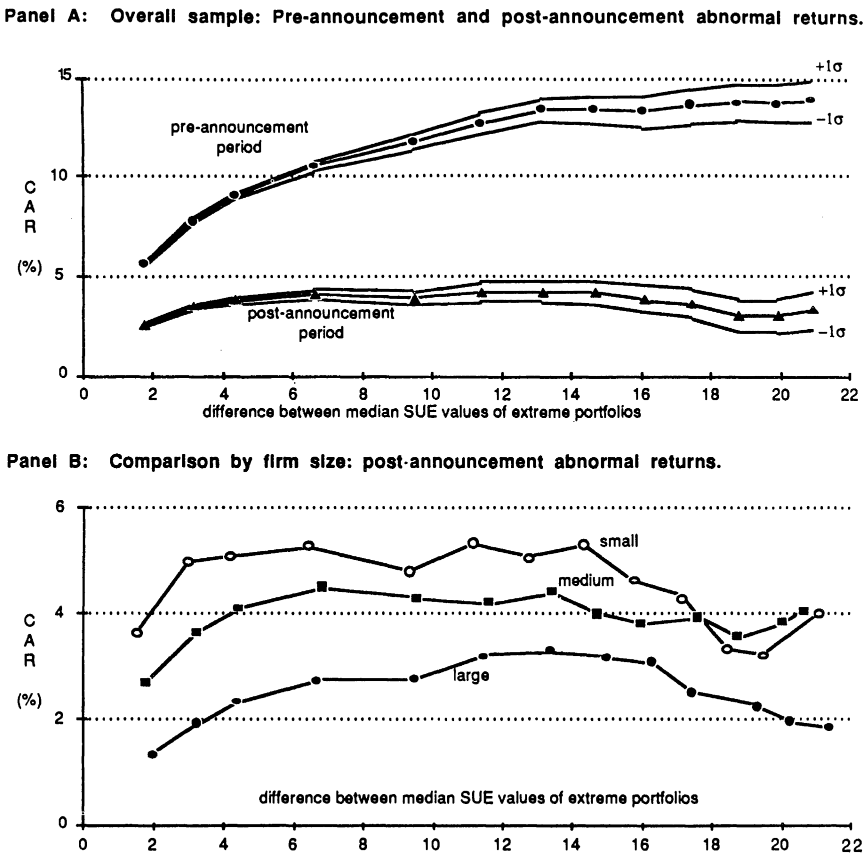

FIG. 6.—Test of an explanation for the drift, based on costs that impede trading. The plot presents the difference in drifts or cumulative abnormal returns (*CARs*) over 60 days after earnings announcements, between the most positive and most negative *SUE* (standardized unexpected earnings) portfolios, constructed by splitting the sample into 2, 3, 5, 10, 20, . . ., 100 portfolios based on *SUE*. The hypothesis predicts that, if the drift is caused by costs that impede trading, the postannouncement drift should remain less than those costs, regardless of the *SUE* difference between extreme portfolios. Thus, as differences between *SUEs* of extreme portfolios increase (represented by movement toward the right of the graph), the postannouncement *CARs* should level out, despite increases in the preannouncement *CARs*. *CARs* are the sums over 60-trading-day pre- and postannouncement holding periods of the difference between daily returns and returns for NYSE-AMEX firms of the same size decile. *SUE* represents forecast errors from a first-order autoregressive earnings expectation model (in seasonal differences) scaled by its estimation-period standard deviation (see section 3.2 for details). Small, medium, and large firms are in size deciles 1 to 4, 5 to 7, and 8 to 10, respectively, based on January 1 market values of equity for all NYSE and AMEX firms.

results, the misspecification argument would have to introduce a "kink" in the relation between unexpected earnings and risk. That is, unexpected earnings would have to proxy for an omitted risk factor up to some point, but then additional increases in unexpected earnings could no longer be correlated with increases in risk.

4.3.2. Are abnormal returns for short positions greater than those for long positions? If the costs of trading do play some role in explaining postannouncement drift, then we might expect the abnormal returns to short positions in bad news firms to exceed those for long positions in good news firms, to compensate for restrictions on short sales.

When we calculate abnormal returns using the FOS approach, our data appear consistent with this hypothesis. The estimated abnormal returns to short positions in bad news firms are larger, and last longer, than the estimated abnormal returns on good news firms. Across all size groups, the abnormal return to the short position over 60 and 180 postannouncement days is 2.3% and 5.5%, respectively, compared to 2.0% and 2.6% for the long position. However, recall that the FOS calculation of abnormal returns involves *summing* daily returns. As indicated in section 3.2.2, summing returns can introduce noise in the calculations which can be eliminated by compounding the returns. While summing and compounding yielded similar results for the *combination* of long positions in good news and short positions in bad news stocks in all of the previous tests, comparisons *between* the returns to the long and short positions *are* sensitive to the choice between summing and compounding.

Using compounded returns in the FOS size-control portfolio strategy, the differences between postannouncement abnormal returns to long positions in good news stocks and to short positions in bad news stocks are small. The abnormal return to the short position over 60 and 180 postannouncement days is 1.9% and 4.4%, respectively, compared to 2.8% and 5.4% for the long position.

In summary, we have some results which indicate that there is an upper bound on the postannouncement drift, which is consistent with a transactions-cost-based explanation. On the other hand, we find weaker results that restrictions on short sales cause the returns to the short position to exceed the returns to the long position.

Even if certain features of the data are consistent with a transactions-cost-based explanation for the drift, the explanation raises several difficult questions, which we discuss in section 5.

4.4 TESTS OF WHETHER PRICES FAIL TO REFLECT FULL IMPLICATIONS OF CURRENT EARNINGS FOR FUTURE EARNINGS

We now briefly consider one last possibility that could lead to a delayed response to earnings information. Specifically, we consider whether market prices fail to reflect the full implications of current quarterly earnings for future quarterly earnings. Although we initially doubted the viability of this hypothesis, we were motivated to test it based on discussions with a large insurance company that sells information necessary to trade on postannouncement drift.

It is well known that seasonally differenced quarterly earnings tend to be positively correlated from one quarter to the next (Foster [1977] and

Freeman and Tse [1989]). As a result, when earnings in quarter t are up, relative to the comparable quarter of the prior year, an efficient market would generate a higher expectation for earnings of quarter $t + 1$ than otherwise. After factoring in the implications of quarter t earnings, the expectation for quarter $t + 1$ would be unbiased and the *mean* reaction to the announcement of quarter $t + 1$ earnings would be zero.

Suppose though that the market fails to recognize the full extent of the serial correlation in seasonally differenced quarterly earnings. That is, the market fails adequately to revise its expectations for quarter $t + 1$ earnings upon receipt of the news for quarter t. The full implications of quarter t earnings might not be assimilated until analysts subsequently revise and publish forecasts or (in the extreme) until earnings for quarter $t + 1$ are announced. In that extreme case, the market would tend to be "pleasantly surprised" when earnings for quarter $t + 1$ are up relative to the prior year (and vice versa), even though the increase could have been predicted based on quarter t earnings.[28]

Table 5 provides results from our test of this possibility. We identify firms in extreme deciles, based on the *SUE* from quarter t. We then examine the average reaction to the announcement of quarter $t + 1$ earnings (measured over days (−4, 0) relative to that announcement). Note that the portfolios held over those five trading days are completely identified on the basis of information available approximately three months earlier; the returns to those portfolios should, on average, reflect no "surprise" under the hypothesis that stock prices fully reflect publicly available information.

Table 5 indicates that one *can* predict the average reaction to quarter $t + 1$ earnings, based on the *SUE* for quarter t. When extreme good news arrives in quarter t, the market tends to be "pleasantly surprised" again in quarter $t + 1$, producing average abnormal returns at the second announcement of 1.3%, 0.7%, and 0.3% for small, medium, and large firms, respectively. When extreme bad news arrives in quarter t, the market tends to be "disappointed" again in quarter $t + 1$, with average abnormal returns at the second announcement being −0.8%, −0.7%, and −0.4% for small, medium, and large firms, respectively.

On the basis of our prior tests, one would expect to observe *some* predictable abnormal returns surrounding the next earnings announcement. However, if the drift documented previously were "smooth" over time, abnormal returns as large as those in table 5 would *not* be expected. Since the five trading days examined in table 5 constitute an event period

---

[28] Some readers have suggested that such behavior is to be expected, because even statistical models that attempt to take the serial correlation in earnings into account generate estimates of unexpected earnings that are themselves serially correlated (see FOS [1984, table 1]). However, note that this is a characteristic of the estimates of unexpected earnings from an imperfect (inefficient) statistical model, not a characteristic of "actual" unexpected earnings in an efficient market. In an efficient market, unexpected earnings would not be serially correlated (by definition).

TABLE 5
Mean Stock Price Reactions to Quarter t+1 Earnings, for Firms Grouped on Quarter t SUE[1]

SUE Decile for Quarter t	Percentage Abnormal Return in [−4,0] Window Surrounding Earnings Announcement for Quarter $t+1$ (t-values in parentheses)		
	Small Firms	Medium Firms	Large Firms
10 (good)	1.32 (7.81)	.68 (5.84)	.31 (3.93)
1 (bad)	−.82 (−5.28)	−.65 (−5.26)	−.37 (−4.01)
Difference (*CAR* for long [short] position in *SUE* 10 [*SUE* 1] firm)	2.14	1.33	.68
As fraction of 60-day drift	40%	29%	25%

[1] Firms are grouped according to quarter t *SUE*, and abnormal returns are cumulated over the five-trading-day window [−4,0] surrounding the announcement of quarter $t+1$ earnings. If market prices fail to reflect the full implications of quarter t earnings for quarter $t+1$ earnings, then the reaction to quarter $t+1$ earnings should be predictable, based on quarter t *SUE*.

Abnormal returns are differences between daily returns and returns for NYSE firms in the same size decile. *SUE* represents forecast error from a first-order autoregressive earnings expectations model (in seasonal differences) scaled by its estimation-period standard deviation.

only 8% as large as the 60-trading-day period used in most of our tests, a smooth drift would cause abnormal returns in table 5 equal to 8% of the total drift observed over the 60-day period. However, the abnormal returns in table 5 are 40%, 29%, and 25% as large as the 60-day drift reported earlier for small, medium, and large firms, respectively. In other words, a disproportionately large fraction of postannouncement drift is concentrated in the few days preceding and including the next quarter's earnings announcement.

The results are consistent with a market that fails to recognize the full implications of current earnings for future earnings. At the same time, the results shed additional doubt on explanations for the drift based on research design flaws, including a failure to adjust fully for risk. It is difficult to imagine why extreme earnings would lead to risk shifts that tend to occur three months later and are coincident with the announcement of the next quarter's earnings.

The results in table 5 are related to, but distinct from, those reported by Freeman and Tse (henceforth FT) [1989], who advance a hypothesis for a "rational delayed reaction to earnings news." As FT explain, the reaction of an efficient market to quarter $t+1$ earnings can be conditional on earnings for quarter t. Given that earnings "innovations" (defined by FT as seasonal differences) are serially correlated, quarter $t+1$ innovations should be less surprising if they have the same sign as quarter t

innovations. For example, the reaction (abnormal return) to a quarter $t + 1$ *positive* innovation that follows a quarter t positive innovation (say, R_{pp}) should be smaller in absolute value than the reaction to a *negative* quarter $t + 1$ innovation that follows a positive quarter t innovation (say, R_{pn}); that is, $R_{pp} < -R_{pn}$.

FT supply evidence consistent with $R_{pp} < -R_{pn}$, indicating at least some degree of "rationality" in the market. However, there is a stronger condition implied by market efficiency. Specifically, if the probability of a like-sign innovation is π, then $\pi(R_{pp}) + (1 - \pi)(R_{pn}) = 0$; that is, the weighted average abnormal return for all firms with positive innovations in quarter t should be zero. If this condition does not hold, one could simply hold *all* firms with a positive innovation in quarter t and expect to earn positive abnormal returns in quarter $t + 1$. Evidence presented throughout this paper (including table 5), in certain of FT's tests, and in prior research (e.g., FOS [1984]) indicates this stronger condition is violated.

FT also present evidence that at least part of the drift following the announcement of quarter t earnings can be recharacterized as a response to the predictable portion of quarter $t + 1$ earnings. (Of course, this raises the question of why the market is responding to something that could have been predicted in a prior quarter.) That evidence is consistent with the results in our table 5 and with earlier evidence documented by Rendleman, Jones, and Latane [1987]. What table 5 demonstrates beyond FT and the prior research is that much of the response to the predictable portion of quarter $t + 1$ earnings does not occur until the five days surrounding the announcement of those earnings.

5. *Discussion and Conclusions*

Much of the evidence presented here casts doubt on *CAPM* misspecification as an explanation for post-earnings-announcement drift. In section 5.1, we summarize implications of the evidence for various forms of misspecification. Section 5.2 then reviews the plausibility of alternative explanations.

5.1 IMPLICATIONS OF THE EVIDENCE FOR CAPM MISSPECIFICATION

CAPM misspecification can assume several different forms. They can be divided into (1) risk mismeasurement and (2) other misspecifications. In turn, risk mismeasurement can include (a) misestimation of systematic risk and (b) exclusion of risk factors other than systematic risk.

5.1.1.a. Risk mismeasurement: misestimation of beta. Our evidence fails to support the BKW [1988] suggestion that beta shifts might explain a large fraction of post-earnings-announcement drift. The key results are as follows. (1) Estimated beta shifts were only about 8% as large as would be necessary to explain fully the magnitude of the drift (section 4.2.1).

(2) The BKW hypothesis suggests that a strategy based on postannouncement drift (long in good and short in bad news firms) would have a positive beta, thus performing poorly in bear markets. However, the *SUE* strategy yielded consistently positive returns in both bull and bear markets (sections 4.2.1 and 4.2.3).

5.1.1.b. Risk mismeasurement: exclusion of risk factors other than systematic risk. Our results are also inconsistent with this potential explanation for post-earnings-announcement drift. (1) We find no evidence that an *SUE* trading strategy is risky along any of the five dimensions identified by Chen, Roll, and Ross [1986] as important factors in asset pricing (section 4.2.2). (2) If the *SUE* strategies are risky on some unidentified dimension, then there is little evidence of that risk surfacing in the form of losses whose cost (in terms of utility) could plausibly be commensurate with the value of the supposed risk premium (section 4.2.3). The consistent profitability of the *SUE* strategies raises the question, "Where's the risk?" (3) According to capital-asset-pricing theory, expected total returns on risky assets can be less than risk-free returns only under special conditions that appear implausible in this context. However, subsequent to earnings announcements, bad news firms had mean *total* returns that were less than T-bill yields during the first week, and only slightly greater than T-bill yields during the first two months (section 4.2.4). (4) The drift is initially increasing in unexpected earnings but appears to reach an upper bound beyond which the drift remains constant as unexpected earnings rise (section 4.3.1). In order to reconcile this result with *CAPM* misspecification, one would have to believe that unexpected earnings proxy for an unidentified risk factor only to some point, with further increases in unexpected earnings being uncorrelated with the unidentified risk. (5) A disproportionate amount of the drift is concentrated around the following quarter's earnings announcement (section 4.4). It is difficult to imagine the reasons risk would tend to shift with a three-month delay, and why the risk shift would be most extreme at a point that coincides with the subsequent earnings announcement.

5.1.2. Other forms of CAPM misspecification. CAPM misspecification could also involve a failure to allow for market imperfections such as taxes. If the difference between ordinary and capital gains tax rates affects pricing, then a "dividend yield effect" would exist in stock returns. However, as indicated in section 4.2.2, differences in dividend yields between the high and low unexpected earnings firms are so small that they are unlikely to explain any significant fraction of the drift.

5.2 DELAYED PRICE RESPONSE AS AN EXPLANATION

Since arguments based on *CAPM* misspecification cannot plausibly be reconciled with our data, we turned to alternative explanations which view the drift as a delayed price response.

5.2.1. Transactions costs as an explanation. If transactions costs explain postannouncement drift, then the drift should not exceed transactions cost bounds, even for the most extreme values of unexpected earnings. Section 4.3.1 did indeed indicate that the drift appears to be "constrained" by an upper bound that is approximately equal to round-trip transactions costs for the individual investor. Moreover, the bound varies across firm size in the same way transactions costs do.[29] On the other hand, we did not find strong evidence that abnormal returns to short positions in bad news stocks exceed the abnormal returns to long positions in good news stocks, as would be predicted if restrictions on short sales play a role in causing the drift (section 4.3.2).

Although some of our results in section 4.3.1 may support a transactions-cost-based explanation, this explanation still raises several difficult questions. First, why does trading continue throughout the postannouncement period? If a price response is delayed because transactions costs discourage traders from entering the market, then no trading should occur. Alternatively, if a trade ultimately does occur, it should occur at a price that fully reflects available information. Personally, we are unable to explain why investors are willing to trade even while the price appears not to reflect fully the available earnings information. A related question is, why don't specialists or other market makers move the price to the "appropriate" level upon the first trade after the earnings announcement?

There are also other questions which undermine the viability of a transactions-cost argument. For example, why is the drift not eliminated by traders who face no commissions and can bypass the specialist's bid–ask spread (thus facing trivial transactions costs); or why would transaction costs necessarily cause underreaction to new information, as opposed to simply introducing noise in prices? Finally, if transactions costs cause the drift, why is so much of it concentrated around the next quarter's earnings announcement?

5.2.2. Failure of market to recognize fully the implications of current earnings for future earnings. The finding of section 4.4—that much of the drift is concentrated around the next quarter's earnings announcement—is difficult to explain except as a reflection of market prices that fail to recognize fully the extent of serial correlation in seasonally differenced quarterly earnings. Although the result is surprising, it is consistent with Foster's [1977] evidence that estimates of unexpected earnings which ignore such serial correlation (i.e., those based on a

[29] If indeed trading costs (including direct transactions costs and other costs of implementation) do explain post-earnings-announcement drift, then we should observe drifts for other information events as well. It is interesting to note that drifts are observed after a variety of events, including, for example, 13-D filings to announce the acquisition of at least 5% of a firm's stock (Larcker and Lys [1987]), repurchase tender offers (Lakonishok and Vermalean [1988]), dividend announcements (Charest [1978]), bond rating downgrades (Holthausen and Leftwich [1986]), and earnings forecast revisions by managers (McNichols [1989]) and analysts (Brown, Foster, and Noreen [1985]).

seasonal random walk model) are more highly correlated with stock returns than proxies that do reflect the serial correlation.

Our only result that is not consistent with incomplete updating of earnings expectations is the one from section 4.3.1, which indicated the drift appears to have an upper bound (section 4.3.1). That is, if market prices fail to reflect fully the implications of current earnings for future earnings, then we would expect the drift to be always increasing in the magnitude of the current unexpected earnings rather than having some upper bound.

One possibility that could reconcile the two results is that market prices fail to reflect the full implications of current earnings for future earnings, but once such a discrepancy exceeds a certain threshold, there are sufficient incentives for speculators to trade until it is reduced. But again, this leaves unanswered the question of why some investors are willing to trade at the "wrong" price in the meantime. However, the coexistence of some traders who are either uninformed or unsure about whether the price fully reflects past earnings information, and informed speculators who can exploit the others only at some cost, may be the only explanation that is simultaneously consistent with (1) the rational use of "recent earnings surprise" as a buy/sell signal among several institutions and investment houses, and (2) the persistence of the drift, despite this activity. Whether this or another explanation can resolve the enigma is left for future research.

5.3 CONCLUSIONS

In this study we have attempted to discriminate between two alternative explanations for post-earnings-announcement drift: a failure to adjust abnormal returns fully for risk and a delay in the response to earnings reports.

We conclude that much of our evidence cannot plausibly be reconciled with arguments built on risk mismeasurement but is consistent with a delayed price response.

Although these results support a dismissal of an important category of explanations for postannouncement drift, they also raise some difficult unanswered questions. The nagging general question is what kind of equilibrium would support market prices that only partially reflect information as widely disseminated and freely available as earnings. A more specific question (also raised by Freeman and Tse [1989]) is why the market would appear to react with surprise to earnings information that is predictable, based on earnings for the prior quarter. A similar question is suggested by the findings of Ou and Penman [1989*a*; 1989*b*], who conclude that market prices fail to reflect detailed financial statement information that is useful in predicting future earnings reversals, and by Dietrich [1984] and Hand [forthcoming], who find reactions to (possibly "cosmetic") accounting gains that are predictable, based on previously published information.

CAPITAL MARKETS RESEARCH AND THE GOODWILL DEBATE

The goodwill accounting controversy concerns two central questions:

- What measurement rules are appropriate to determine the asset value (if any) carried on the balance sheet and the annual amortisation expense recorded in the profit-and-loss statement?
- Do Australian accounting requirements concerning goodwill place Australian businesses at a competitive disadvantage in the international sphere?

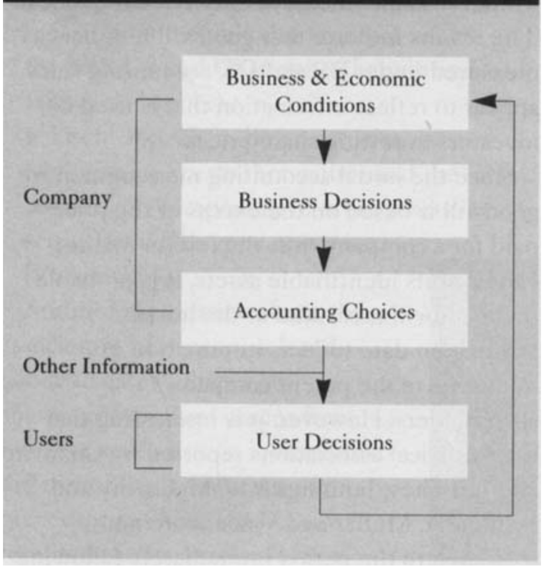
The first is a technical accounting question concerning how best to reflect the economic reality associated with goodwill in financial statements, while the second relates to potential economic consequences associated with restricting companies' choices of goodwill accounting measurement approaches. The intensity and nature of recent public debate reveals a high level of interest relating to both questions.

This paper reviews capital markets research relating to these two questions. The range of interests represented in the goodwill debate and the level of dispute suggest that definitive answers are out of reach. However, it is possible to describe what research has been undertaken, and what light it has cast on the questions of accounting measurement and economic consequences.

Prior to reviewing the relevant research literature it is important to describe carefully what capital markets research entails, and

This paper provides a review of capital markets research relevant to the goodwill accounting debate. Results indicate that the reported goodwill asset under United States GAAP is associated with share values, but there is no clear evidence of a similar association for goodwill amortisation. Similarly, there is no clear evidence of a competitive disadvantage associated with the requirement to amortise goodwill.

FIGURE 1: SIMPLE FRAMEWORK FOR CAPITAL MARKET RESEARCH



discuss how it can inform the debate on goodwill accounting. I devote the next section to this task. The subsequent literature review is not exhaustive. Nevertheless, the papers I discuss present the main results available to date relevant to the goodwill debate. I conclude with comments on some areas where additional research might assist the debate.

THE NATURE OF CAPITAL MARKETS RESEARCH

Capital markets represent a large area of research in the academic accounting literature. It involves investigating the association between accounting numbers (or decisions) and capital market activity. For example, a large body of research has explored the extent to which corporate releases of earnings information affect stockmarket prices, trading volume and volatility.[1]

Capital markets research relies on several assumptions underlying the link between information and the behaviour of capital market participants. Without these assumptions, it is not possible to interpret the research findings beyond simple statistical associations. Of particular importance is the idea that observable characteristics of capital markets (such as share prices and trading volume) might be used to gauge investors' perceptions of the business and economic conditions facing a company. This idea is explained in Figure 1, which shows business and economic conditions faced by a company feeding into management decisions, which in turn are reflected in accounting and other disclosures of the company. This and other information is used by various parties (investors, regulators, employees, etc.) in their particular decision settings, and potentially feeds back to affect business and economic circumstances facing the company. Since observable market activities such as prices and trading volume result from the decisions of one class of users — investors — it is presumed that they will reflect investors' perceptions of business and economic conditions, and perhaps of accounting numbers used by companies to communicate to investors.

Particularly important for interpreting capital market research relating to accounting measurement questions (such as goodwill accounting measurement issues) is an understanding of two links:

- how business and economic conditions are reflected in accounting numbers and choices; and
- how business and economic conditions are linked to observable characteristics of market activity.

In Figure 1, these two links relate to the connections between business and economic conditions, company decisions and users' decisions.

The extent to which these links need to be developed can range from a relatively loose statement of association to the need for a precise model of economic behaviour, depending on the research question being addressed. For instance, a relevant question relating to the goodwill debate might be to what extent the goodwill asset number disclosed in companies' balance sheets is associated with investor perceptions of underlying business prospects. This would involve specifying what aspects of business and economic conditions the accounting number purported to measure (eg, future economic rents from a recent takeover, with greater rents associated with larger measured goodwill numbers), and how those conditions are expected to be reflected in share prices (eg, greater perceived economic rents lead to higher share prices). With these two links in place the association between share prices and accounting goodwill numbers could serve as an indicator of the extent to which goodwill accounting measurements reflect information of potential value to investors. Without these links the meaning of any observed association is unclear.

A final link — completing the connection between the consequences of users' decisions and business conditions facing a company — becomes important when capital markets research is used to address the economic consequences of accounting choices. This is because the objective of such research is to use observed market activity (eg, prices) to infer something about the consequences of an accounting choice for a company's economic environment. Finally, note that in this research setting the first link — how accounting numbers reflect business conditions — is often less important. Rather, the focus is on how the accounting numbers are used.

A further point is worth noting. Since capital markets research focuses on only one group (investors) of users of accounting information, it cannot provide answers to prescriptive questions such as how goodwill amortisation should be measured. As Malcolm Miller's accompanying discussion clearly reflects, various constituencies will often view such questions differently, presumably because each experiences different consequences. In such circumstances, capital markets research can be used to inform the debate but cannot resolve it.

RESEARCH RELATING TO ACCOUNTING GOODWILL MEASUREMENT

Two issues relating to accounting goodwill measurement have been addressed by capital markets research:

- Is the asset value for goodwill disclosed in companies' balance sheets positively associated with share market value?
- Is the goodwill amortisation expense associated with market values or share returns?

Accounting measurement of the goodwill asset

Chauvin and Hirschey (1994), Jennings *et al* (1995), McCarthy and Schneider (1994), Muller (1994) and Vincent (1994) all directly investigate the association between disclosed goodwill asset values and companies' market values. Each performs regressions of company market values on reported goodwill asset numbers (and additional potential explanatory variables) and report that the association is positive and significant (using a variety of statistical tests). Chauvin and Hirschey, Jennings et al, McCarthy and Schneider and Vincent base their analyses on US firms; Muller's sample includes only UK companies.[2] The results indicate that goodwill numbers as measured under US and UK accounting rules appear to reflect information that is used by investors in setting share prices.[3]

Since the initial accounting measurement of goodwill is based on the excess of the price paid for a company over the fair (or market) values of its identifiable assets, it is probable that goodwill measured at the initial acquisition date reflects information of relevance to the parent company's shareholders. However, it is interesting that the statistical associations reported by Chauvin and Hirschey, Jennings *et al*, McCarthy and Schneider, Muller and Vincent are not restricted to the period immediately following corporate acquisitions. For example, Jennings *et al* use a reported goodwill number that potentially includes both recent and distant acquisitions. Moreover, Vincent performs separate associations for periods up to five years after an acquisition and reports that the association between market values and goodwill after amortisation remains significant over the five years. Thus it appears that even after amortisation over several years, the disclosed goodwill asset values reflect information of relevance to investors. (This is related to the research directly concerning goodwill amortisation discussed below.)

Each of the five papers also provides evidence comparing the association between market values and goodwill numbers, and the association between market values and other company assets. A summary of the relevant results indicates:

- There is no clear and consistent evidence that goodwill asset numbers are more or less strongly associated with sharemarket values than are tangible non-current assets included on a company's balance sheet. Chauvin and Hirschey, Jennings *et al*, and Muller provide conflicting results depending on the specification of their tests, while Vincent reports a stronger association for goodwill. McCarthy and Schneider provide marginal support for Vincent's results, but their results are not consistent over time.
- The association between goodwill and equity market values is apparent only for companies in non-manufacturing industries. Manufacturing firms exhibit no clear association. (Chauvin and Hirschey).

- The association between goodwill and equity market values appears weaker than the association between other separately measured intangibles and market values for both US and UK firms (Chauvin and Hirschey, Muller).
- There appears to be no association between equity market values and the revaluation component of other assets on acquisition of target companies (Vincent).[4]

Additional evidence about the association between disclosed goodwill asset values and sharemarket values comes from two recent studies on international differences in accounting procedures. These studies use required disclosures by foreign companies trading on US securities markets, reconciling results reported in domestic financial statements with what would be reported under US accepted accounting procedures. Amir, Harris and Venuti (1993) and Barth and Clinch (1995) use these disclosures to investigate how differences in accounting procedures are associated with share prices.[5] For a pooled sample of UK and Australian firms, Amir *et al* report that the difference in accounting for the goodwill asset under domestic accounting procedures and US accounting is positively associated with share prices. Barth and Clinch separately investigate samples from the UK and Australia and report similar results.

THE ABILITY OF REPORTED GOODWILL NUMBERS TO REFLECT ACQUISITION BENEFITS IS LIKELY TO BE RELATED TO THE NEGOTIATING STRENGTH OF ACQUIRING FIRMS.

The results for UK firms are particularly relevant since the difference between UK and US accounting rules simply represents the goodwill asset value that would appear on the balance sheet under US accounting procedures. This means that, for their sample of UK firms, market values appear to be associated with the goodwill asset even though the asset does not actually appear on the firms' (UK) balance sheets. The results of Barth and Clinch (1995) are therefore consistent with those of Jennings *et al* (1995), Muller (1994) and Vincent (1994). However, Barth and Clinch did report that the association between the goodwill asset (under US accounting procedures) and share prices was not as strong as for other net assets represented on the balance sheet. As noted, the evidence on this issue in the other papers is mixed.

An interesting aspect of existing research is its failure to explore the link between reported goodwill numbers and the underlying economic and business conditions they are presumed to reflect, and the implications for observed capital market associations. For example, the possibility that reported goodwill might represent a better measure of future economic benefits associated with corporate acquisitions for some firms than others has not been investigated. In particular, the ability of reported goodwill numbers to reflect acquisition benefits is likely to be related to the negotiating strength of acquiring firms. If acquiring firms are forced to pay fully for anticipated benefits in the acquisition price, then accounting goodwill may be a more reliable measure of future "intangible" benefits associated with the acquisition. In contrast, if acquiring firms have some bargaining power and are able to purchase target companies at "bargain" prices, the resulting goodwill measure will likely understate the value of future economic benefits. If bargaining power varies across companies and circumstances, we should expect the association between reported goodwill and share values to vary similarly across different companies and circumstances.[6] Existing capital market research does not investigate this possibility.

Accounting measurement of goodwill amortisation

With the exception of Chauvin and Hirschey (1994), McCarthy and Schneider (1994) and Muller (1994), the authors of each of the papers discussed above also investigated the association between the goodwill amortisation expense and share prices and/or returns. However, the results are less certain — there is no consistent association between reported goodwill amortisation and either share prices or returns. Jennings *et al* (1995) observe such an association for some of their tests but not for others. Similarly, Vincent (1994) reports no consistent association.[7]

In contrast, Barth and Clinch (1995) report a significant association between goodwill amortisation and share returns for their sample of UK firms. Amir, Harris and Venuti (1993) reported no association between share returns and the differences in goodwill amortisation expense across various countries, although it is difficult to interpret their results because they combine firms from several different countries with different goodwill accounting procedures.

Thus there is little (if any) firm evidence that goodwill amortisation expense used in the measurement of periodic profit reflects information that is used by investors in setting share prices and returns. In particular, it is not clear that higher amortisation expense is associated with lower share returns or prices. Moreover, the evidence which does support such an association (Barth and Clinch 1995) is based on a sample of UK firms where goodwill amortisation is not included in the calculation of profit reported in their domestic financial statements.

> IT IS NOT CLEAR THAT HIGHER AMORTISATION EXPENSE IS ASSOCIATED WITH LOWER SHARE RETURNS OR PRICES.

It is not clear why reported goodwill asset values are associated with share values while there is no clear association between reported amortisation expense and share returns. It is possible that goodwill amortisation is of less importance to investors than other components of net income and any association is difficult to observe through the experimental noise in existing research. Alternatively, goodwill may not be viewed as an amortisable asset by investors.

ECONOMIC CONSEQUENCES ASSOCIATED WITH GOODWILL ACCOUNTING

As noted by Miller (1995), a major part of Pacific Dunlop's concern with Australia's goodwill accounting standard is the claim that mandatory goodwill amortisation results in Australian companies facing a competitive disadvantage in the international arena. Although the precise nature of the competitive disadvantage is not specified, it mirrors similar claims in the US that mandatory amortisation of goodwill puts US companies at a disadvantage (against, primarily, UK firms) in the international corporate acquisition market. This argument has been repeated recently by the Australian company Gibson Chemical Industries when claiming to have passed up a potentially valuable acquisition because of the impact on future reported profits from amortising goodwill from the deal. (See "New blast at goodwill standard" in *The Age*, 20 October 1994, p. 26.)

Although not clearly articulated, the anti-competitiveness arguments appear to reflect a concern that mandated amortisation of goodwill translates into lower future reported profits and, eventually, into lower share prices. Since companies domiciled in several other countries (notably the UK) do not face this requirement (or face less restrictive amortisation periods), they do not face the potential drag on future reported profits and prices and can afford to bid a higher price for target companies than can Australian companies.

A crucial aspect of this argument is the perceived link between lower profits reported by companies required to amortise goodwill and subsequent lower share prices. As noted, this link has received no clear support in the capital markets literature. In most studies there has been no association between goodwill amortisation and share returns or prices. Moreover, the one study which reported such an association (Barth and Clinch 1995), used a sample of UK firms. That is, firms not required to amortise goodwill under their home country accounting principles exhibited an association between share returns and goodwill amortisation they would have been required to record under US accounting principles.

Nevertheless, the competitive disadvantage argument has received support from two studies which directly compared the takeover premiums paid by companies facing several different goodwill accounting environments. Choi and Lee (1991) compared takeover premiums — acquisition price less pre-acquisition market value of the target company — for acquirers from the UK (who are not required to amortise goodwill in the determination of periodic net profit) and US (who must amortise goodwill over a maximum of 40 years). They found that premiums paid by UK acquirers were higher than premiums paid by US acquirers. They also reported that the premiums paid by UK firms were more closely associated with a proxy for accounting goodwill than for US acquirers.[8] Their conclusion was that UK firms did pay higher amounts for corporate acquisitions, and that this was related to different goodwill accounting requirements in the two countries.

A potential weakness in the Choi and Lee study is that they did not explicitly specify and test the link between goodwill accounting and subsequent economic consequences. It is not clear why recognition and amortisation of goodwill encourages US acquirers to bid less than their UK counterparts. Choi and Lee refer to the possibility that managers of US acquirers might be concerned with the impact of goodwill amortisation on their compensation entitlements (through reduced reported profits), and so may be less willing to bid high for potential targets. Yet, they do not explicitly test this possibility. It is important because it is possible that other features of their research procedures could be influencing their results. In particular, differences between the environment faced by UK and US acquirers (eg, the tax treatment of acquired subsidiaries) unrelated to the goodwill accounting issues could affect the amount companies are willing to bid for targets. Without a clear specification of how goodwill accounting affects the acquiring companies, it is not possible to distinguish between the alternative explanations.

Similarly, it is difficult to unambiguously interpret a follow-up study by Lee and Choi (1992) which compared the acquisition premiums paid by a small sample of US, Japanese and German acquirers. They reported that premiums paid by both Japanese and German acquirers were larger than those paid by US acquirers. They also reported that the association between the merger premium paid and a proxy for accounting goodwill was stronger for German acquirers than for Japanese acquirers. (In fact, there was no clear evidence of an association for Japanese acquirers.) Since German accounting treatment of goodwill is more favourable than the treatment in Japan, they concluded that the difference in premiums paid resulted from goodwill accounting differences.

Some additional, although marginal, support is provided by Robinson and Shane (1990) who report that US companies who use the pooling method to account for corporate acquisitions tend to offer higher merger premiums than acquirers that use the purchase method.[9] Since the pooling of interests method involves no goodwill asset (nor subsequent amortisation expense) these results are similar to, though weaker than, Choi and Lee's (1991) results for UK versus US firms. Note, however, since pooling and purchase firms differ along other dimensions than simply their treatment of goodwill accounting, it is difficult to determine whether the goodwill accounting difference is driving their results.

In contrast to the studies by Choi and Lee, Lee and Choi and Robinson and Shane, several papers have investigated the behaviour of share prices of acquiring firms around the acquisition time period, based on the subsequent accounting approach employed. These papers include Hong, Kaplan, and Mandelker (1978) and Davis (1990). Both papers report that companies that use the purchase method of accounting for acquisitions (ie, recognise and subsequently amortise goodwill) appear to earn higher share returns over the acquisition period than do pooling firms (ie, with no goodwill). That is, firms using the accounting method that subsequently depresses reported profits outperform companies that do not. Because the bulk of the higher returns are earned before the acquisition (and before knowledge of the accounting choice becomes public) it is difficult to attribute this difference to the accounting choice. However, the results do provide a contrast to research indicating higher premiums paid by pooling (or UK) acquirers.

In summary, the results from capital markets research relating to goodwill accounting driven economic consequences are equivocal. Because no clear explanation of the link between the accounting choice and effects on business and economic conditions facing companies is provided, the results are, at best, suggestive.

ADDITIONAL COMMENTS AND CONCLUSION

Briefly, the major results from capital markets research relevant to the goodwill debate are:

- the goodwill accounting asset as disclosed on balance sheets is associated with share market values;
- there is no reliable evidence of an association between reported goodwill amortisation and share prices and returns; and
- there is some evidence of an association between merger premiums paid by acquiring firms and the subsequent accounting treatment of goodwill, but methodological concerns caution against concluding that goodwill accounting is the cause.

The conclusions are modest, and, as suggested in the introduction, do not provide final answers to the goodwill debate. Nevertheless, they do shed light on some aspects of the debate.

Several directions remain open for future capital markets research, with the potential to increase our understanding of how goodwill accounting choices affect market participants. First, existing research concerning goodwill measurement issues employs actual goodwill numbers reported by firms. Alternative measurement (and amortisation) procedures have not been considered. For example, Philip Brown's accompanying paper compares the impact of several alternative amortisation methods on reported amortisation expense (and as a consequence, reported income numbers). It would be interesting to extend this research to a large sample of firms and compare the extent to which alternative goodwill measurements associate with share prices and returns. Potentially, we would learn which measurement approach most closely reflects investors' perceptions.[10] Moreover, the extent to which investors accept alternative measurement approaches such as the recently controversial reverse-sum-of-years'-digits method might be revealed. Some evidence along these lines is available in existing research.

A further extension might use the observed relation between goodwill and future earning capacity to determine empirically an appropriate measurement approach (perhaps for individual companies or industries).[11] The resulting measurements could then be compared with alternative amortisation approaches (eg, straight-line, reverse-sum-of-years'-digits) and associated with share prices and returns. The potential here is to inform us of how well existing measurement approaches appear to capture the business and economic conditions they purport to reflect, and how well they portray (or omit) information relevant to investors.

A final direction for research relates to the economic consequences associated with goodwill accounting. As discussed, existing research is less than adequate in specifying how goodwill accounting measurements affect firms' economic environments. Without such a link, apparent effects on merger premiums and the like cannot confidently be attributed to accounting procedures. Research is needed which clearly spells out how goodwill accounting interacts with the economic environment facing firms, and which provides evidence of this link, explaining differences in observable characteristics of the environment.[12] Until such evidence becomes available, claims concerning the economic consequences of goodwill accounting measurements will be difficult to evaluate.

NOTES

1 For excellent reviews of various capital market research streams in the accounting literature see Brown (1994), Beaver (1986), and Watts and Zimmerman (1986).

2 Since most UK firms immediately write off goodwill against reserves on acquisition, Muller (1994) used the amount of goodwill written off as his measure of the goodwill "asset" for UK firms. Thus, in the case of Muller's sample, the goodwill asset used in his regressions did not actually appear on the companies' published balance sheets except for a small number of firms who did not follow the immediate write-off approach.

3 The results cannot indicate whether the disclosed goodwill measurements were the

actual means of providing relevant information to investors since there are other potential sources of information relating to the value (or otherwise) of corporate acquisitions. The statistical association simply indicates that some information of use to investors is also reflected by the reported goodwill asset.

4 On acquisition, the acquired company's net assets are revalued to fair value with any remaining increment of price paid over net assets defined as goodwill. Vincent (1994) investigates the association with share market values of both goodwill and the revaluation increment of net assets.

5 Other similar studies, which do not consider goodwill accounting, include Pope and Rees (1992), and Bandyopadhyay, Hanna and Richardson (1994).

6 Related research indicates that, on average, acquiring firms do not appear to experience substantial share price increases in the period surrounding an acquisition. This suggests acquirers have little ability to obtain "bargain" acquisitions. Nevertheless, the evidence also indicates that in some circumstances acquirers do exhibit substantial share-price appreciation over the acquisition period. (See Jensen and Ruback (1983) for a review of related literature.)

7 Jennings *et al* (1995) indicate that US firms do not always disclose goodwill amortisation separately, nor sufficient data to reliably estimate it. In those cases they used amortisation amounts obtained directly from the company via a survey instrument (but not available to investors). Since Duvall *et al* (1992) provide evidence suggesting that investors find it difficult to estimate goodwill amortisation when it is not explicitly disclosed, it is possible this influences the reported (lack of) association between goodwill amortisation and equity market values. However, Vincent (1994) employs only sample companies for which she could determine goodwill amortisation from information disclosed in the financial statements.

8 A proxy for accounting goodwill was required because of difficulties in obtaining reported goodwill numbers relating to specific acquisitions. The proxy employed was the difference between the market value of the offer and the book value of net assets acquired.

9 The pooling method is available only in certain restrictive circumstances (primarily relating to form of payment) and results in the assets and liabilities of both entities being combined at existing carrying values, with no goodwill recognised. The purchase method (required in Australia) results in the target's net assets being restated to fair value, with any remaining difference from price paid recognised as goodwill.

10 Some existing research provides evidence along these lines. For example, the papers by Muller (1994) and Barth and Clinch (1995) based on samples of UK companies suggest that goodwill is viewed as an asset by investors despite the immediate write-off adopted by most UK firms. Similarly, Barth and Clinch (1995) report additional results suggesting goodwill amortisation under US procedures (over a maximum of 40 years) is viewed as too low by investors.

11 This type of approach has been used to determine appropriate capitalisation and amortisation rates for intangible assets related to research and development and advertising expenditures. See, for example, Peles (1970), Ben-Zion (1978), Hirschey and Weygandt (1985), Shevlin (1991), and Lev and Sougiannis (1994).

12 Conceivably the interaction between goodwill accounting and firms' economic environment could draw on contracting or other arguments as in Crawford (1986), Robinson and Shane (1990), and others. Observable characteristics that might form the basis of empirical evidence might include merger premiums (as in Choi and Lee 1991), or even differential share price movements at times when mandated goodwill accounting rules change.

How naive is the stock market's use of earnings information?

Abstract

Rendleman, Jones, and Latané (1987) and Bernard and Thomas (1990) hypothesize and report evidence that investors use a 'naive' seasonal random walk model, at least in part, for quarterly earnings. We show that the market acts as if it: (1) *does not* use a simple seasonal random walk model; (2) *does* exploit serial correlation at lags 1–4 in seasonally-differenced quarterly earnings; (3) *does* use the correct signs in exploiting serial correlation at each lag; but (4) *underestimates* the magnitude of serial correlation by approximately 50% on average. We discuss the consistency of alternative hypotheses with our evidence.

Key words: Anomalies; Capital markets; Time series forecasts

1. Introduction

Rendleman et al. (1987) hypothesize, and report confirming evidence, that investors are unaware that firms' seasonally-differenced quarterly earnings are serially correlated. Consequently, investors do not fully exploit the information in past earnings changes, and make or imply inferior predictions of future earnings changes. Bernard and Thomas (1990) hypothesize that, due to the unexploited information, abnormal returns at earnings announcements can be predicted from past earnings. They report evidence that is seemingly immune to problems in measuring expected returns and that is startlingly consistent with this hypothesis.

While this evidence is consistent with the market not fully exploiting the information in past earnings changes, it neither explicitly nor implicitly reveals the extent to which the market *does* utilize past earnings information. Furthermore, interpretation of the evidence is clouded by inconsistent and ambiguous conclusions. For example, Bernard and Thomas (1990, p. 338) are careful to conclude that 'while prices may *partially* reflect [the information in past earnings concerning future earnings], they evidently do not reflect *all* available information'. However, it is unclear what 'partially' means in this context: is it knowledge of some but not all of the attributes of an optimal earnings expectation model (seasonals, random walks, drifts, serial correlation), incomplete knowledge of the parameter values of an optimal model, or some combination of these? In an attempt to clarify the issue, we investigate the expectation model that is implied by the market's reaction to seasonally-differenced quarterly earnings.

Using the Bernard and Thomas (1990) data, we show that the market does not act as if using a naive earnings expectation model. The price reaction to current earnings is consistent with investors being aware of both the existence and the sign pattern of serial correlation in seasonally-differenced quarterly earnings. The market acts as if aware of the sign of the serial correlation at each of the four lags in question, and for each of the three Bernard and Thomas size groups (i.e., in twelve of twelve instances). However, we also show that the market acts as if it underestimates the magnitude of the serial correlation, by approximately 50%.

Showing that the market acts as if aware of serial correlation does not contradict the empirical anomaly reported by Rendleman et al. (1987) and Bernard and Thomas (1990). Nevertheless, the result helps to clarify the anomaly and provides new clues concerning its source. Using the correct form of the time-series model for quarterly earnings, but with seemingly-incorrect parameters, is qualitatively different from using a totally incorrect model. The result rules out the 'naive expectations model' hypothesis. It directs attention instead to possible sources of bias in investors' assessments of serial correlation, or alternatively to biases in researchers' assessments of the ability of earnings to predict abnormal returns.[1]

2. The 'naive expectations model' hypothesis

The ability of current earnings information to predict future abnormal returns, known as 'post earnings announcement drift', has attracted considerable attention since it appeared in Ball and Brown (1968). The literature is surveyed in Ball (1992) and Bernard (1993).

Rendleman et al. (1987, pp. 142–143) hypothesize that at least part of this 'drift' is due to investors misunderstanding the time-series behavior of earnings:

> If investors fail to recognize the correlation that exists in *SUE*s [standardized unexpected earnings] over time, stock prices are unlikely to adjust to their equilibrium values at the time earnings are announced. However, over subsequent holding periods, excess returns should be realized as stock prices adjust to next quarter's *SUE*s, which are highly correlated with those of the current quarter.

SUE is defined as change in earnings relative to the equivalent quarter last year, detrended and scaled by standard deviation. Their hypothesis thus is that investors use a seasonal version of the Ball and Brown (1968) 'naive model', namely a seasonal random walk model.[2] Investors are assumed unaware of exploitable serial correlation in the model's forecast errors. In contrast, the existence of serial correlation in seasonally-differenced quarterly earnings has been known *to researchers* for two decades.[3] If investors are more naive than researchers in forming earnings expectations, then it is possible for researchers to earn abnormal returns by trading under more sophisticated models. Rendleman et al. (1987) report evidence that this is possible.

Bernard and Thomas (1990) provide a more direct and thorough test of this hypothesis. They focus on abnormal returns at the time of earnings

[1]The latter could be due to earnings-related survival biases (Brown, Goetzmann, and Ross, 1995; Brown and Pope, 1995) or to earnings proxying for errors in estimating abnormal returns (Ball, 1978, 1992), for example.

[2]Following normal practice, we refer to this variable as Standardized Unexpected Earnings (*SUE*). This is a misleading term in our view. The earnings expectation assumes a seasonal random walk model for quarterly earnings, ignoring serial correlation in the seasonal differences. This is neither plausible (see Section 6), nor the optimal time-series model (Table 1), nor the model implicit in the actual market response to earnings (Table 3).

[3]See Watts (1975), Foster (1977), Griffin (1977), Brown and Rozeff (1979), Bernard and Thomas (1990), and Bartov (1992).

announcements, which they show can be predicted by a model that exploits the (+ , + , + , −) signs of the serial correlation, over four lags, in *SUE*s.[4] For example, they simulate trading strategies that are implemented at the time of an earnings announcement but are based on past earnings. Long positions are taken in the decile of the highest past-*SUE* stocks, and short positions are taken in the lowest past-*SUE* decile. The simulated strategy earns estimated abnormal returns of +1.32%, +0.70%, +0.04%, and −0.66% (*t*-statistics of +14.63, +8.46, +0.45, and −7.86; see their Table 2) when it is based on earnings announced 1–4 quarters previously, respectively. This implies a total of +2.72% abnormal return in the average quarter from trading on 'stale' earnings news.[5] Their full-sample regressions give similar results.

An attractive feature of the Bernard and Thomas (1990) research is that it develops and tests a refutable alternative to the efficient market hypothesis. If abnormal returns are not (1) observed at the time of subsequent quarters' earnings announcements and (2) a predictable function of past *SUE*, then the alternative is refuted. It clearly is not. Another attractive feature is that the results are seemingly robust to problems of measuring expected returns, because the estimated abnormal returns cover only three-day intervals (short enough to suggest 'small' expected returns) and are positive in all thirteen years studied (regular enough to suggest they are not returns for bearing some unmeasured risk).[6] Furthermore, the sample exceeds 80,000 earnings announcements, and the results are corroborated by Freeman and Tse (1989), Wiggins (1990), Abarbanell and Thomas (1992), Bartov (1992), Bae, Hughes, and Lee (1995), and Ball and Bartov (1995). These features of the research design, together with the novel and startling nature of the results, help explain the considerable impact that Bernard and Thomas (1990) has had on thinking about the relation between earnings and stock prices.

Nevertheless, there is some confusion as to the implications of this evidence. Rendleman et al. (1987, pp. 142–143) conclude that investors use a simple seasonal random-walk model, without incorporating serial correlation in *SUE*. Bernard and Thomas (1990, p. 307) reach much the same conclusion:

> A stock market in which prices are influenced by traders who anchor on a comparison of year-to-year changes in quarterly earnings, much like the financial press does in its coverage of earnings announcements (e.g., the Wall Street Journal's Digest of Earnings Reports), represents a disturbing departure from what would be predicted by existing models of efficient markets.

[4]The correlation at lag 3 is small, so this pattern sometimes is described as (+ , + , 0, −). In Table 1 it is significantly positive for all size groups, so we describe the pattern as (+ , + , + , −).

[5]Calculated as 1.32 + 0.70 + 0.04 + 0.66, reversing the sign at lag 4 to exploit the negative correlation.

[6]Expected returns increase with the return interval, so the problem of earnings proxying for expected returns (Ball, 1978, 1992) becomes larger in magnitude over longer intervals.

These interpretations credit investors with awareness of the fundamental random-walk property of earnings, but have them misapplying the model to seasonal (quarterly) earnings. In a review of the evidence, Bernard et al. (1993, p. 54) state a stronger conclusion:

> the market fails to appreciate fully even the most basic properties of the evolution of earnings.

Other statements are carefully qualified. For example (Bernard and Thomas, 1990, p. 307, emphasis added):

> What we study here is the possibility that market prices can be modeled *partially* as reflections of naive expectations.

But even these conclusions are ambiguous, in several senses. First, one could obtain the impression that the market is *totally* unaware of the serial correlation in a seasonal random-walk model's prediction errors. This cannot be clarified from the regressions reported by Bernard and Thomas (1990), which neither estimate nor imply an estimate of the extent to which the market acts as if aware of the serial correlation. That is not their purpose. Second, it is not clear whether 'partially' in this context refers to partial knowledge of components of the correct forecasting model (random walks, drifts, seasonals, existence of serial correlation, signs of the correlation at each lag) or to partial knowledge of parameter values in the correct model. Third, if it refers to partial parameter knowledge, does this mean systematically underestimating parameters for all stocks, systematically overestimating, or making random parameter estimation errors across time and/or stocks? To clarify the issue, we therefore offer some direct evidence.

3. A direct test of the 'naive expectations model' hypothesis

We investigate the expectation model implicit in the price reaction to current earnings, using a regression of form:

$$CAR_0 = k + a_0 SUE_0 + a_1 SUE_{-1} + a_2 SUE_{-2} + a_3 SUE_{-3} + a_4 SUE_{-4} + u_0. \tag{1}$$

The first independent variable (current SUE) is announced during the 'event window' in which the dependent variable (CAR) is observed. The other independent variables (lagged SUEs) measure components of the expectation of current SUE. We use the estimated coefficients on lagged SUEs, in a regression controlling for current SUE, to infer the extent to which investors incorporate the information in the prior four quarters' earnings when forming earnings expectations. This section outlines the rationale for making such an inference.

Prior research (see Fn. 3) shows that SUE_0 can be approximated as a linear function of lagged SUEs:

$$SUE_0 = b_0 + b_1 SUE_{-1} + b_2 SUE_{-2} + b_3 SUE_{-3} + b_4 SUE_{-4} + \varepsilon_0, \quad (2)$$

where $b_1, b_2, b_3 > 0$, $b_4 < 0$, and ε_0 is the white-noise current earnings innovation. The question is the extent to which the market acts as if aware of the form of (2) and the magnitudes of the coefficients b_1 through b_4. To address this question, we compare the values of the coefficients estimated from earnings data in (2) with those implied by the market's use of past earnings information in (1).

Consider initially the case where the market is fully informed about the process generating SUE, including the magnitude of its parameters, and makes full use of the information in past earnings. That is, assume the market acts as if Eq. (2) best describes the time-series process of earnings. In this case, the price response (CAR_0) is linear in the earnings innovation (ε_0) alone:

$$CAR_0 = \alpha + \beta\varepsilon_0 + \omega_0, \quad (3)$$

where $\beta > 0$ and ω_0 is white noise. It follows from Eqs. (2) and (3) that

$$\begin{aligned} CAR_0 = \alpha^* + \beta SUE_0 - b_1\beta SUE_{-1} - b_2\beta SUE_{-2} - b_3\beta SUE_{-3} \\ - b_4\beta SUE_{-4} + \omega_0, \quad (4) \end{aligned}$$

where $\alpha^* = \alpha - b_0\beta$. The fully-informed case therefore predicts both the signs and the magnitudes of the coefficients on lagged SUEs, *in a regression controlling for* SUE_0.

In a regression of form (1), if the market is fully informed about the earnings process, the predicted *signs* of the coefficients on lagged SUEs exhibit a $(-, -, -, +)$ sign pattern. The predicted pattern is reversed relative to the $(+, +, +, -)$ sign pattern in SUE's serial correlation in (2). The sign reversal occurs because abnormal return is an increasing function of the earnings innovation ε_0 $[= SUE_0 - E(SUE_0)]$, and thus is a decreasing function of $E(SUE_0)$. Note that the predicted signs of the coefficients on lagged SUEs also are reversed relative to those reported by Bernard and Thomas (1990, Table 5), whose regressions do not control for currently-announced SUE.

Furthermore, in a regression of form (1), the *magnitudes* as well as the signs of the coefficients on past SUE can be predicted under the hypothesis that the market is fully informed about the earnings process. If the market has perfect information on both the form of the process generating SUE and the magnitudes of the serial correlation coefficients, then the predicted values of the coefficients on SUE_{-1}, SUE_{-2}, SUE_{-3} and SUE_{-4} are $-b_1\beta$, $-b_2\beta$, $-b_3\beta$, and $-b_4\beta$, respectively. β can be estimated as a_0, the coefficient on current SUE in (1), and b_1 through b_4 can be estimated as the partial correlation coefficients on lagged earnings in regression (2).

Consider next the case where investors use a 'naive' seasonal random walk model, totally unaware of the serial correlation in *SUE*. (This is the original Rendleman et al. hypothesis.) Then, the predicted coefficients on lagged *SUE*s are zero. That is, CAR_0 is independent of SUE_{-1}, SUE_{-2}, SUE_{-3}, and SUE_{-4}, *when controlling for* SUE_0, because in this case investors react *only* to current earnings changes and ignore their predictability from past earnings changes.

Finally, consider the case where the market uses the correct expectations model, but systematically over-(under-)estimates the magnitude of serial correlation in *SUE*. Then, the predicted coefficients on lagged *SUE* are larger (smaller) in absolute value than predicted in the fully-informed case. Taken at face value, estimates of the coefficients on lagged *SUE* thus provide evidence on the markets assessment of the magnitude of serial correlation in *SUE*s.

4. Data

Data from their studies were kindly supplied by Bernard and Thomas. They require (1989, p. 6; 1990, Fn. 3) a minimum of nine earnings changes (ten quarters of earnings) to estimate the drift and standard deviation components of *SUE* plus four consecutive lagged *SUE*s for their (1990, Eq. 9) regression. We require one additional consecutive observation to control for current *SUE*.[7] Our sample comprises 70,728 quarterly earnings announcements made by NYSE–AMEX firms during 1974–86.

The variables in the Bernard and Thomas data set are earnings (*SUE*) and returns (*CAR*) by firm and quarter. *SUE* is seasonally-differenced quarterly earnings per share, detrended and scaled by its standard deviation estimated from prior observations, transformed to its cross-sectional decile rank, then scaled to range over the interval [0,1]. *CAR* is size-adjusted daily return cumulated over a three-day (− 2, 0) window, where 0 is the earnings announcement day.

5. Results

We first replicate prior results in our sample. We then show that the market incorporates lagged *SUE*s into its earnings expectation model, and reconcile this with prior results. Finally, we comment on the effects of size as a variable,

[7] Without this additional requirement, the sample comprises 76,034 observations. Requiring fifteen consecutive quarters of earnings data likely induces survival biases. Brown and Pope (1995) argue that requiring four subsequent quarters' earnings deletes firms that failed or were acquired over the following year from the sample, and that because these events are not independent of both future returns and current earnings, it induces a spurious dependence between current earnings and both future earnings and future returns. They suggest this explains in part the Bernard and Thomas (1989, 1990) results.

Table 1
Prediction of current *SUE* on the basis of lagged *SUE*s: Serial correlation in seasonally-differenced quarterly earnings

Model: $SUE_{i,t} = b_0 + \sum_{j=1}^{4} b_j SUE_{i,t-j}$

	b_0	b_1	b_2	b_3	b_4	Adj. R^2
Panel A: Full sample						
(n = 70728)	0.291	0.443	0.133	0.054	− 0.215	28.57%
	(0.00)	(0.00)	(0.00)	(0.00)	(0.00)	
Panel B: By firm size						
Small firms	0.327	0.408	0.123	0.059	− 0.264	26.68%
(n = 24480)	(0.00)	(0.00)	(0.00)	(0.00)	(0.00)	
Medium firms	0.276	0.454	0.142	0.055	− 0.208	29.99%
(n = 20894)	(0.00)	(0.00)	(0.00)	(0.00)	(0.00)	
Large firms	0.277	0.462	0.130	0.044	− 0.183	29.39%

The definitions of all variables are identical to those in Bernard and Thomas (1990). $SUE_{i,t}$ is the forecast error of the ith firm for quarter t from a seasonal random walk with trend, scaled by its estimation-period standard deviation. *SUE* deciles are based on rankings within the calendar quarter of the announcement of quarter t earnings. In all regressions, the values of the *SUE* variables are replaced by their decile rankings and then scaled so that they range from 0 (for the lowest decile) to 1 (for the highest decile). Small, medium, and large firms are in size deciles 1 to 4, 5 to 7, and 8 to 10, respectively, based on January 1 market values of equity. *P*-values in parentheses.

including survivorship effects. Following Bernard and Thomas, we estimate all regressions from pooled cross-section and time-series data.

5.1. Replication of prior results

Tables 1 and 2 verify that prior results hold in our sample. Table 1 reports pooled regressions of *SUE* on its four lagged values. The coefficients are estimated partial serial correlations from a multiple regression as in Eq. (1). Their signs follow the familiar (+ , + , + , −) pattern. Results for small, medium and large firms are similar.

Table 2 closely replicates the Bernard and Thomas (1990, Table 5) pooled regression of three-day size-adjusted returns (CAR) on four lagged values of *SUE*.[8] In this regression, there is no control for the currently-announced *SUE*.

[8]One difference is that we use *SUE*s as explanatory variables whereas Bernard and Thomas use the errors from a Foster (1977) first-order autoregressive earnings expectation model (in seasonal differences). Since the *SUE*s and the errors from the Foster (1977) model are highly correlated, it is not surprising that we get similar results. Our coefficient on *SUE* at lag 3 is negative, though insignificant (see Fn. 4).

Table 2
Relation between return at current earnings announcement and lagged (past) quarterly earnings, Bernard and Thomas (1990) regression, no control for current earnings

Model: $CAR_{i,t} = k + \sum_{j=1}^{4} a_j SUE_{i,t-j}$

	k	a_1	a_2	a_3	a_4	Adj. R^2
Panel A: Full sample						
(n = 70728)	− 0.160	1.204	0.322	− 0.052	− 0.829	0.78%
	(0.00)	(0.00)	(0.00)	(0.51)	(0.00)	
Panel B: By firm size						
Small firms	− 0.047	1.790	0.368	0.149	− 1.323	0.91%
(n = 24480)	(0.66)	(0.00)	(0.04)	(0.40)	(0.00)	
Medium firms	− 0.384	1.226	0.462	− 0.188	− 0.654	0.97%
(n = 20894)	(0.00)	(0.00)	(0.00)	(0.15)	(0.00)	
Large firms	− 0.207	0.719	0.194	− 0.098	− 0.426	0.63%
(n = 25354)	(0.00)	(0.00)	(0.02)	(0.25)	(0.00)	

The definitions of all variables are identical to those in Bernard and Thomas (1990). $CAR_{i,t}$ is the sum of daily abnormal returns in the three days − 2 to 0 relative to the earnings announcement date (day 0) of firm i in quarter t. Daily abnormal returns are the differences between daily returns of firm i and the returns for NYSE–AMEX firms of the same size decile, based on January 1 market values of equity. $SUE_{i,t}$ is the forecast error of the ith firm for quarter t from a seasonal random walk with trend, scaled by its estimation-period standard deviation. *SUE* deciles are based on rankings within the calendar quarter of the announcement of quarter t earnings. In all regressions, the values of the *SUE* variables are replaced by their decile rankings and then scaled so that they range from 0 (for the lowest decile) to 1 (for the highest decile). Small, medium, and large firms are in size decilies 1 to 4, 5 to 7, and 8 to 10, respectively, based on January 1 market values of equity. All parameter estimates are multiplied by 100. P-values in parentheses.

The absolute values of the coefficients on the four earnings lags sum to 2.44%, compared with the 2.59% they report. This sum can be interpreted as the regression estimate of the abnormal return from exploiting serial correlation.

5.2. *Incorporation of lagged SUEs into earnings expectations*

Table 3 reports the relation between lagged earnings and returns at the current earnings announcement, controlling for current earnings. The evidence rejects the hypothesis that investors use a naive seasonal random-walk expectations model for quarterly earnings. In an F-test for the incremental effect of the four lagged *SUE* variables, relative to a regression of returns on current *SUE* alone, the F-statistic of 78.32 is significant at the 0.001 level. Lagged *SUEs* contribute significantly to the explanatory power of the regression of returns on

Table 3
Relation between return at current earnings announcement and lagged (past) quarterly earnings, controlling for current earnings

Model: $CAR_{i,t} = k + \sum_{j=1}^{4} a_j SUE_{i,t-j}$

Panel A: Full sample							
(n = 70728)	− 1.592	4.924	− 0.981	− 0.333	− 0.319	0.231	7.09%
	(0.00)	(0.00)	(0.00)	(0.00)	(0.00)	(0.00)	
F test: $a_{-1} = a_{-2} = a_{-3} = a_{-4} = 0$, $F(4, 63177) = 78.32$, p-value = 0.000							
Panel B: By firm size							
Small firms	− 2.727	8.191	− 1.557	− 0.645	− 0.340	0.843	10.08%
(n = 24480)	(0.00)	(0.00)	(0.00)	(0.00)	(0.04)	(0.00)	
Medium firms	− 1.622	4.481	− 0.811	− 0.176	− 0.435	0.281	7.42%
(n = 20894)	(0.00)	(0.00)	(0.00)	(0.16)	(0.00)	(0.02)	
Large firms	− 0.947	2.667	− 0.512	− 0.153	− 0.218	0.062	5.17%
(n = 25354)	(0.00)	(0.00)	(0.00)	(0.07)	(0.00)	(0.42)	

The definitions of all variables are identical to those in Bernard and Thomas (1990). $CAR_{i,t}$ is the sum of daily abnormal returns in the three days − 2 to 0 relative to the earnings announcement date (day 0) of firm i in quarter t. Daily abnormal returns are the differences between daily returns of firm i and the returns for NYSE–AMEX firms of the same size decile, based on January 1 market values of equity. $SUE_{i,t}$ is the forecast error of the ith firm for quarter t from a seasonal random walk with trend, scaled by its estimation-period standard deviation. *SUE* deciles are based on rankings within the calendar quarter of the announcement of quarter t earnings. In all regressions, the values of the *SUE* variables are replaced by their decile rankings and then scaled so that they range from 0 (for the lowest decile) to 1 (for the highest decile). Small, medium, and large firms are in size deciles 1 to 4, 5 to 7, and 8 to 10, respectively, based on January 1 market values of equity. All parameter estimates are multiplied by 100. P-values in parentheses.

current *SUE*, contrary to the hypothesis that investors ignore past earnings changes in forming expectations of current earnings.

Further, the coefficients on the four lagged *SUE* variables all have the predicted reversed (− , − , − , +) signs. Each is significant at the 1% level (t-statistics are − 12.86, − 4.34, − 4.17, and + 3.24). Each changes sign from the Bernard and Thomas (1990) regression, which does not control for current *SUE*. When the sample is stratified by firm size, twelve of the twelve signs (four lags for each of the three size groups) are consistent with investors being aware of the signs of the serial correlation in seasonally-differenced earnings. Thus, the evidence is consistent with investors being aware of both the *existence* and the *signs* of serial correlation for *all* of the four lags.

The *magnitudes* of the coefficients are consistent with the market systematically underestimating serial correlation in *SUE*s. For example, if investors fully incorporated the partial correlation between SUE_0 and SUE_{-1} in their expectation of SUE_0, then the coefficient on SUE_{-1} in Table 3 would be -2.181 ($-b_1\beta$, estimated as $-0.443 * 4.924$). The actual estimate is -0.981, which is 45% of the predicted value. Likewise, the coefficients for all four lagged *SUE*s are consistent with prices incorporating 45%, 50%, 119%, and 22% of the serial correlation at lags 1–4 respectively, in earnings expectations. Considering all lags together, the price response to current and past earnings is consistent with an approximately 50% underestimation of the magnitude of serial correlation in seasonally-differenced quarterly earnings.

Table 4 expresses these results in terms of point estimates of average partial correlations in *SUE*. For the full sample, the market acts as if using coefficients

Table 4
Serial correlation in seasonally-differenced quarterly earnings: Comparison of time-series estimates with estimates implied by market reaction to earnings

		Time-series estimate	Implied market estimate	Proportion
Panel A: Full sample				
Lag 1		0.443	0.199	45%
2		0.133	0.067	50
3		0.054	0.064	119
4		−0.215	−0.047	22
Panel B: By firm size				
Lag 1	Small firms	0.408	0.190	47%
2		0.123	0.078	63
3		0.059	0.041	69
4		−0.204	−0.102	50
Lag 1	Medium firms	0.454	0.181	40%
2		0.142	0.039	27
3		0.055	0.097	176
4		−0.208	−0.062	30
Lag 1	Large firms	0.461	0.192	42%
2		0.130	0.057	44
3		0.044	0.081	184
4		−0.183	−0.023	13

All correlations are point-estimates of partial correlations from pooled regressions. Time-series estimates are regression slopes (b_1, b_2, b_3, b_4) from Table 1. Implied market estimates are ratios of regression slopes for lagged *SUE* relative to regression slopes for current *SUE* (a_1/a_0, a_2/a_0, a_3/a_0, a_4/a_0) from Table 3. Proportion is implied market estimate as a percentage of time-series estimate. Small, medium, and large firms are in size deciles 1 to 4, 5 to 7, and 8 to 10, respectively, based on January 1 market values of equity.

of + 0.20, + 0.07, + 0.06 and − 0.05 at lags 1–4, compared with the equivalent time-series estimates of + 0.44, + 0.13, + 0.05, and − 0.22 from Table 1. Overall, the evidence is consistent with the market being aware of the existence and sign pattern of serial correlation, but underestimating its magnitude (i.e., underestimating the sizes of the correlation coefficients).

5.3. Reconciliation with prior results

The regressions reported in Tables 2 and 3 have a common dependent variable, abnormal return at the time of the current earnings announcement, but they have different objectives and thus different independent variables. The Table 2 replication of the Bernard and Thomas (1990) regression does not control for current earnings, and shows that the market does not fully exploit past earnings information. Conversely, the Table 3 regression controls for current earnings, and shows that the market does not fully ignore past earnings information.

The two approaches are easily reconciled, because the Bernard and Thomas (1990, Table 5) regression, as replicated in our Table 2, is a direct implication of the regressions reported in our Tables 1 and 3.[9] Table 3 shows that the price reaction to current and lagged earnings for the average firm/quarter is

$$CAR_0 = -1.592 + 4.924 * SUE_0 - 0.981 * SUE_{-1} - 0.333 * SUE_{-2} - 0.319 * SUE_{-3} + 0.231 * SUE_{-4} + \omega_0 .$$

Table 1 shows that

$$SUE_0 = 0.291 + 0.443 * SUE_{-1} + 0.133 * SUE_{-2} + 0.054 * SUE_{-3} - 0.215 * SUE_{-4} + \varepsilon_0 .$$

where ε_0 is independent of lagged *SUE*s by construction. By simple substitution, these two equations imply

$$CAR_0 = -0.159 + 1.200 * SUE_{-1} + 0.321 * SUE_{-2} - 0.053 * SUE_{-3} - 0.827 * SUE_{-4} + \varepsilon'_0 ,$$

where $\varepsilon'_0 = 4.924 * \varepsilon_0 + \omega_0$ is independent of the four lagged *SUE*s. With rounding error, this is the central Bernard and Thomas result, as replicated in our Table 2.

[9]However, the reverse is not possible, which is the principal reason that the Bernard and Thomas (1990) results do not imply an estimate of the extent to which the market *does* seem aware of serial correlation. A subsidiary reason is that they appear to report simple, not partial, serial correlation coefficients in their equivalent of our Table 1.

5.4. Size effects

It is well-known that the relation between earnings and stock prices is a function of size (Atiase, 1985; Freeman, 1987). Thus, in Bernard and Thomas (1990, Table 6) and in our results (Tables 2 and 3), the coefficients on *SUE*s and the regression R^2s decrease with the size grouping.[10] Two other results are more of interest. First, in Table 4 the closeness of the serial correlation implied by the market's reaction to earnings to the time-series estimate decreases with size. This is particularly the case at lags 1, 2 ,and 4 (lag 3 contains little information about future earnings). Second, the sample selection bias is particularly severe for small firms: while they are sampled from the bottom 40% of firms, they comprise only 34.6% of the firm/years in the sample. In contrast, medium and large firms are sampled from only 30% of the population, but comprise 29.5% and 35.8% of the firm/years, respectively.

6. Interpretation of results

As noted earlier, an attractive feature of Rendleman et al. (1987) and Bernard and Thomas (1990) is that a refutable hypothesis is proposed and tested as an alternative to market efficiency. In this section, we discuss what the alternative theory must look like to accommodate our finding that investors act as if aware of the existence and sign pattern of serial correlation in seasonally-differenced quarterly earnings, but also as if underestimating its magnitude.

Bernard and Thomas (1990, p. 307) refer to 'the possibility that market prices can be modeled partially as reflections of naive expectations'. If 'partial' is interpreted as meaning systematic underestimation of serial correlation magnitudes, to be consistent with our results, then this alternative hypothesis requires investors to be: (1) aware of random walks in earnings; (2) aware of seasonals in earnings; (3) aware of both the existence and the (+ , + , + , −) sign pattern of the correlation in seasonally-differenced earnings across adjacent calendar quarters; but (4) unaware that they systematically underestimate the correlation. We discuss each attribute in turn.

1. Aware of random walks in earnings. The alternative hypothesis has investors employing a random-walk model for quarterly earnings. One does not employ seasonal random-walk expectation models for (say) the daily temperature; one typically bases forecasts on the average historical temperature for the day, not the temperature on the same day last year, thereby seasonally adjusting a mean-reverting process. In the case of *annual* earnings, a random walk would

[10] The statistics are estimated from a single pooled regression for each size group, and thus reflect within-group dispersion.

be a well-informed choice (Ball and Watts, 1972), and there is evidence of its widespread use. For example, the practice of calculating P/E as the ratio of price to the most recent annual earnings observation is consistent with random walks in earnings, but not with other basic time-series models. A mean-reverting process would imply calculating the ratio of price to an average of past years' earnings. Common practice was approximately consistent with the actual time-series behavior of annual earnings well before Ball and Watts (1972) reported that annual earnings do approximate a random walk. Further evidence is provided by the literature on the magnitude of stock-price responses to reported earnings. A random-walk model implies that the amount of price change is a multiple of the amount of change in earnings per share, whereas a mean-reverting process implies that earnings and price changes are approximately the same in magnitude (Ball and Watts, 1972, pp. 665–666). Kothari and Sloan (1992) report that the price response to earnings is a multiple of earnings, consistent with awareness of random-walk earnings processes.[11]

2. *Aware of seasonal.* Quarterly earnings exhibit obvious seasonal behavior. The alternative hypothesis assumes investors allow for seasonals when forming earnings expectations.

3. *Aware of existence and form of serial correlation.* The original hypothesis of Rendleman et al. (1987), that investors use a 'naive' seasonal random-walk expectation model for quarterly earnings, assumes that investors regard the evolution of earnings in each of the four fiscal quarters as independent of its evolution in the other three quarters. Each quarter's earnings is assumed to take its own random walk, evolving as the accumulation of past earnings innovations *in that fiscal quarter alone.* The levels of the four quarterly series diverge over time, as each random-walk accumulates its own annual innovations. The firm effectively is viewed as four separate entities with four separate earnings processes, which in our view is an implausible model of investor behavior ('naive' or otherwise).[12] To accommodate our findings, this model must be modified to allow investors who, while presumably unaware of the language of serial correlation, nevertheless *act as if* aware of the (+ + + −) error pattern in the model's forecasts.

[11]For a random walk, price change is a $(1 + 1/r)$ multiple of earnings change, where r is the interest rate. Kothari and Sloan (1992) estimate the mean multiple as 5.45 and argue that the appropriate $(1 + 1/r)$ is approximately 7–8.

[12]For example, at lag 1 the model assumes that change in a quarter's earnings (relative to the previous year) implies *absolutely nothing* about the next quarter's earnings (relative to the previous year). A precipitous fall in 1995.Q2 sales relative to 1994.Q2 is ignored in forming expectations for 1995.Q3 earnings. The inherent implausibility of the seasonal random walk model is one reason for our view that the *SUE* variable is misnamed.

4. But systematically underestimate the magnitude of dependence. For the 'partially naive investors' hypothesis to explain our results, investors in general must systematically underestimate the magnitude of the serial correlation in a seasonal random-walk model's prediction errors. Why not *over*estimate systematically? Or have unbiased but inefficient assessments of the magnitude (underestimation for some firms and some investors, but overestimation for other firms and investors)? What theory predicts systematic underestimation, for firms and investors in general, consistently over time (at least, in every year studied by Bernard and Thomas, 1990)?

One theory is that investors systematically *over*react to news, and thus prices exhibit subsequent corrections.[13] In his review of the relevant literature, Thaler (1993, p. xix) states:

> DeBondt and I were familiar with the work of Daniel Kahneman and Amos Tversky which showed that people have a tendency to make predictions that are not sufficiently regressive. That is, rather than being proper Bayesian decision makers, people tend to overweight recent information and underweight long-term tendencies (prior odds).

This theory is difficult to reconcile with post-earnings-announcement 'drift'. Thaler (1993, p. xix) acknowledges this when he refers to 'the apparent underreaction of stock prices to earnings announcements' as 'a seemingly contrary set of results'.[14]

Nor is it easy to reconcile the DeBondt and Thaler (1985, 1987) theory, that investors systematically overreact to the most recent information and then correct their mistakes, with evidence that investors systematically underestimate positive serial correlation at lags 1 and 2. Their theory implies price reversals, not continuations. Any reconciliation attempt would require a theory with three phases of investor behavior, in the following sequence: (1) underreaction to earnings information in the short term (approximately six months); (2) overreaction in the medium term; and then (3) long-term correction of the medium-term overreaction.

Bernard and Thomas (1990, p. 307) propose that investors 'anchor' on the earnings of the equivalent quarter in the previous year. 'Anchoring' is

---

[13] See DeBondt and Thaler (1985, 1987), Chopra, Lakonishok, and Ritter (1992), Ball and Kothari (1989), Ball, Kothari, and Shanken (1995), and Kaul and Nimalendran (1990).

[14] Shiller's (e.g., 1981,1989) theory is that the market overreacts to information at the aggregate level, with the stock index therefore exhibiting excess volatility. Seemingly-unaware of the evidence on post-earnings-announcement drift, he concludes (1989, p. 426): 'price overreacts to current [index-level] dividends. ... . Price might also be described as overreacting to current earnings.' Bernard (1993, Ch.11) argues that price overreactions to information generally are logically consistent with price underreactions to quarterly earnings.

underreacting to recent information and overweighting older information.[15] As a theory of investor use of information generally, anchoring seems inconsistent with the theory and evidence of DeBondt and Thaler. Further, the theory does not explain why investors would 'anchor' on earnings reported as far back as four quarters ago, ignoring the intervening three quarters. Why don't investors anchor on the most recent quarter's earnings? Nor does the theory explain why investors use random-walk models, as distinct from anchoring on some average of past year's earnings.

In support of their hypothesis, Bernard and Thomas (1990, p. 307, cited in Section 2 above) state that anchoring on a comparison with earnings four quarters earlier is a feature of the financial press generally, and of the Digest of Earnings Reports in the *Wall Street Journal* in particular. We doubt that this institutional feature explains the results, for several reasons. First, there are many competing reporting institutions, and no single institution sets market prices. For example, *Value Line*'s digests commonly report the past four years of quarterly earnings, thus providing data for much more than the three lags in question and not anchoring on a single-quarter comparison. Second, even the *Wall Street Journal* does not restrict itself to a comparison with the equivalent quarter last year. Its practice is to report a comparison of total earnings in the company's fiscal year to date (YTD) with the equivalent YTD total last year, along with the comparison of earnings this quarter with the equivalent quarter last year.[16] Only in the company's first fiscal quarter of the year does this practice 'anchor' on earnings four quarters previously. Third, because the *Journal*'s YTD figure gives information about more lags in the later quarters of the fiscal year, we can test whether its reporting practices have any effect on the market's incorporation of lagged *SUE*s into prices. The *Journal*'s practice in the fourth fiscal quarter is to report a comparison of total fiscal-year earnings with the equivalent in the previous year, so the information in SUE_{-1}, SUE_{-2}, and SUE_{-3} is reported alongside SUE_0, thus providing a test of whether its practice in other quarters misleads investors to ignore serial correlation at those lags. Our results (unreported) imply otherwise: we find no discernable difference between the fourth quarter and other quarters in the market's use of lagged *SUE*s in forming expectations. We conclude that the data are inconsistent with this institutional version of the anchoring hypothesis.

Hand (1990) hypothesizes that 'unsophisticated' investors are more likely to invest in stocks with lower capitalization or a lower proportion of institutional investors (size and institutional following are highly correlated). This hypothesis

---

[15]See Libby (1981).

[16]This is the practice for NYSE–AMEX stocks. For example, in the Digest of Earnings on 27 October 1995, 272 of 301 announcements had a comparison of year-to-date (YTD) earnings with the previous YTD. Of the 29 missing a YTD comparison, 23 were NASDAQ firms.

predicts that small stocks are most likely to behave as if investors are unaware of the serial correlation in their *SUE*s. However, we earlier noted the Table 4 result that the opposite tends to occur. The small-firm group incorporates the *largest* proportion of the serial correlation into its implied earnings expectation.

In our view, the evidence remains anomalous, that is difficult to reconcile with any refutable theory. To accommodate all of the results, including our evidence that the market acts as if aware of, but also as if underestimating, the serial correlation in seasonally-differenced quarterly earnings, the combination of hypothesized investor behaviors required seems likely to be *ad hoc*. Our results do not contradict the predictability of estimated abnormal returns at future earnings announcements (Bernard and Thomas, 1990). Our results do change the tenor of the anomaly, because they rule out theories in which investors act as if naively unaware of the principal attributes of earnings behavior. They direct attention toward possible biases in investors' assessments of serial correlation magnitudes, or alternatively to biases in researchers' assessments of the ability of earnings to predict abnormal returns (such as sample selection bias).

THE ACCOUNTING VARIABLE AND STOCK PRICE DETERMINATION

Stanley C.W. Salvary*

ABSTRACT

Several tests have been conducted to determine which valuation model best fits stock price data. Given very little success, those studies suggest the need for a clear understanding of the market process of stock price determination. This paper advances the concepts of product costing and product pricing, which pertain to financial accounting valuation and the stock market price determination, respectively. This research effort presents a workable hypothesis of stock price determination.

I. Introduction

The most popular stock valuation models are the dividend model and the stock-returns model. Tests of stock pricing using these models are not found to be satisfactory [Scott, 1985; Kleidon, 1986; Shiller, 1990]. Theoretically, the variables used in these models to test for fit with stock price determination are inadequate descriptions of the variable which is the locus of stock price determination. Last, but not least, among the popular valuation models is the price/earnings model [Phillips and Ritchie, 1983, pp.160-161], which is primarily the inverse of a price yield model. While yields have to be compared with yields of similar risks, there is no inherent measure of risk implicit in the price/earnings model, thus this model lacks the theoretical base needed for an intrinsic valuation model. It is essentially a rule of thumb approach to stock valuation. While these models have contributed to our knowledge, more work is necessary to deal with the shortcomings of those models.

The works of Kleidon [1986], Kormendi and Lipe [1987], and Campbell and Shiller [1988] have strongly suggested that the accounting earnings variable represents fundamental value, and this variable has few competitors for this role. The findings of Kormendi and Lipe [1987] and Campbell and Shiller [1988] are reinforced by the

*Professor of Accounting, Canisius College, Buffalo, New York 14208

findings of Guo and Chang [1993], who found that: (1) accounting based returns were measures at the ordinal level which enabled ranking of firms by their security returns, and (2) the usefulness of such accounting information increased over the twenty years that were covered by the study. From both empirical and intuitive viewpoints, the studies cited above implicitly recognize the use of accounting information as a fundamental variable in stock price determination; presumably accounting information underlies the fundamental valuation approach employed in the capital market.[1] Nevertheless, the cited studies suggest that a more comprehensive theory is needed to explain the stock pricing mechanism. Accordingly, this research is motivated by the desire to provide a working hypothesis based upon the accounting variable that would enable a better understanding of the stock price mechanism.

The Accounting Variable: The accounting variable, which is presented in this paper, is based upon the works of Salvary [1985, 1989, 1992, 1997]. Those works have rejected historical cost and have established "estimated recoverable cost" (ERC) as the measurement property/attribute of financial accounting. Those studies have demonstrated by logical analysis and have provided a rigorous proof that ERC is based upon: (a) the essential characteristics of accounting phenomena (investments as a set) and (b) the measurement/valuation rules of financial accounting which have evolved up to the early part of the twentieth century. ERC, which is linked to investments and explicated by the capital budgeting model, provides the logic which explains the apparent diverse valuation rules of financial accounting [Salvary, 1992, p. 236]. ERC, which is a decision oriented property, is the amount of resource outlay that is justified by the rate of return which guides the investment decision; it is a measure of what money commitments would have been made, given current market conditions [Salvary, 1992, p. 266]. The accounting valuation rules, which have been identified, produce such a measure. With ERC as the measurement property, the term book value can now be appropriately replaced with the proper measurement term: residual cash commitment/residual value of committed finance. While some accounting rules have been identified as being incompatible with the ERC [Salvary, 1985, 1992, 1997], it is the inadvertent failure to recognize the proper measurement property and the derivation of the emergent valuation rules which has resulted in the elimination of the use of the "lower of cost and market" valuation for marketable equity securities with Statement of Financial Accounting Standards (SFAS) 115: Accounting for Certain Investments in Debt and Equity Securities [FASB, 1993].

In this paper, a strong theoretical link is established between financial accounting valuation and stock price determination. The financial accounting measurement process--the generation of financial accounting information--is depicted as a financial product costing process related to the production plans of firms operating in the commodity market. The financial product costing process is the measurement of current cash flows generated by a firm's production plan. It is accounting earnings (i.e., estimates of future earnings) and accounting residual value (i.e., current residual cash commitments--the estimated recoverable cost) as a unit that is priced in the capital market; hence, capital market valuation is a financial product pricing process. The financial product pricing process is the valuation of estimated future cash flows expected to be generated by a firm's production plan and any expected residual cash value. Thus, it is quite clear why the pricing process is distinguished from the costing process.

Working Hypothesis: Financial accounting valuation (with its underlying rationale the capital budgeting model) is the costing of a financial product (periodic returns generated by and residual resources committed to a production plan) in the commodity market. Capital market valuation (current value of an equity security - stock price determination) is the pricing of a financial product--the capitalization of expected market returns on and the terminal value of the equity security in the capital market. A difference exists between the two valuations and the magnitude of the difference is further influenced by changes in the interest rate and the effect of uncertainty on the surrogate variables used in the pricing model.

II. Research Issue

For a firm whose shares are traded in the securities market, the value (K) of its net assets (stockholders' equity) as reflected in its financial statements invariably differs from the aggregate current market value (S) of its equity securities as reflected by the market price in the securities market. Also, the value of that firm's net assets (K) presented in its financial statements differs from the aggregate replacement cost (RC) of that firm's assets. These values - market value and replacement cost - are signals which act as guides to actions for entry, use and exit decisions for an operating system; viz. the firm in its implementation of the production plan.[2] For example, the ratio of firms' net assets at current market value and net assets at replacement costs provides a meaningful decision variable: Tobin's q ratio. In this setting, financial accounting valuation would constitute information from an operating system; while, current market value and replacement cost are signals from a signaling system based upon expectations.[3]

In the static case for the initial commitment of money, Turnovsky [1970] has termed the difference, between capital market valuation (S) and financial accounting valuation (K), the 'net present value'--an all encompassing term, which is not limited to, but includes, monopoly rents. Turnovsky [1970] maintains that the market value of the firm's equity (S) is described by the following equation:

$$S = (\pi - rD)(i)^{-1},$$

and the net present value (N) is captured by equation (1):

(1) $N = (\pi - rD)(i)^{-1} - K = S - K$

- K = Equity Book Value or Equity Money Capital Invested in the Firm
- i = Stockholders' Required Rate of Return on Equity
- r = Market Rate of Interest on Debt
- π = Expected Operating Income Stream Generated by the Firm
- D = Book Value of the Firm's Debt

Vickers [1970; 1968] has stressed that the underlying value of financial assets (VFA) in the capital market is dependent upon the "intensity in the use of money capital" (x): VFA = h(x); whereas, the value of real assets (VRA) in the commodity market depends upon "taste, technology and employment conditions" (u): VRA = j(u). This situation establishes a clear basis for two distinct valuations which are necessary for an efficient functioning of the interdependent capital and commodities markets: the market for financial assets and the market for real assets. The importance of the interdependence is stressed by Greenberg, et al [1978, p. 241]. Arzac [1975], in advancing the work of Vickers and Turnovsky, maintained that the net present value of equity is independent of the financial structure of the firm. Though intuitively appealing, no explicit reason is given why the difference between market value of an equity security (S) and financial accounting value (K) should be the net present value (N), and not simply as monopoly rents. One reason is that the excess of market value over replacement cost is already termed monopoly rent, and this difference would be less than the difference between S and K.

In this paper, the model for stock price (S) determination as developed is based upon: (1) ERC–the measurement property of financial accounting, which provides for periodic earnings (Ep) and the residual cash commitment/residual value of committed finance (K) of the investment, and (2) an investment horizon (n) and a risk adjusted discount rate (i). The model is described below:

$$S_t = K_t + \Sigma E_{p^*}(1+i)^{-n},$$

where K_t is a residual value stated at present value, and E_{p^*} is expected future earnings which will be discounted by the appropriate discount rate. While it is clear from this perspective that $S_t \neq K_t$ except when $E_p = 0$, the analysis which follows will provide the full particulars for non-equivalence of S_t and K_t. This paper attempts to demonstrate that financial accounting valuation and capital market (finance) valuation differ in the magnitudes they produce because they are derived from/represent two different and distinct processes; these two valuations serve two distinct but interdependent markets (the commodity and capital markets). The difference between these two valuations is occasioned by: (a) the intertemporal inseparability in the commodity market of an investment base from its earnings stream, and (b) the intertemporal separability of market prices of the earnings stream (for the intertemporal transfer of savings) from the investment base due to continuous changes in the opportunity costs in the capital market.

Contribution to the Literature

In this two markets setting, the nature of each market, the roles of the participants in these markets, and the valuations necessary for the efficient functioning of these separate but interdependent markets are explored. The valuations are shown to be time dependent and participant oriented. Financial accounting valuation (measurement of current cash flows and current residual cash commitments) and capital market valuation (pricing of future cash flows and future residual cash commitments) are shown to be two different but interrelated processes. This finding provides a sufficient reason for the difference between S and K to be termed net present value (N) and not monopoly rents. In stock price formation, both N and K are components of S, where N is the earnings component and K is a residual (terminal) component. Changes in the interest rate (r) have a systematic effect on S and uncertainty affects expectations of the value of K, these factors prevent the difference between S and K from being arbitraged or insured. The analysis in this study shows that what is true for the static model is also true for the dynamic model. Essentially, this study complements the studies cited above.

III. Research Methodology

This paper is an analytical paper, which focuses on the time perspective and uncertainty facing the production/operating decision as differentiated from those of the savings decision. It establishes the validity of the distinction and the interdependence between the commodity and capital markets. The latter, which provides for liquidity of claims against future earnings, is shown to be a necessary adjunct of the former. A proof of one theorem, which is developed around the concepts of present value and net present value necessitated by the production (investment) decision, demonstrates that the capital market is a by-product of the commodity market.

This work examines the source of the difference between the two valuations: the net present value (N). To simplify the analysis, the firm: (1) has no debt; (2) operates by paying cash immediately for all goods and services; and (3) declares no dividends. In the absence of debt, Total Assets (C^*) = Total Stockholders' Equity (K). Given C^* = K, then equation (1) can be restated as:

(1a) $N_{st} = S_t - C^*_{st}$ (s = per share, t = index)

In an analysis which includes liabilities, $C^* - D = K$ would be used in place of $C^* = K$.

IV. Theoretical Framework

Any discussion of values and valuation models must not confuse the world of uncertainty with a world of certainty. The former gives rise to interrelationships--relationships among committed finance, market value, and replacement cost--but not identical existences. The differences among these items are necessary consequences of an uncertain world and the concept of the amount at risk would be equated with committed finance. Since the difference in interest rates is a reflection of difference in risk, then in the absence of risk there would be one rate. Thus, in a world of certainty, the risk-free rate of interest would be meaningless since the term risk would not exist.

In a world of certainty, while concepts such as replacement cost and market value would not exist, the concept of committed finance to a cash flow plan would exist. Having perfect knowledge, the world would experience steady state growth and the trading in risk would not be a factor. The capital market would not be a place for interpersonal trading of risk/return preferences. In reality, however, the world is an uncertain world characterized by limited and imperfect knowledge in which risk trading and the commodity and capital markets exist. To demonstrate the interdependence of the commodity and capital markets, two models are used: (a) production without a capital market; and (b) production with a capital market.

Production Without a Capital Market (The Producer's Present Value Model)

In a surplus oriented economy, production by the individual is in excess of personal requirements; the excess production is to enable the augmentation of one's wealth. This augmentation process is accomplished by selecting a specified combination of factors of production (an input value) to generate a certain amount of tradable items (an output value) which would maximize the net value--profit. The basic assumptions of the model are: (a) two producers - Producer A and Producer B; (b) two goods and services are produced - Good A (consumable goods) and Good B (all other goods and services); (c) two production periods: (d) the individual producer finances production; and (e) money serves only one function that of a unit of account. Each producer's output is distributed to the employees of that producer. The goods are then exchanged in a general trading store for the other producer's output. (Although the transactions will be undertaken by means of physical exchanges, reference is made to money prices to facilitate the exposition.) Exchange ratios constitute relative money prices which are determined by market demand and supply conditions. The rate of exchange for one unit of an individual's output is based on the prevailing money prices which have been established from the exchange ratios for the commodities produced in this economic community.

Each producer's decision is based upon the expected price of his/her output at time of trading. Given that production extends over two time periods, the decision to commit resources to production is guided by a decision model as depicted in equation (2.0):

$$(2.0) \quad C \leq C^* = \sum E_p(1+r^*)^{-2}$$

C = Resources to be Committed (Outlay Required)

C^* = Present Value of Investment (Discounted Benefits)/Total Assets

E_p = Profit/Earnings (Benefits from Disposal of Output)

r^* = A Hurdle Discount Rate (Desired Minimum Rate)

The commitment of resources (e.g., resources to be exchanged for the productive equipment) is based upon the recoverability of such resources. The stream of net benefits (E) is the difference between the resource outflows (excluding the cost of the productive equipment) and the resource inflows. While C (the "investment cost") is the actual outlay required to undertake the investment, C^* (the discounted stream of benefits) is an estimate of the recoverable amount of investment cost. (C^* = the estimated recoverable cost/total assets.) Therefore, C can be less than, equal to or greater than C^*. The decision rule (guiding the capital budgeting decision) states that if the sum of the discounted stream of benefits (C^*) is equal to or greater than the actual outlay required to undertake the investment (the resources to be committed - C), then undertake the investment.[4]

In equation (2.1), unlike equation (2.0) in which C^* is determined from the PV model, the internal rate of return (R) is the variable to be determined and the DCF model is used :

$$(2.1) \quad C = \sum E_p(1+R)^{-2}$$

The result R (internal rate of return) is compared to r^* (hurdle discount-rate). If $R \geq r^*$, then the investment is to be undertaken. However, when $R > r^*$, then $C < C^*$ and the internal rate of return (R) is substituted for the desired return (r^*) in the PV model. Thus, in the new calculation, the investment cost (C) is equal to the investment base (C^*).

In this setting, there is no intermediary; the producer and the financier are one. The planning horizon of the financier and the investment duration of the producer are identical. There exists only one market: the commodity market. Accordingly, there is only one valuation (C^* - financial accounting valuation). This valuation serves both the financing and the producing decisions. (As indicated earlier $C^* = K$; thus from this point on, K will be used and not C^*.) The foregoing discussion provides the necessary outline of the first model - the producer's present value model.

Production With A Capital Market (The Financier's Present Value Model)

In a money economy (an economy in which generally all goods and services are exchanged for money), a measure of nominal money input and of nominal money output provides an unambiguous measure of the change in money holdings. In this setting, money serves as a medium of exchange and as a store of uncertain value. What emerges now is the concept of capitalized value--the valuation of a sum or sums of money to be received at some future point in time, based upon demand and supply conditions for money reflecting changes in the risk-free interest rate and the inherent risk in the existing supply alternatives of future cash flows/earnings. Individuals who hoard money (a store of uncertain value) are now suppliers of money capital - financiers. Thus, the financier's role is explicit and distinct from that of the producer.

Now producers can sell, for immediate cash, a financial product--the future earnings from production and any residual value--to financiers. A new market comes into existence - the capital market. This market provides for the interpersonal transfer of cash for claims against future earnings. To accommodate this new process of intertemporal transfer--trading in the capital market--capital market valuation emerges as an adjunct to financial accounting valuation. Financial instruments (financial assets) are used to represent the claims to future earnings. The values of the financial instruments (assets) will and do differ over time from the initial valuation because of changes in the interest rates and relevant risks. This new valuation model captures the financier's discounting process; it is the financier's present value model: S.

Two distinct valuation models (a costing model and a pricing model) have emerged to serve the two interdependent (commodity and capital) markets. The Costing Model provides measures of: (a) the resources committed to the production plan (K), and (b) the effect of actual inputs and actual outputs--profit/earnings (E_p) generated in the past period. The valuation, which focuses on firm's production plans over time, serves the commodity market. The Pricing Model places a value on the future prospects of each firm's production and distribution plan for several years into the future. The value (S) in the capital market is placed on an aggregate of expected annual earnings (E_f which is a proxy for E_p) and a terminal nominal value (S*). This valuation process, which is a projection of possible effects of changes in financiers' beliefs about risks and liquidity, facilitates interpersonal and intertemporal transfers of current cash.

Financial Product Costing - Financial Accounting Measurement

Financial accounting measurement is the costing of units of each of several money flows. Such a unit of money-flow (output money-value less input money-value) generated in the commodity market emerges as a financial product--profit/earnings (E_p)[5] plus the residual value (K- the estimated recoverable cost) for sale in the capital market. In financial accounting, E_p is measured for a fiscal year (t) and K is measured at the end of the fiscal year. Hence, the combination of E_p (a periodic measure of a firm's performance) plus K (the residual value of committed finance) is a financial product whose cost is a function of the commodity market. $E_{pt} = P_t - TC_t$, where, P = Sales and TC = Total Cost.

Since there are alternative uses of money and a cost (interest) for the use of money, decisions in the commodity market are based on the concept of the rate of return (R^*) on money invested. R^* is a relative magnitude of a purely nominal money dimension which serves as a means to an efficient capital market. It is a guide to action in production and distribution decisions; for each and every year, the amount of profit/earnings (E_p) is translated into R^* as follows: $R^*_t = E_{pt}/K_{t-1}$. However, $E_{pt} = (K_{t-1} \times R^*_t)$ is a tautology.

Intertemporal Inseparability of Investment Base and Earnings

In equation (2.0) the hurdle discount rate (r^*) reflects the desired minimum rate of return (e.g., the cost of capital), and hence provision is made for earnings - the means of augmenting the initial resource input. Each investment is undertaken to generate an earnings stream. Each investment has an "investment cost" which is the outlay that is required to undertake the investment and an "investment base" which is the estimated recoverable amount of invested money - the estimated recoverable cost. (In this analysis, the terms "investment base," "money in use," "committed finance" and "estimated recoverable cost" are used interchangeably.) The "investment base" is the amount of resource outlay that is justified by the rate of return which guides the investment decision. If actual returns are less than expected returns for the given risk, then there has been an error in the planning stage, and the investment base has to be reduced to reflect the planning loss. However, the converse does not hold. If actual returns exceed expected returns, then the internal rate of return (R) was underestimated. In this case, there is no change in the investment base, only a note to the effect that a higher internal rate of return (R) exists. Accordingly, over the life of an investment, the earnings stream is inseparable from the investment base.

Financial Product Pricing - Capital Market Valuation

The market value (S) of an equity security (a financial asset) is based upon the sum of: (i) an estimate of expected return of investment (K_{st}), and (ii) an estimate of future earnings (E_p^*) relating to that financial asset. This price formation process is the pricing of a firm's financial product in the capital market. The measures provided by financial accounting for K_s and E_{ps} (which is modified for anticipated future conditions in order to estimate future earnings (E^*)) become informational input which enable a value to be assigned to accommodate personal intertemporal transfers of money capital. Equation (3) [Salvary, 1982] is offered as a plausible stock valuation model which characterizes the price formation process:

$$(3) \quad S_t = \sum_{n=1}^{k} E'_s \lambda^n + K_{stn} \lambda^n$$

where:

S	=	Present Value of Expected Future Cash Flows (Price of An Equity Security in the Capital Market)
K	=	Estimated Recoverable Cost of Investment attributable to Shareholders (Equity Book Value or Equity Money Capital Invested in the Firm)

E'	=	N-Year Moving Average of Earnings (E_p)
λ	=	$(1+R')(1+i)^{-1}$
R'	=	Firm's N-Year Moving Average of Rate of Return (R^*)
i	=	Risk Adjusted Discount Rate
n	=	Financier's Planning Horizon - Number of Periods ($n = 1,2,3, \ldots k$)
t	=	Index/Date (t, t+1, t+2, ...)
s	=	Per Share
$K_{stn}\lambda^n$	=	Residual value

The investor buys into the production plan by: (a) purchasing future earnings ($\Sigma E^*\lambda^n$) and (b) making a deposit of the per share value of the investment base's residual value ($K_{sm}\lambda^n$). The deposit is refundable subject to the inherent operating risk, in which case the amount can be greater or larger at the termination date of the investor's participation in the plan.

Another plausible model is the finite horizon valuation model (FHVM) [Phillips and Ritchie, 1983, p. 157]. A modified version of that model (with symbols modified to be comparable with those of equation (3)) is presented in equation (4):

$$(4)\ S_0 = E_0 l \sum_{t=1}^{T} (1+g)^t(1+i)^{-t} + E_0 M_c(1+g)^T(1+i)^{-T}$$

E_0	=	Current earnings per share
l	=	The dividend payout ratio in each holding period
g	=	Anticipated compound annual growth rate of earnings per share
M_c	=	Multiplier applied to earnings per share in the terminal year to determine the selling price

The differences between the two models (equations 3 and 4) are to be found in: (a) the use of a single period earnings as opposed to an n-period average earnings, (b) the use of the dividend payout ratio, and (c) the manner of determining the terminal value (stock price) at time of ownership discontinuation.

The FHVM model, which differs from the model presented in equation (3), is theoretically problematic due to the ad hoc treatment of M_c. Equation 3 is a sequential expectations adjustment model (SEAM); it reflects periodic adjustments based upon expectations related to the sequential release of accounting information.[6] This position obtains because the values of equity securities are tied to the multi-year production plans of the many firms that are operating in the commodity market. Invariably, each firm's product costs (K and E_p) are measured annually--on a period by period basis. At the end of each period, with the release of accounting information on each period, a sequential adjustment begins--the number of earnings period is reduced by one year, and the initial value of the investment (K_{t0}) is adjusted to reflect a new value K_{t+1}:

$$K_{t+1} = K_{t0} + E_p - D_c. \quad (D_c = \text{Cash Dividends})$$

Intertemporal Separability of Market Price from Investment Base

In the capital market, a surrogate (E_f) is used for E_p in the estimation of future earnings. E_f is the average (weighted by the probabilities in the probability distribution of E_f given heterogeneous expectations) of the individual estimates of future cash dividends (D_c) plus the change in the price of the equity security (ΔS)--$E_f = D_c + \Delta S$. However, the variables used to define E_f are inextricably linked to E_p, since dividend (D_c) is a function of E_p and ΔS is influenced by: (a) changes in retained earnings (E_p - D_c), (b) the interest rate (r), and (c) the level of liquidity (l*). Thus, $D_c = f(E_p)$ and $\Delta S = f^*(\{E_p - D_c\}, r, l^*)$. This surrogation renders the price of an equity security (S) intertemporally separable from the investment base (K).

To illustrate the foregoing point, assume that a production plan is for a three-year period. In the case of the costing/measurement model, the following holds:

$$K_{t0} = S_{t0},$$
$$K_{t1} = K_{t0} + E_{p1},$$
$$K_{t2} = K_{t1} + E_{p2}, \text{ and}$$
$$K_{t3} = K_{t2} + E_{p3}.$$

However, S_{t1}, S_{t2}, and S_{t3} cannot be defined in the same fashion as given for K_{t1}, K_{t2}, and K_{t3}, because S is some function of i, n, E_f, and K. In the case of the pricing/valuation model, the following holds for S_{t1}, S_{t2}, and S_{t3}:

$$S_{t1} = \Sigma E_f(1+i)^{-3} + S^*_{t4\cdot}(1+i)^{-3},$$
$$S_{t2} = \Sigma E_f(1+i)^{-2} + S^*_{t4\cdot\cdot}(1+i)^{-2}, \text{ and}$$
$$S_{t3} = \Sigma E_f(1+i)^{-1} + S^*_{t4\cdots}(1+i)^{-1}.$$

In Diagram 1 (S^*_t is an approximation of K^*_t), an insight is provided into the differences between the costing/measurement and the pricing/valuation models. The costing model focuses on measuring past performance and the residual value committed finance, whereas the pricing model places a value on expected future earnings and expected residual value but it depends on the information from the costing model to arrive at the estimates of future performance and residual value. While the financial product costs (K and E_p) are relatively constant, the financial product's price (S) is highly variable. This condition holds since two elements (i and n) of the pricing/valuation model are highly sensitive to money market conditions and to personal expectations (the planning horizons of individuals - n). The discount rate, i, is highly sensitive to changes in the interest rate (r) which reflect the availability of money; and n, the financier's planning horizon, is highly sensitive to liquidity (l*) considerations.

V. Analysis

In the foregoing framework a link has been provided between the commodity market and the capital market and two separate but related functions are identified as being served by financial accounting and capital market valuations. Accounting information disseminated periodically reflects risk-return combinations of firms' financial products, which are priced in the capital market based upon the existing demand and supply conditions and liquidity conditions.

Interdependence of the Two Markets

In the two markets there are three participants (producers, financiers and consumers) - all of whom may not be involved in both markets (Diagram 2). The producer is confronted with two interdependent decisions: a production decision and a financing decision. In the capital market, the producer is on the demand side and the financier is on the supply side. In Diagram 2 market roles are identified; however, nothing prevents a consumer from being a financier or a producer, or any of the other related combinations.

The producer-financier relationship is motivated by the cost of capital consideration (the availability of capital); this condition is true even if the producer is also the financier. In the commodity market, the producer is on the supply side and the consumer is on the demand side. The consumer in great part determines what commodities will be produced. The financier is faced with selecting the preferred risk-return combination among financial assets. The consumer is faced with maximizing consumption (utility) given a budget constraint. Though all financiers are consumers, only some consumers are also financiers.

Axioms

The following four axioms are introduced for a money economy from which a theorem is derived. The emerging theorem (N = S - K) will be discussed later on.

(1) Producers incur the cost of (commit finance for) producing and distributing goods and services for the sake of profit. (Cost of producing and distributing includes the cost of financing the output up to the time of sale.)

(2) Profit is the gain from an undertaking. It is a function of uncertainty since it is conditioned by the ability to acquire (produce) goods and/or services at a total cost which is lower than the price anticipated to be derived from the subsequent delivery of the goods and/or services at some future point in time.

(3) Financiers supply money capital at a cost. This process gives rise to claims against the producers.

(4) The cost-of-capital is the cost for the use of money or credit, which is based solely on the length of time and the risk to which money or credit is made available.

Financing Production

Money in use (money committed to a plan) comes into existence because production, which is characterized as a process over time, has to be financed. If production was timeless (instantaneous), then production would not have to be financed; there would be only one market--the commodity market--and only one set of values--the measures (E_p and K) arrived at by financial accounting. However, production takes place over time, and to finance production the firm issues titles to claims (financial assets) against the firm which are traded in the capital market. The transfer of rights to future earnings and residual value from the firm's production plan is made possible by the capital market; accordingly, the liquidity of financial assets is ensured. Thus, the commodity market coordinates production; while the capital market coordinates finance.

Markets and Valuations: Coordinates and Momenta

It is postulated (Diagram 3) that S in the capital market and K in the commodity market constitute paired symbols, which are coordinates and momenta; each coordinate having a momentum paired with it. The coordinates and momenta emerge from the process of investment, which involves: (a) raising money-capital in the capital market by issuing financial instruments (the creation of financial assets); then (b) acquiring in the commodity market the necessary factors of production (real and strategic assets). Diagram 3 illustrates investments in a market economy as a manifold of four dimensions, which includes a time dimension (n - the financier's planning horizon). The investment consequences to the firm are captured by the financial accounting (product costing) model, which measures E_p and K as discrete values in one year time sequences. Essentially Diagram 3 is indicative of a field of attraction in economic space related to K, in which $S_\bullet$ represents all the points in the field.

Deducible from the diagram is a value function. Point events emerge representing the pricing process in the capital market (e.g., S_1,S_2). Line $S_\bullet$ epitomizes the market value model (financial product pricing). Equation (3) provides the model - the basis of the pricing mechanism - in which $S_t = g(K,E_p,i,n)_t$. However, in the capital market an operating proxy is used for equation (3): $S_t \approx \Sigma E_f(1+i)^{-n} + S^*_m(1+i)^{-n}$. By the definition given earlier, E_f for any value of n, when $0 < n < \infty$ will not be equal to E_p.

Production and its financing create a field of attraction in economic space analogous to a gravitational or magnetic field in physical space. This field consists of money in use (K) as the core, and current market value of title to claims (S) as the outer region of the field.[7] Once a production and distribution plan is started a particular stream of cash flows is set in motion, and this cash flow stream is always subject to valuation at the margin.

Periodic Measure vs Cumulative Valuation

As illustrated in Diagram 1, the capital market valuation is a cumulative valuation process, based upon the expectation of remaining future earnings, the risk adjusted discount rate for the same risk class, and the residual value of the investment. Since entrepreneurial undertaking is under conditions of uncertainty, it is rather rare that actual annual earnings will coincide with expected annual earnings. This condition is an inherent risk under conditions of uncertainty. However, with the issuance of the firm's annual financial report, the financier becomes knowledgeable of his/her model's prediction error.

While firms engage in continuous multi-project financing rather than discrete single-project financing, the several individual investment plans are viewed as a single investment package. Accordingly, financial assets are bought and sold at any point in time based upon the information available at the particular time pertaining to the firms' cash flows. Of necessity, the basis for measuring cash flows as they occur in stages is totally independent from the pricing of those cash flows. That is, ex post measurement is concerned with: how much is the current cash flow?[8] This question is independent of the question of ex ante pricing: How much is the future cash flows from the given money commitment worth given current and anticipated conditions?

At this juncture, the investment process is used to further reinforce what has been established above--the interdependence between the valuation of claims (S) and the measurement of estimated recoverable money commitments (K). Diagram 4 illustrates the investment process. The investment process is depicted in part as a money transfer function in which: (1) savers exchange money (M) in the capital market for the present value (S) of future cash flows, and (2) savings (money received - M) becomes money in use (K) in the commodity market.

As stated earlier, this analysis is limited to equity capital. The amount of money changing hands in this process is M, which is interchanged with S and then converted to K. $M = S$; $M = K$; hence, $S_t = K_t$. If $S_t = K_t$, then how is it that they do diverge in subsequent periods, in which case one of two conditions would obtain: (i) $S_{t+1} > K_{t+1}$, or (ii) $S_{t+1} < K_{t+1}$? The reason for this divergence is that immediately upon the transfer of M, uncertainty enters the picture and the psychology of the capital market takes over. The financier participates in the capital market to adjust his/her liquidity requirements. Exchanges in the secondary market occur to meet the liquidity needs of the financier.

Integration of Concepts and Emerging Theorem

In Diagram 3, a static instantaneous discounting process is represented by the points along S., where S. is a connection of an infinite number of point events because security price formation (S) is instantaneous and continuous. Savings (money) flow into the capital market in exchange for the present value (S_1,S_2, etc.) of financial assets. For example, S_1 is the assessed present value of a specific equity security at a particular point in time. Hence, all points, which form the line S., represent current market values (ΣE^* discounted at risk adjusted rate i for n periods). High liquidity requirements among financiers would depress the present values of future money flows in the secondary capital market. The reverse is true. The effect, of savers' desire for high liquidity, in the primary capital market would be the scarcity of the availability of money (capital), accompanied by a higher than usual cost for the then available money (capital).

Financial accounting valuation begins with the receipt and use of money by the firm. Line K. (the finance committed to a production plan). in Diagram 4 represents financial accounting valuation as an extemporaneous compounding process. A change in K occurs over time ($t \mid t=0,1,2,3.... \infty$). Each year when K is measured, E_p realized by the firm from its investment plan is measured. Capital market forces (i.e., interest rates and liquidity requirements) dictate returns on financial assets, whereas, the commodity market forces (and the capital market via cost of capital) dictate profits derived from real assets.

Diagram 5 illustrates the fact that the commodity market is affected by consumer demand, production technology, money-capital availability and the interest rate, and environmental uncertainty. To locate any point, in this field of attraction in economic space, a four coordinate system is used.

In Diagram 5, K, E_p, i, and n are four spatial directions and distances from the common origin. These variables are affected respectively by the production technology plane, the consumer taste and income level plane, the liquidity and financial capital intensity plane, and the level of uncertainty plane. These interactive forces produce the earlier-mentioned field of attraction in economic space, which is investment. This environmental setting leads to the determination of value within the field. Thus, in a money economy, the market price of an equity security cannot have meaning in the absence of money committed to a production plan. This condition holds since earnings

(E_p) and residual value (K), the critical items being valued, are derived from the money commitment to the production plan.

Value Determinacy

As argued earlier, K, E_p, i, and n in Diagram 4 constitute a manifold of four dimensions, and the line S. is a mapping function. As illustrated in Diagram 6, there is a unique point in line S. for a given set of values for K, E_p, i, and n. However, an infinite number of combinations of values for K, E_p, i, and n will produce S_1, S_2 or any point along S. Thus, $\Sigma n(K_1E_{p1})\alpha = \Sigma n'(K_1E_{p1})\alpha' = \Sigma n'(K_1E_{p1})\alpha' = \ldots$; where $\alpha = (1+i)^{-n}$. Evidently, heterogeneous expectations can and do produce price consensus (i.e., the same S_1 is arrived at for different values of K, E_p, i, and n given differing beliefs about the future). While, i and n (some factors which influence security prices) are investor specific, K and E_p, which are shaped by commodity market forces, are firm specific.

While there is no absolutely true E_p, there are comparable E_ps, and comparability is all that is necessary for proper security price formation. Despite the misuse of existing accounting methods which are incorrectly construed as alternatives, mandatory disclosure of significant accounting policies enables the financier to compare E_ps across firms. Since it is expected earnings (E^*), which is past experience as modified by future expectations that underlies current market value, then in the absence of K, S is indeterminate.

Interdependency of Valuations

Given investment as a field of attraction in economic space as analogous to a gravitational or magnetic field, when projections of market returns (E_f) are further away from the measurement of earnings from actual production (E_p), the field's intensity decreases as an exponential function of time (given the number of years in advance of the actual production). Invariably, the intensity of the field's attraction (the relationship between financial accounting value and current market value) will be reduced but it can never be terminated, even when E_f is significantly different from E_p and the time period (number of years) is very long. No matter how tenuous the link between market returns (E_f) and corporate profits (E_p) becomes in periods of capital market booms (highly speculative markets), they nevertheless are linked together.

What has been established is that S_j, the market price of firm j's equity security, is based upon: (1) specific K and E_p values, and (2) a multiplicity of i and n values. This latter condition is so, since i (a risky discount rate) as well as n (the planning horizon) are highly personalized due to heterogeneous beliefs about risk and time horizons among equity investors. Accordingly, a change in market price (ΔS) is determined by the change in the point of intersection of two intersecting planes: R^* - the rate of return duo-plane (K, E_p) in the commodity market, and d - the discount duo-plane (i, n) in the capital market. Line S. is the intersection of the two duo-planes; therefore, S. is the locus of all points in both planes. For any given moment in time the individual change in the price of a firm's security varies with ΔE_p; ΔS obeys the relation:

$$(5)\ \Delta S \quad = f(R^*)/d = \text{constant}$$

Also, for a given E_p, ΔS varies with the planning horizon (n), and the discount rate (i); accordingly, equation (6) holds:

$$(6)\ \Delta S \quad = f(d)/R^* = \text{constant}$$

Theorem and Proof

In this section, the intertemporal separability of capital market transfer-prices from the commodity market investment-base is developed fully. As stated earlier, the two markets are functionally connected by the producer (see Diagram 2) and, hence, are interdependent. This interdependence provides the rationale for the two valuations S and K in equation (1), since they relate not to one market but to two distinct markets. This condition leads not to one discounting process but to two discounting processes: (a) that of the financier (S) and (b) that of the producer (K).

Emergent Theorem

The emerging theorem (the net present value as defined by Turnovsky [1970]: N = S - K) can be inferred from Tobin's [1978, p. 423] position: the divergence of the discount rate [i], implicit in the market valuation of securities, from the marginal efficiency of capital (MEC) regulates investments by producers. This theorem links the valuation in the capital market with the valuation in the commodity market, and explains the difference between capital market value and committed finance.

When the firm uses the cost of capital approach for evaluating projects, the Net Present Value of the Investment (N) emerges. N serves as an initial screening device; only projects with positive Ns are considered. However, the firm's management uses its internal rate of return (R) as the discount rate to arrive at the money (K) it intends to commit to a production and distribution plan. The amount of money the financier (equity investor) transfers in exchange for a share of common equity is that financier's estimate of the present value of the future money flows from the security. The financier (equity investor) uses his/her risk adjusted discount rate (i) which provides for a return commensurate with the risk inherent in the firm. The financier's discounting process--pricing of the financial product - equation (3) as modified--is as follows:

$$(7)\ S_t = \sum_{n=1}^{k} (E_{fn})\alpha + S^{*}_{tn}\alpha$$

Financiers' planning horizon (n) underlying S_t are relatively small. In general, the equity financiers are looking for satisfactory returns (E_f) among competing alternatives and buying into a firm for a short period. This condition necessitates a terminal value/deposit ($S^{*}_{tn}\alpha$) on the part of the financiers; and in those situations where the firm is terminated $S^{*}_{tn}\alpha = K^{*}_{tn}$.

Firms are continually selling their plans in divisible shares in the capital markets at a value (S). As stated earlier, in the initial stage, $S_t = K_t$, when $t = 0$ and $i = R$. Also, in the long run, when the firm is terminated ($t = \infty$ and $R = i$), then $S_t = K_t$ Thus, in the two extreme situations $N = 0$. In the absence of these two situations, then $N =$ or > 0; and in a liquidity crisis period, N can be negative: $N < 0$. In the intervening periods, as long as $R > i$, $S > K$; in the reverse situation when $R < i$, then $S < K$. Also, the two differing views of earnings (E_f and E_p) provide the main reason why in periods of stock market booms S_t would be significantly larger than K_t. However, even when by chance $E_f = E_p$, the different discount rates (R versus i), which are used in the firm's and financier's models, would create a difference in valuation.

R (the firm's internal rate of return) is firm specific. It is different from i (the financier's rate of discount) because the financier's risk assessment is different from the firm's operating risk. The financier has to deal with the systematic risk inherent in the capital market. Thus, the financier uses r (interest rate) as the frame of reference to arrive at i to compensate for the level of risk associated with the market returns and the risk associated with the firm's operation. However, R includes r because r is an opportunity cost. If the firm is to maximize its profits, then R must be greater than r. The firm's (producer's) discounting process, in which case R > r, is as follows:

$$(8)\ K_t = \sum_{w=1}^{z} E_{pw}(1+R)^{-w}$$

Given that that K_t is the committed finance expected to be recovered in equation (8), it is clear that the difference between the two discounting processes would necessitate that $S_t \neq K_t$. As explained, E_f can be greater than, equal to, or less than E_p; therefore, the following properties (which are not exhaustive) hold in time periods $t > 0$ and $t < \infty$:

Property 1: $S>K$ for $(i,\ n)_f = (R,\ w)_p$, if $E_f>E_p$ for all E_f
Property 2: $S<K$ for $(i,\ n)_f = (R,\ w)_p$, if $E_f<E_p$ for all E_f
Property 3: $S>K$ for $(E,\ n)_f = (E,\ w)_p$, if $R>i$ for all R.
(When $i > R$ no investment will take place.)

In equations (7) and (8), for a firm with a short life span and no change in equity owners, where R and i would be equal, E_f and E_p would be identical; n and w also would be identical. However, in that case there is no trading of equity interest. In the absence of intertemporal trading of savings, while financial accounting valuation would persist, market value would have no significance. However, intertemporal trading of savings is a reality. Given an unlimited life of the firm, a firm's policy of retaining a portion of annual profit, and equity owner's search for better risk/return opportunities, the variables n and E_f *in equation (7) will differ from w and* E_p *in equation (8)* even though i and R may be equal. Due to differences in E_f and E_p ($E_f \neq E_p$), there will be a difference in the expected earnings. When E_f

$> E_p$, a prospective gain (δ)usually exists, where: $\delta = E_f - E_p$. Now, equation (7) can be restated as (9):

$$(9)\ S_t = (K_m)\alpha + \sum_{n=1}^{k} (E_{pn} + \delta_n)\alpha$$

Since price appreciation (a component of E_f) is affected by the liquidity requirements of financiers, then the discounted value of the prospective gain (δ) is the factor which the financier uses as the basis of comparison when alternative forms of savings with the same risks exist; naturally, the financier selects the alternative in the same risk class with the highest δ.

Evidently N, the difference between S_t (the sum of: a refundable deposit plus discounted future dividends plus equity security price appreciation) and K_π (the estimated recoverable cost from operations in the commodity market), which can be positive, negative or zero, would not exist in the absence of the two distinct markets. Accordingly, the origin and the relevance of financial accounting valuation as financial product costing and capital market valuation as financial product pricing are unequivocally established. As outlined, N is readily explainable as consisting of a monopoly power component (S - RC) based upon the earnings dichotomy (E_f vs E_p) and a valuation model earnings component (RC - K) based upon the rate of return/discount dichotomy (R vs i).

VI. Conclusion

Motivated by that implicit recognition of accounting information as a fundamental variable in stock price determination, this paper has explained how accounting information becomes part of the fundamental valuation approach employed in the capital market and offers a more comprehensive theory of the stock pricing mechanism. This research has provided: (1) a workable hypothesis of stock price determination amply supported by analysis, (2) a theoretical framework for understanding the issues raised by the empirical findings in the studies cited [Scott, 1985; Kormendi and Lipe, 1987; Campbell and Shiller,1988; Guo and Chang, 1993], and (3) support for the intuitively appealing propositions of Turnovsky [1970] and Arzac [1975].

In this paper, a strong theoretical link is established between financial accounting valuation and stock price determination. In this process, the interdependence of the commodity and capital markets was established via the properties of investment (a field of attraction in economic space analogous to a gravitational or magnetic field in physical space). The field approach enabled a mapping function. The derivation and proof of one theorem enabled a linking of the valuations (financial accounting and capital market) in the two markets and established the validity of the difference between the two valuations (S and K) as being appropriately termed net present value. The extent to which S and K will converge or diverge is dependent on the differences in: (1) expectations of accounting earnings (E_p) and market returns (E_r), and (2) the internal rate of return (R) and the market rate of discount (i). Future empirical tests should focus on the degree of convergence and divergence between S and K arising from those two factors.

The combination of the estimated recoverable amount of an invested sum of money in the business enterprise's productive assets and earnings of the business enterprise, which are measured in financial accounting, constitute a financial product having its origin in the commodity market. The empirical findings cited in this paper do support a strong relationship between accounting earnings and stock prices but solely based upon statistical goodness of fit. The explanation for this stalwart finding is due to the fact that the estimated recoverable cost is a sound measure of the residual cash commitment/residual value of committed finance, as long as proper accounting methods are used to measure the activities of the organization. Certain accounting methods (e.g., LIFO inventory valuation, bad debts estimates based on sales, and current value for marketable securities) merely introduce noise into the resulting accounting information and prevent the accounting measurement from being a proper measure of the estimated recoverable cost; those methods produce a distortion of the residual value of committed finance. The added drawback is that the data generated by those methods do not lend themselves to good forecasts.

Financial analysts have always appreciated appropriate disclosures and continue to show great concern for the quality of accounting measurements. Yet, it remains to be seen whether the accountants will make a more serious effort to ensure the quality of accounting measurements by selecting accounting methods which best depict the earnings process and residual value of committed finance. One can only hope that they will not continue to be indifferent in the selection of accounting methods.

ENDNOTES

1. There is quite an extensive body of research in support of the information content of financial accounting information (e.g., Ball and Brown [1968]; Beaver [1968]; Brown and Kennelly [1972]; Beaver, Clarke, and Wright [1979]; Patell and Wolfson [1979/1984]; Beaver, Lambert, and Ryan [1986]). Also, Ohlson [1992], in an elegant mathematical work, has related earnings and unexpected earnings to market returns.

2. For a discussion of this topic, see Salvary [1989, p. 52]

3. Lindenberg and Ross [1981] compare accounting data and market data to determine the extent, distribution, and history of monopoly rents in one sector (industrial) of the economy. Lindenberg and Ross [1981, p. 3] maintain that the excess of q over 1 is attributed to monopoly rents, and it is maintained that the "q value of the firm will provide an upper bound to its monopoly rents." While this line of reasoning is implicitly accepted, the focus in this paper is on an explanation of stock price which is conditioned by interperiod uncertainty on rates of return which produce interperiod variation of expectations by the suppliers of capital as implied by Thomadakis [1976, p. 161]. According to Thomadakis [1976, p. 161], "the random character of market rates of return will result from differentiated stochastic mechanisms whose relative weight will depend on the firm's monopoly power." The perceptions of monopoly rents on the part of the suppliers of finance affect the market returns which is accountable for the difference between S and RC - the firm's monopoly power.

4. In financial accounting, if $C > C^*$, then the estimated unrecoverable amount $(C - C^*)$, which is tantamount to the cost of an expired option, is written off so that only the estimated recoverable cost (C^*) remains as the investment base - money in use. While this loss $(C - C^*)$ can be insured, there is no benefit since the cost of the insurance would be essentially the amount of the loss. Concerning the recoverable cost as the measurement property observed in financial accounting measurement, see Salvary [1992; 1989; 1985].

5. E_p consists of two components [Salvary, 1992, p. 241]: (1) a current cash flow component (Ccf) (earnings realized in the form of cash - current cash returns) plus (2) a future cash flow component (Cff) (earnings realized in the form of credit - an accrual of estimated discounted future cash returns): $E_p = C_{cf} + C_{ff}$.

6. Since n and i are investor specific, this valuation model can only provide insights on either the average planning horizon or the average discount rate for a particular stock. Given assumptions about the average discount rate, the average planning horizon is determinable and vice versa.

7. For an analogy with physics whereby the recoverable cost (money committed to the production plan) is viewed as the nucleus and other valuations as electrons, see Salvary [1989, pp. 50-52].

8. A proxy for cash flow is the accounting measure of profit plus depreciation as reported in the income statement.

Abstract. Brand value estimates are significantly positively related to prices and returns, incremental to accounting variables. Questionable brand value estimate reliability underlies lack of financial statement recognition for brands. Findings suggest estimates are relevant and sufficiently reliable to be reflected in share prices. Simultaneous equations estimation reveals inferences are unaffected by potential bias resulting from simultaneity between brand value estimates and equity market value. Brand value estimates are positively associated with advertising expense, operating margin, and market share. Yet, brand value estimates provide significant explanatory power for prices incremental to these variables, and to recognized brand assets and analysts earnings forecasts.

There is growing recognition that intangible assets are important determinants of firm value. Examples of intangible assets include brands, technology, customer loyalty, and the human capital and commitment of employees. U.S. Generally Accepted Accounting Principles (GAAP) do not consistently recognize such intangible assets as accounting assets. A major reason for not according these assets financial statement recognition is concern about whether their values are reliably estimable. This study tests hypotheses relating to whether brand values estimated and published by a well-respected financial magazine reflect valuation relevant information and are sufficiently reliable and timely to be reflected in share prices and returns.

In 1992, *FinancialWorld* (FW) began publishing an annual survey of brand values estimated using a methodology developed by an established brand valuation consulting firm, Interbrand, Ltd., and described in the Appendix. The inaugural survey published in 1992 reported fiscal year 1991 values for 42 brands. By 1997, the survey included over 330 brands, owned by firms in a variety of industries. The estimated values indicate that brands are large assets of many sample firms; the estimates represent approximately forty percent of market value of equity and recognized assets for the median sample firm.

This paper examines the association between FW's brand value estimates and equity share prices of firms owning the brands. We test the joint hypothesis that brand values are relevant to equity valuation of firms owning brands and FW's brand value estimates are sufficiently reliable to be associated with share prices and returns. To test this hypothesis, we estimate the association between the brand value estimates and share prices, controlling for equity book value and net income, and the association between year-to-year changes in brand value estimates and annual share returns, controlling for net income and changes in net income. Our sample extends from 1991 to 1996. We find consistent evidence that the brand value estimates are significantly associated with equity market values in both specifications, providing evidence in support of our hypothesis.

Estimates from a system of simultaneous equations provide evidence that our primary findings are not attributable to estimates of brand values being based on share prices. This analysis also reveals that, as predicted, the brand value estimates are significantly positively associated with advertising expense, brand operating margin, and brand market share. However, contrary to predictions, the estimates are not significantly positively related to sales growth. Additional analyses reveal that brand value estimates provide significant explanatory power for share prices incremental to advertising expense, operating margin, growth, and market share. Brand value estimates also are significantly positively related to share prices after controlling for recognized brand assets and analysts' earnings forecasts. Several sensitivity checks indicate that our findings are robust.

Taken together, our findings indicate that the FW brand value estimates capture information that is relevant to investors and are sufficiently reliable to be reflected in share prices and returns.[1] Because our priors are that brand values are relevant to equity investors, these findings call into question concerns of those who believe that brand value estimates are too unreliable to be the basis for recognition as an intangible accounting asset.

The remainder of the paper proceeds as follows. Section 1 discusses institutional background relating to brand values and related research. Section 2 describes the data and presents descriptive statistics. Section 3 outlines our research design and Section 4 presents our empirical findings. Section 5 offers some additional analyses and Section 6 summarizes and concludes the study.

1. Institutional Background and Related Research

1.1. Institutional Background

Although definitions of brands differ (see, e.g., Aaker, 1991, 1996, and Keller, 1997), the underlying notion is that of a distinctive name with which the consumer has a high level of awareness and a willingness to pay either higher than otherwise average prices or make higher than otherwise purchase frequency. Keller (1997) lists the following benefits of a brand name: greater loyalty from customers, less vulnerability to competitive marketing actions, less vulnerability to marketing crises, larger margins, more inelastic consumer response to price increases, more elastic consumer response to price decreases, greater trade cooperation and support, increased marketing communication effectiveness, possible licensing opportunities, and additional brand extension opportunities. The net effect of these benefits is that a branded product potentially provides a firm with a higher level of operating earnings over time than does an otherwise unbranded product. However, although cost incurred is a potential measurement alternative for brands, not all expenditures made in promoting a brand result in increases in brand value. For example, an expensive advertising program that misfires may, at best, have a minimal effect on sales and, at worst, turn away existing or potential customers. It is an empirical issue whether the potential benefits listed above are realized for a given brand, thereby translating into increased firm value.[2]

U.S. GAAP for brands has at least three features that are the subject of debate. First, recognition of brands is inconsistent across firms. Internally developed brands are not recognized as assets whereas acquired brands, e.g., through a purchase business combination, typically are recognized and amortized against net income over the brand's estimated useful life, which cannot exceed forty years. Second, even though brand values can change markedly from period to period, changes in brand values largely are unaccounted for, even for brands recognized as assets. Although U.S. GAAP requires write-downs for impaired recognized brand assets, U.S. GAAP does not permit recognition of increases in brand values. Third, expenditures that increase brand values, such as advertising, are expensed in the period incurred rather than capitalized. This can result in firms that invest in brand name development reporting depressed earnings while brand values are increasing.[3]

U.S. GAAP requires disclosure, and the Financial Accounting Standards Board (FASB) is considering requiring recognition, of fair values of all financial instruments. Although currently there is no U.S. proposal to disclose or recognize non-financial assets at fair value, fair values of all assets likely are relevant to financial statement users. One reason the FASB distinguishes financial and non-financial assets is the belief that values are not reliably estimable for non-financial assets, especially intangible assets such as brands. However, GAAP in countries other than the U.S., e.g., Australia, permits recognition of the value of internally developed intangible assets, such as those associated with brand names (see, e.g., Barth and Clinch, 1998).

1.2. Related Research

The marketing and management literatures include several empirical studies linking brand attributes and security prices and/or returns. Simon and Sullivan (1993) outline a technique for estimating a firm's brand equity, based on firms' market value. In their technique, the replacement cost of tangible assets is first subtracted from the firm's market capitalization to estimate the value of intangible assets. Second, this value of intangible assets is apportioned into a brand value component, a non-brand value component, e.g., research and development and patents, and an industry component, e.g., regulation. Simon and Sullivan use their intuition to validate Wall Street's cognizance of marketing factors. They find, as one might expect, that industries and firms with commonly known brand names have high estimates of brand equity.

Aaker and Jacobson (1994) examine associations between measures of brand quality and security returns, using the EquiTrend measure of brand quality. The EquiTrend brand quality measure is based on a study by Total Research Corporation, which surveyed a nationally representative sample of consumers from 1991 to 1993 to evaluate the quality of 100 major brands. Aaker and Jacobson examine whether returns in the twelve months preceding each annual survey reflect the unexpected change from one survey to the next in the brand's quality measure. They find that the relation between brand quality and returns is positive, as predicted, and statistically significant.

Related studies in the accounting literature, e.g., Abdel-khalik (1975), and Hirschey and Weygandt (1985), investigate whether advertising expenses are value-relevant, which one would expect if advertising expense is a proxy for the development of valuable brand names. These studies find evidence consistent with this conjecture. However, Bublitz and Ettredge (1989) conclude that benefits from advertising expenditures are short-lived, consistent with recognizing them as current-period expenses. More recently, Barth and Clinch (1998) provide evidence that recognized revalued intangible assets of Australian firms, a substantial proportion of which relate to brand names, are value-relevant. Some studies also investigate firms' and analysts' actions associated with non-recognition of intangible assets, such as brand names. In particular, Barth and Kasznik (1998) find that firms' decisions to repurchase shares on the open market and the market's reaction to the repurchase announcement are significantly positively related to proxies for unrecognized intangibles, including brand names. Also, Barth, Kasznik, and McNichols (1998) find that unrecognized intangible assets, including brand names, are significantly positively related to analyst coverage and the effort analysts expend to cover firms.

2. Data and Descriptive Statistics

We obtain estimated brand values from FW's 1992 to 1997 annual surveys of brands that relate to brand values for fiscal years from 1991 to 1996 (*FinancialWorld*, 1992–1997). FW reports value estimates, sales, and operating margins for individual brands, by industry. It also reports the percentage change in the brand value estimate from the previous year. The Appendix describes the methodology FW uses to estimate brand values, which is designed to estimate the increased firm value associated with the firm's brand names. Our sample comprises 1,204 brands with value estimates reported by FW during the sample period. To obtain estimated brand value for a particular firm-year observation, we sum the estimated values of the brands owned by a particular firm and reported by FW in that year.[4] This results in 595 sample firm-year observations, relating to 183 publicly traded U.S. firms.[5] We obtain data for other variables from the 1996 Full Coverage Compustat and CRSP databases.

Table 1 presents selected descriptive statistics relating to brand value estimates. Panel A presents statistics relating to the temporal distribution of sample firms and brand names and reveals that, over the sample period, FW expanded coverage of brands and firms. The 1991 sample includes 37 brands owned by 26 firms, whereas the 1996 sample includes 299 brands owned by 152 firms. Panel B presents statistics relating to the number of FW reported brands owned by each sample firm and reveals that in each sample year, the median (mean) firm has approximately one (two) brand(s). However, the number of brands owned by a particular firm ranges up to 17 in 1995. Panel C of Table 1 presents descriptive statistics relating to values of individual brands. It shows that, over the sample period, the mean (median) brand values ranges from \$1,538 (\$541) million in 1993 to \$4,098 (\$1,454) million in 1991. The large brand values in 1991 are primarily attributable to the inaugural survey focusing on major brand names, e.g., Marlboro, Coca-Cola, Budweiser, and Pepsi-Cola.

Figure 1, Panel A, graphs the distribution of one-year changes in estimated brand values for the 1,083 brands of 520 firms for which we have brand value estimates in two consecutive years.[6] It indicates that brand values in our sample have, for the most part, increased over

Table 1. Summary of 1,204 brand value estimates, for 595 firm-year observations from 1991–1996 surveys, reported in *FinancialWorld* (1992–1997).

Panel A: Number of sample firms and brand names

	Firms	Brand Names	
Year	Number	Number	% of Total
1991	26	37	3
1992	58	95	8
1993	108	240	20
1994	106	229	19
1995	145	304	25
1996	152	299	25
Total	595	1,204	100

Panel B: Number of brands per firm

Year	Firms	Mean	Median	Std Dev.	Min	Max
1991	26	1.4	1.0	0.9	1.0	4.0
1992	58	1.6	1.0	1.2	1.0	5.0
1993	108	2.2	1.0	2.5	1.0	12.0
1994	106	2.1	1.0	2.4	1.0	12.0
1995	145	2.1	1.0	2.7	1.0	17.0
1996	152	2.0	1.0	2.3	1.0	14.0
Pooled	595	2.0	1.0	2.3	1.0	17.0

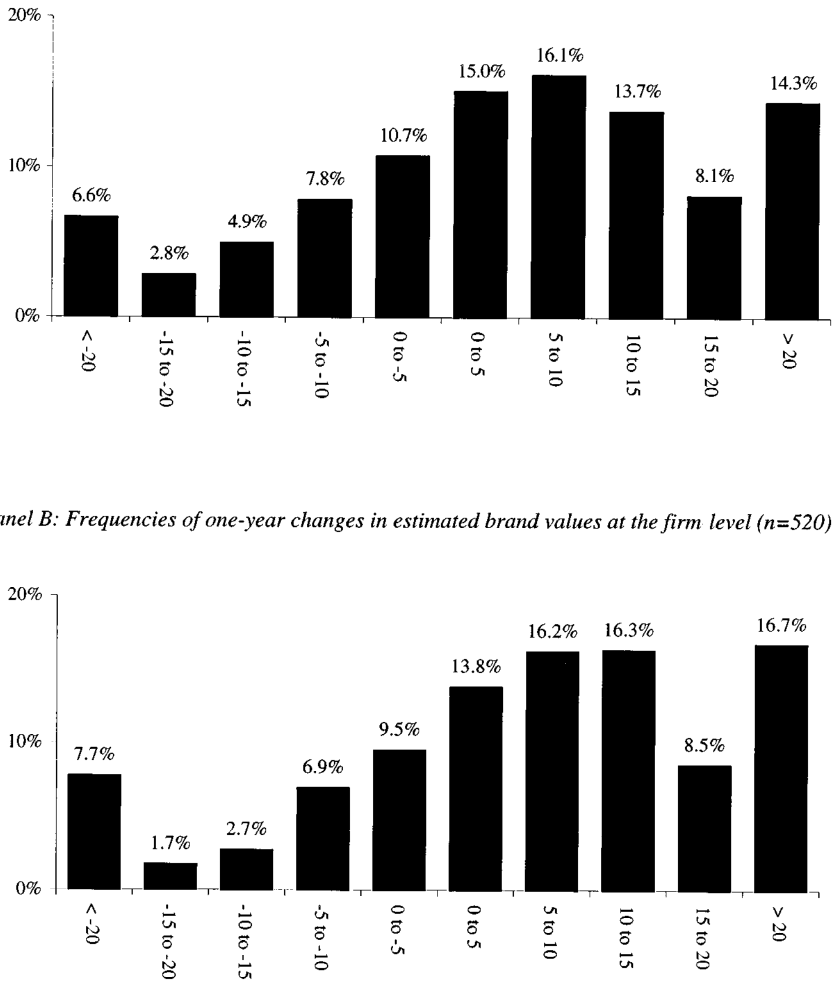
Panel C: Brand values (in $ million)

Year	Number	Mean	Median	Std Dev.	Q1	Q2
1991	37	4,098	1,454	6.524	582	3,732
1992	95	2,696	1,058	5,644	436	2,378
1993	240	1,538	541	3,612	185	1,434
1994	229	2,091	739	4,416	256	1,900
1995	304	1,900	633	4,388	222	1,651
1996	299	2,267	880	4,898	328	1,994
Pooled	1,204	2,085	745	4,591	256	1,879

time, although many have decreased. Figure 1, Panel B, shows that the one-year change in estimated brand values at the firm-level also varies considerably. Untabulated statistics indicate that the mean (median) year-to-year changes in brand values at the brand- and firm-levels are 6.7% (6.0%) and 8.3% (7.0%), respectively. They also indicate that 67.2% and 71.5% year-to-year changes in brand values at the brand- and firm-level are increases, 30.2% and 28.1% are decreases, and only 2.6% and 0.4% are unchanged.

Figure 2 presents multi-year changes in estimated brand values for the 1993 to 1996 period, over which FW brand value estimates are available for a substantial number of brands. We base the figure on brands for which FW reports estimated values each year in

Panel A: Frequencies of one-year changes in estimated values at the brand level (n=1,083)



Panel B: Frequencies of one-year changes in estimated brand values at the firm level (n=520)

Figure 1. Frequencies of one-year percentage changes in estimated individual and firm brand values. Based on one-year changes in estimated brand values at the brand and firm levels, from 1992–1996.

this period, enabling us to calculate a sequence of three successive brand value changes.[7] Figure 2, Panel A, first partitions the 1993 to 1994 estimated brand value changes into those that are positive and those that are negative or zero. For each of these partitions, we repeat the sign-partitioning for 1994 to 1995 estimated value changes, and repeat the entire process for 1995 to 1996 changes. This results in eight portfolios representing different combinations of the sign of successive annual estimated brand value changes. For each

Panel A: Brand-level analysis ($n = 184$)

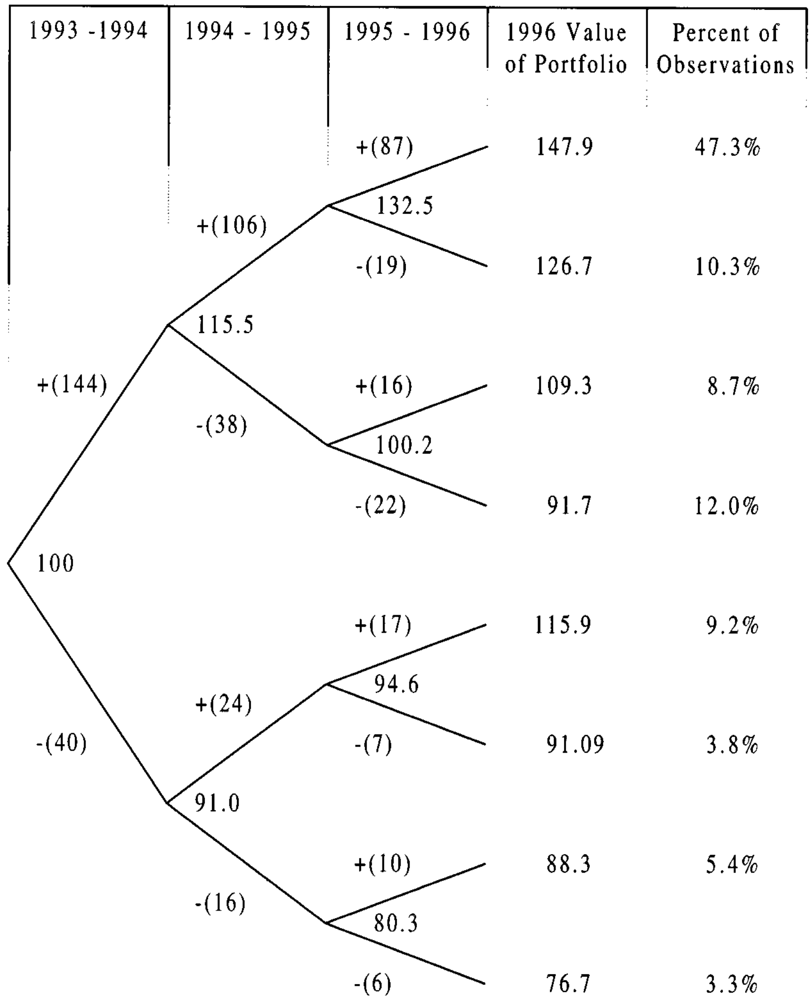


Figure 2. Sequence of changes in estimated individual and firm brand values over the period 1993–1996 (values are normalized by setting 1993 brand value estimates to 100). Based on brands with value estimates for each of the years 1993–1996.

portfolio, we set the 1993 estimated brand value equal to 100 and then compute the mean estimated brand value of each portfolio in 1996 relative to the normalized 1993 value. Thus, brands that increase in value after 1993 have calculated amounts greater than 100. Panel B presents analogous statistics for year-to-year changes at the firm level.

Consistent with Figure 1, Figure 2, Panel A, reveals a substantial proportion of brands with three consecutive years of increased value, 47.3% of the sample brands. These brands

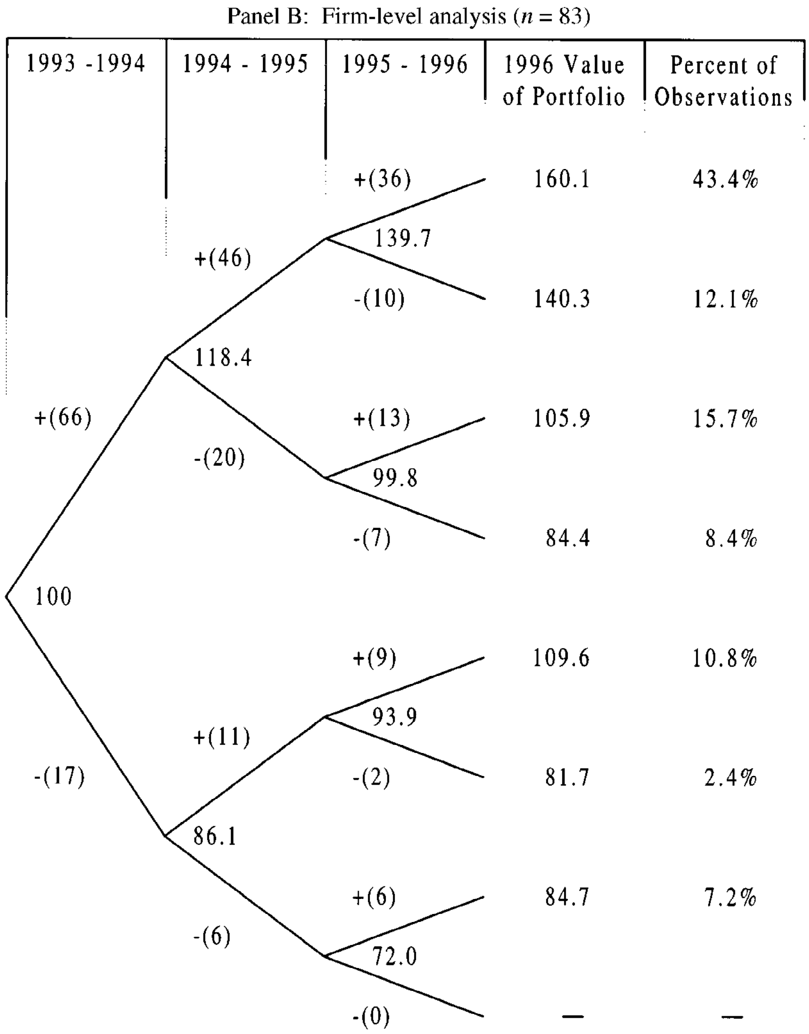

Figure 2. Continued.

have a 1996 mean normalized value of 147.9, which means that, on average, these brands increased in value 47.9% over the 1993 to 1996 period. The 3.3% of sample brands with a sequence of three negative changes in brand value have a 1996 mean normalized value of 76.7%, which means that, on average, these brands decreased in value 23.3%. Panel B reveals a similar pattern for firm-level brand value estimates, although there are no firms with three consecutive years of total brand value decreases.

Figures 1 and 2 highlight several features of estimated brand values that are pertinent to existing financial reporting rules. First, a policy of assuming brand values do not increase

Table 2. Descriptive statistics for 595 firm-year observations for 183 firms, from 1991–1996 surveys, with brand value estimates reported in *FinancialWorld* (1992–1997).

Panel A: Industry classification of the 183 sample firms

Industry	Frequency in Sample		Frequency in Compustat	Ratio of (1) to (2)
	No.	% (1)	% (2)	
Mining, Oil and Gas, Construction	3	1.6	6.4	0.25
Food, Tobacco	42	22.9	2.1	10.90
Textile, Apparel	5	2.7	1.4	1.93
Lumber, Furniture, Paper, Printing	5	2.7	3.3	0.82
Chemicals and Allied Products	30	16.4	6.4	2.56
Rubber, Plastics, Leather, Glass	14	7.7	2.1	3.67
Metal Industries	2	1.1	2.8	0.39
Machinery	13	7.1	6.2	1.15
Electrical Equipment	14	7.7	6.5	1.18
Miscellaneous Manufacturing	15	8.2	8.4	0.98
Transportation	8	4.4	2.3	1.91
Communications	8	4.4	3.2	1.38
Utilities	0	0.0	3.4	0.00
Durable goods wholesale	0	0.0	4.1	0.00
Retail trade	4	2.2	6.2	0.35
Financial services	3	1.6	19.0	0.08
Software	11	6.0	7.3	0.82
Real Estate	0	0.0	1.1	0.00
Others	6	3.3	7.8	0.42
Total	183	100.0	100.0	

over time, absent a change in brand ownership, is inconsistent with the evidence; the average one-year sample brand value increase is more than 6%. Second, there is considerable variation in the sign and magnitude of brand value changes over time. This variation is not surprising given the diverse factors that can affect brand values, including factors beyond the control of the firm owning the brand, such as actions by competitors.[8]

Table 2 presents descriptive statistics relating to sample firms, for firm-year observations with available data. The industry statistics in Panel A are based on two-digit SIC codes. The last column in the panel reports the ratio of sample firms' industry membership percentage to the Compustat population percentage. A ratio greater than 1.00 means that the industry has greater than average representation in this study. Panel A reveals that the sample includes more food and tobacco, chemicals and allied products, and rubber, plastic, leather, and glass firms than one would expect based on the Compustat population. The industry group with a markedly lower representation in our sample relative to the Compustat population is financial services, 1.6% in the sample versus 19% in Compustat.

The size and performance measure statistics in Panel B reveal that sample firms are relatively large; the mean (median) market value of equity, MV, is \$13,673 (\$6,777) million. The book value of equity, BV, for these firms is substantially lower, with mean (median) value of \$3,682 (\$1,700) million. The sample firms' mean (median) market-to-book ratio

Table 2. Continued.

Panel B: Size and performance measures for sample firm-years

Variable	No.	Mean	Median	Std dev.
MV	515	13,673	6,777	19,581
BV	536	3,682	1,700	4,936
M/B	504	4.75	3.38	4.91
ASSETS	537	12,789	5,050	26,340
SALES	536	10,631	5,897	14,930
NI	536	697	310	1,143
MARGIN	536	4,331	2,507	5,645
ADV	536	344	120	572
SALES_GRWTH	530	10%	8%	12%
NI/AVG_MV	497	5%	6%	6%
NI/AVG_ASSETS	531	8%	7%	9%
NI/AVG_BV	511	22%	20%	22%
RETURN	506	1%	−2%	31%

MV is market value of equity at fiscal year end.
BV is book value of equity at fiscal year end.
M/B is market-to-book ratio, for firms with positive book value of equity.
ASSETS is total assets at fiscal year end.
SALES is total sales.
NI is income from continuing operations.
MARGIN is sales minus cost-of-goods-sold.
ADV is advertising expense.
SALES_GRWTH is sales growth, measured as $(\text{sales}_{t-1}/\text{sales}_{t-(1+i)})^{1/i}$, where $3 \leq i \leq 5$.
AVG_MV, *AVG_ASSETS*, and *AVG_MV* reflect the average of beginning and ending balances.
RETURN is year t stock return, measured from three months after end of year $t-1$ to three months after the end of year t, minus the CRSP value-weighted return.
For purposes of this table, all variables are expressed in $ million, except for variables expressed in percentage form. As regression variables, they are deflated by number of shares outstanding.

is 4.75 (3.38), which compares with an untabulated mean (median) of 3.18 (1.83) for all Compustat firms. These statistics are consistent with the notion that, on average, sample firms have substantial unrecognized net assets, presumably such as brand names. Untabulated statistics reveal that adjusting book value of equity by adding the brand value estimates results in mean and median market-to-book ratios that are closer to, but still greater than, unity; i.e., 1.91 and 1.43, respectively.

Table 2 also reveals that sample firms are, on average, profitable, with mean (median) net operating income, *NI*, of $697 ($310) million, or 5% (6%) of mean market value of equity. The ratio of net income to book value of equity is substantially higher, with mean (median) ratio of 22% (20%). The table also indicates that the sample firms, on average, have 10% annual sales growth. Untabulated tests reveal that the 1% (−2%) mean (median) annual market-adjusted return for sample firms is not significantly different from zero.

Table 3 presents summary statistics associated with sample firms' brand values (Panel A)

Table 3. Estimated values of brand names, for 595 firm-year observations from 1991–1996 surveys, reported in *FinancialWorld* (1992–1997).

Panel A: Firms' brand value estimates

Variable	No.	Mean	Median	Std dev.
BRANDS	595	4,220	1,748	7,855
BRANDS/MV	515	44%	37%	43%
BRANDS/ASSETS	537	70%	42%	85%
BRANDS/BV	520	209%	105%	335%

Panel B: One-year changes in firms' brand value estimates

Variable	No.	Mean	Median	Std dev.
Δ*BRANDS*	520	278	68	1,587
Δ*BRANDS/AVG_MV*	439	1%	2%	13%
Δ*BRANDS/AVG_ASSETS*	462	4%	2%	18%
Δ*BRANDS/AVG_BV*	450	11%	5%	41%

BRANDS is the firm's total estimated value of brand names.
ASSETS is total assets at fiscal year end.
MV is market value of equity at fiscal year end.
BV is book value of equity at fiscal year end.
Δ*BRANDS* is the one-year change in the firm's total estimated value of brand names.
AVG_MV, *AVG_ASSETS*, and *AVG_MV* reflect the average of beginning and ending balances.
BRANDS and Δ*BRANDS* are expressed in $ million.

and annual changes in these values (Panel B). The statistics reveal that the mean (median) firm-year has brand values estimated at $4,220 ($1,748) million, and that these unrecognized assets represent a significant portion of sample firms' recognized assets. For example, the mean (median) ratio of estimated brand values to market value of equity is 44% (37%). Moreover, the mean (median) ratio of estimated brand values to recognized assets is 70% (42%), and the mean (median) ratio of estimated brand values to book value of equity is 209% (105%). Thus, including estimated brand values on the balance sheet could have a significant effect on reported financial statement amounts.[9] Consistent with Figures 1 and 2, the statistics in Panel B suggest that the average one-year change in sample firms' brand value is positive. Specifically, the mean (median) one-year change in brand values is $278 ($68) million, which represents 1% (2%) of market value of equity and 11% (5%) of book value of equity.

3. Research Design

Our objective is to assess whether FW's brand value estimates are associated with share prices and returns. Finding that they do is evidence that brand names are relevant for equity valuation of firms owning brand names and that FW's brand value estimates are sufficiently reliable to be reflected in share prices.[10] Because our priors are that brand values are relevant to investors, we interpret failure to detect a significant relation as evidence that error in estimating brand values is substantial. Thus, we interpret a significant relation as evidence that brand value estimates are sufficiently reliable to be reflected in share prices. We test our predictions using two specifications, one relating brand values to share prices, and one relating one-year changes in brand values to annual share returns.

3.1. *Brand Values and Share Prices*

The first set of tests examines the association between market value of equity and brand value estimates. Specifically, we estimate the following cross-sectional regression:

$$MV_{it} = \sum_{Y=91}^{96} \alpha_{0Y} YR_{Yit} + \alpha_1 BV_{it} + \alpha_2 NI_{it} + \alpha_3 BRANDS_{it} + \varepsilon_{1it} \tag{1}$$

where MV is share price at fiscal year end; BV is book value of equity per share; NI is earnings per share from continuing operations; $BRANDS$ is the total of the firm's FW brand value estimates per share, i.e., the sum of the individual brand value estimates, deflated by number of shares outstanding; and YR_Y is an indicator variable that equals one if the observation is from fiscal year Y, and zero otherwise.[11] i and t denote firms and years, respectively. We permit the regression intercept to vary across years to control for mean calendar time-specific effects. We also estimate equation (1), excluding YR_Y, separately for each year, thereby effectively permitting all coefficients to vary across years.

One can interpret equation (1) using the Ohlson (1995) valuation model. For example, one can interpret $BRANDS$ as an "other information" variable in Ohlson's model. Thus, observing $\alpha_3 > 0$ is evidence that estimated brand values capture valuation-relevant information not reflected in BV or NI. Alternatively, focusing on the possibility of recognizing brand values on the balance sheet, one could interpret $(BV + BRANDS)$ as an "as if" book value of equity. This interpretation suggests testing whether α_1 and α_3 are equal.[12] Equation (1) also can be viewed as deriving from an asset-based valuation equation, where earnings is included as a proxy for unrecognized net assets (Barth and Landsman, 1995). All interpretations of the equation lead to predicting a positive α_3. Based on prior research, we also predict the coefficients on book value of equity per share and earnings per share, α_1 and α_2, to be positive.

3.2. *Brand Value Changes and Returns*

One also can examine value-relevance of estimated brand values by investigating the association between annual changes in brand values and contemporaneous annual share returns. Another motivation for estimating a returns specification is to investigate the timeliness of changes in brand value estimates, where timely means that the change in *BRANDS* from one year to the next reflects changes in the value of the firm's brands during that year. If FW's brand value estimates capture valuation relevant information, but are not timely, we can observe a significant relation in the price specification, but not in the returns specification. Thus, observing a significant relation in both specifications is evidence that brand value estimates are timely. Estimating a returns specification also permits us to investigate effects on our inferences of potential specification problems, such as omitted variables. If the omitted variables and coefficients are constant (change) over time, then the price (returns) regression can be misspecified (Landsman and Magliolo, 1988).

The following cross-sectional estimation equation specifies our returns regression:

$$RETURN_{it} = \sum_{Y=92}^{96} \beta_{0Y} YR_{Yit} + \beta_1 NI_{it} + \beta_2 \Delta NI_{it} + \beta_3 \Delta BRANDS_{it} + \varepsilon_{2it} \quad (2)$$

where $RETURN_{it}$ is the firm i's year t share return, measured from three months after year end for $t-1$ to three months after year end for year t. ΔNI_t is NI_t minus NI_{t-1}, and $\Delta BRANDS_t$ is $BRANDS_t$ minus $BRANDS_{t-1}$. Because the number of brands covered by FW increases over time, for purposes of estimating equation (2), we measure $BRANDS_{t-1}$ by applying FW's reported value change percentage to $BRANDS_t$.[13] Other variables are as previously defined and all independent variables, except *YR*, are deflated by market value of equity at the beginning of year t. As with equation (1), we also estimate equation (2) separately for each year.

Assuming FW's brand value estimates provide at least some timely value-relevant information, we predict a positive association between annual changes in brand value estimates and contemporaneous returns, incremental to income and changes in income. Thus, we predict β_3 to be positive. Following Easton and Harris (1991), among others, we include in equation (2) *NI* and ΔNI and predict their coefficients, β_1 and β_2, to be positive.

3.3. Simultaneous Equations Estimation

Our hypothesis is that market value of equity reflects firms' brand values. Thus, we view brand values as "causing" observed share prices, incremental to other value-relevant variables, such as book value of equity and net operating income. However, our estimation equations use a proxy for brand values, rather than the "true" value of brand names. It is possible that FW bases its brand value estimates, at least in part, on observed share prices. That is, it is possible that brand value estimates and share prices are jointly endogenously determined. This possibility raises concerns about whether any relation we document using equations (1) and (2) is attributable to simultaneity bias.

To address this issue, we discussed with FW personnel the process that they use to estimate brand values. They emphasized that their focus is on the brand strength and profitability factors which comprise the Interbrand brand valuation model, as described in the Appendix, and that the valuation process does not involve consideration of the market value of equity of the brand-owner firms.

However, to ensure that our inferences are unaffected by possible simultaneity bias, we also test our hypothesis about value-relevance of the FW brand value estimates using the following system of simultaneously estimated equations. The first is equation (1), which specifies market value of equity as a function of brand values and the second, equation (3), specifies brand values as a function of market value of equity.

$$MV_{it} = \sum_{Y=91}^{96} \alpha_{0Y} YR_{Yit} + \alpha_1 BV_{it} + \alpha_2 NI_{it} + \alpha_3 BRANDS_{it} + \varepsilon_{1it} \tag{1}$$

$$BRANDS_{it} = \sum_{Y=91}^{96} \delta_{0Y} YR_{Yit} + \boldsymbol{\delta_1 \mathrm{FACTORS}_{it}} + \delta_2 MV_{it} + \varepsilon_{3it} \tag{3}$$

where **FACTORS** is a vector of exogenous variables that reflect factors likely considered by FW in estimating brand values. These variables serve to identify equation (3) and thus, ideally, are significantly associated with brand values, but not significantly associated with the error in its estimation. In our implementation, **FACTORS** comprises advertising expense, *ADV*, brand operating margin as reported by FW, *BR_MARGIN*, firm sales growth, *SALES_GRWTH*, and brand market share, *MKT_SHARE*. *SALES_GRWTH* is measured as $(\text{sales}_{t-1}/\text{sales}_{t-(1+i)})^{1/i}$, where $3 \leq i \leq 5$ and sales are obtained from Compustat. *MKT_SHARE* is measured as the weighted average of the firm's sales from brands in a given industry divided by sales of all brand sales in that industry, as reported by FW, with weights equal to the firm's sales relating to brands in a particular industry compared with total firm sales from brands.[14] *ADV* and *BR_MARGIN* are deflated by number of shares outstanding.[15]

To estimate the system of equations, we use two-stage least squares (2SLS). In the first stage, we regress *BRANDS* on all of the exogenous variables in equations (1) and (3), i.e., *BV*, *NI*, *ADV*, *BR_MARGIN*, *SALES_GRWTH*, and *MKT_SHARE*. In the second stage, we estimate equation (1) using the fitted value of *BRANDS* from the first stage, *BRANDS_PRD*, in place of *BRANDS*. By construction, the fitted value does not reflect the association between the estimation error in *BRANDS*, relative to brand value, and market value of equity and, thus, using ordinary least squares in the second stage yields a consistent estimator of α_3. We perform the analogous estimation procedure for equation (3). As explained in Section 4.2, we also estimate a simultaneous estimation equation system for the relation between changes in brand values and returns.

4. Findings

4.1. Value-Relevance of Brand Value Estimates

Table 4 presents summary statistics from estimating equation (1), which provide evidence that brand value estimates are value-relevant. Findings from the fixed-effects pooled regression in the first set of columns indicate that, as predicted, the coefficient on *BRANDS* is significantly positive, incremental to net income and book value of equity (t-statistic = 5.57). This finding is consistent with the brand value estimates capturing valuation-relevant information and being sufficiently reliable to be reflected in share prices. The second set of columns presents summary statistics for the separate-year estimation of equation (1), including two Z-statistics that test coefficient estimate significance across years. The first, Z1,

Table 4. Summary statistics from regression of market value of equity on book value of equity, net operating income, and brand value estimates. Sample of firms with brand value estimates from 1991–1996 surveys, reported in *FinancialWorld* (1992–1997).

		Pooled fixed year effects		Separate-year estimation					
				Coefficient		t-statistic			
Variable	Prediction	Coefficient	t-statistic	Mean	Std dev.	Mean	Std dev.	Z1	Z2
Intercept		–	–	17.77	4.77	5.50	1.79	13.27	6.87
BV	+	0.64	8.84	0.26	0.74	2.57	2.80	6.24	2.05
NI	+	5.23	12.78	8.92	5.17	6.70	2.42	16.13	6.19
BRANDS	+	0.29	5.57	0.25	0.08	2.16	0.88	5.22	5.49
Number	508			84.17	44.38				
Adjusted R^2	0.56			0.66	0.14				

BV is book value of equity at fiscal year end.
NI is income from continuing operations.
BRANDS is the firm's total estimated value of brand names.
All variables are deflated by number of shares outstanding.
Fixed-effects refers to estimation with fixed-year effects. The year-specific intercepts are untabulated.
Z1 equals $(1/\sqrt{T})\sum_{j=1}^{T}(t_j/\sqrt{k_j/(k_j-2)})$ where t is t-statistic, T is number of years, and k is degrees of freedom for regression in year j.
Z2 equals mean $t/(\text{stddev}\, t/\sqrt{5})$.

assumes residual independence, and the second Z2, relaxes this assumption.[16] The Z1 (Z2) statistic of 5.22 (5.49) for the separate-year regressions corroborates the pooled regression findings of significance in the predicted direction for the coefficient on *BRANDS*. Also, as predicted, the coefficients on book value of equity, *BV*, and net income, *NI*, are significantly positive in the pooled and separate-year estimations.[17]

The coefficient on *BRANDS*, 0.29, is significantly less than on *BV*, 0.64, in the pooled specification, consistent with *BRANDS* containing more estimation error than the average component of book value of equity. However, in the separate-year estimation, the mean *BRANDS* coefficient is almost the same as that for the coefficient on *BV*, 0.25 versus 0.26, consistent with *BRANDS* and *BV* being assessed similarly by investors.[18]

Table 5 presents summary statistics from estimating equation (2). The table reveals that, consistent with predictions, one-year changes in brand value estimates are significantly positively associated with contemporaneous returns. The evidence is consistent between the pooled fixed effects estimation (t-statistic = 5.55) and the aggregate separate-year estimation statistics (Z1 = 5.17 and Z2 = 3.47). Untabulated findings indicate that inclusion in the pooled estimation of Δ *BRANDS* increases the adjusted R-squared of the model from 0.12 to 0.18. These findings are consistent with those of the price specification and provide evidence that the finding of value-relevance for estimated brand values is not attributable to effects of omitted correlated variables. Finding that changes in brand value estimates are significantly positively related to contemporaneous returns also indicates that at least some of the change in brand value estimates is timely. Also consistent with predictions, net income and changes in net income are significantly positively associated with contemporaneous returns in both estimation specifications.

Table 5. Summary statistics from regression of returns on net operating income, change in net operating income, and changes in brand value estimates. Sample of firms with brand value estimates from 1992–1996 surveys, reported in *FinancialWorld* (1993–1997).

		Pooled fixed year effects		Separate-year estimation					
				Coefficient		t-statistic			
Variable	Prediction	Coefficient	t-statistic	Mean	Std dev.	Mean	Std dev.	Z1	Z2
Intercept		–	–	−0.09	0.12	−1.94	2.30	−4.29	−1.69
NI	+	1.37	4.79	1.18	2.31	1.92	2.59	4.24	1.48
Δ *NI*	+	0.35	1.68	1.17	1.14	1.26	0.71	2.78	3.55
Δ *BRANDS*	+	0.54	5.55	0.58	0.34	2.36	1.36	5.17	3.47
Number	412			82.20	35.41				
Adjusted R^2	0.18			0.24	0.03				

Returns are market-adjusted returns for the 12-month period beginning three months after the beginning of year t.
NI is income from continuing operations; Δ *NI* is *NI* in year t minus *NI* in year $t-1$.
Δ *BRANDS* is the one-year change in the firm's total value of brand names.
Fixed-effects refers to estimation with fixed-year effects. The year-specific intercepts are untabulated.
Independent variables are deflated by beginning of period price.
Z1 equals $(1/\sqrt{T})\sum_{j=1}^{T}(t_j/\sqrt{k_j/(k_j-2)})$ where t is t-statistic, T is number of years, and k is degrees of freedom for regression in year j.
Z2 equals mean $t/(\text{stddev}\, t/\sqrt{4})$.

4.2. Evidence on Lack of Simultaneity Bias

Table 6 presents summary statistics from estimating the price specification as part of a system of simultaneous equations. Panel A presents findings relating to the brand value estimation equation (3) and Panel B presents findings relating to the market value estimation equation (1) where *BRANDS* is an explanatory variable.

The first set of results in Panel A relates to the OLS regression of *BRANDS* on market value of equity and the four variables we use to identify the brand value equation. It reveals that, as predicted, advertising expense, *ADV*, brand operating margin, *BR_MARGIN*, and brand market share, *MKT_SHARE*, all have significantly positive relations with estimated brand values. These findings indicate that brands of firms that spend more on advertising and brands that have larger margins and market share have larger estimated brand values. The relation between *BRANDS* and *SALES_GRWTH* is insignificant. Also, as predicted, we observe a significantly positive relation between *BRANDS* and market value of equity, *MV*, which is consistent with market value of equity explaining brand value estimates.[19]

The second set of summary statistics in Table 6, Panel A, is from estimating the second-stage regression using the fitted value from the first stage, *MV_PRD*, in place of market value of equity, *MV*. The results are consistent with the OLS estimates for all of the variables except *MV_PRD*, which, as explained below, we obtain from an analogous two-stage estimation procedure. Interestingly, the coefficient on *MV_PRD* is not significantly different from zero, indicating that after controlling for potential simultaneity bias, market value of equity does not explain estimated brand values.

Table 6, Panel B, presents findings related to the effects of potential simultaneity on our

Table 6. Summary statistics from simultaneous equation estimation treating market value of equity and brand value estimates as jointly determined endogenous variables. Fixed year effects estimation for sample firms with brand values estimates from 1991–1996 surveys, reported in *FinancialWorld* (1992–1997).

Variable	Prediction	Coefficient	t-statistic	Variable	Prediction	Coefficient	t-statistic
BV	+	0.63	8.64	*BV*	+	0.62	8.33
NI	+	5.35	12.95	*NI*	+	5.23	12.05
BRANDS	+	0.29	5.49	*BRANDS_PRD*	+	0.34	4.54
Number	487			*Number*	487		
Adjusted R^2	0.57			*Adjusted* R^2	0.56		

BRANDS is the firm's total estimated value of brand names.
BRANDS-PRD is fitted value from estimation of *BRANDS* on all exogenous variables in the system of equations consisting of the equations in Panels A and B.
FACTORS comprises advertising expense, *ADV*, brand operating margin as reported by FW, *BR_MARGIN*, firm sales growth, *SALES_GRWTH*, measured as $(\text{sales}_{t-1}/\text{sales}_{t-(1+i)})^{1/i}$, where $3 \leq i \leq 5$ and sales are obtained from Compustat, and brand market share, *MKT_SHARE*, calculated as the weighted average of the firm's sales from brands in a given industry divided by sales of all brand sales in that industry, as reported by FW, with weights equal to the firm's sales relating to brands in a particular industry compared with total firm sales from brands.
MV is market value of equity measured at fiscal year end.
BV is book value of equity at fiscal year end.
NI is income from continuing operations.
All variables, except for *SALES_GRWTH* and *MKT_SHARE*, are deflated by number of shares outstanding.
YR_Y is an indicator variable that equals one if the observation is from fiscal year Y, and zero otherwise.
Year-specific intercepts are untabulated.

primary regression equation (1). The first set of results relates to OLS estimation using the 487 observations for which we have complete data for estimating equation (3). The results are similar to those in Table 4 for the entire sample. The second set of results reveals that inferences from Table 4 are not attributable to effects of simultaneity bias. Specifically, findings from estimating equation (1) after replacing *BRANDS* by *BRANDS_PRD*, the fitted brand value variable based on a first-stage regression of *BRANDS* on all of the exogenous variables in the system, and, thus, not on market value of equity, are similar to those in Table 4. The coefficient on *BRANDS_PRD* is significantly positive, as predicted.

Consistent with measurement error reduction via the two-stage procedure, the coefficient

Table 7. Summary statistics from simultaneous equation estimation treating market value of equity and brand value estimates as jointly determined endogenous variables. Fixed year effects estimation for sample of firms with brand value estimates from 1992–1996 surveys, reported in *FinancialWorld* (1993–1997).

$$RETURN_{it} = \sum_{Y=92}^{96} \beta_{0Y} YR_{Yit} + \beta_1 NI_{it} + \beta_2 \Delta NI_{it} + \beta_3 \Delta BRANDS_{it} + \varepsilon_{2it}$$

Ordinary Least Squares				2nd stage of 2-stage least squares			
Variable	Prediction	Coefficient	t-statistic	Variable	Prediction	Coefficient	t-statistic
NI	+	1.60	5.52	*NI*	+	1.12	2.87
Δ *NI*	+	0.14	0.67	Δ *NI*	+	−0.08	−0.32
Δ *BRANDS*	+	0.54	5.56	Δ*BRANDS_PRD*	+	1.59	2.74
Number	404			*Number*	404		
Adjusted R^2	0.19			*Adjusted* R^2	0.14		

RETURN is market-adjusted returns for the 12-month period beginning three months after the beginning of year t.
Δ *BRANDS* is the one-year change in the firm's total value of brand names.
NI is income from continuing operations; Δ *NI* is *NI* in year t minus *NI* in year $t-1$.
Δ*BRANDS_PRD* is fitted value from estimation of Δ *BRANDS* on all exogenous variables in the system of equations, where the system comprises the returns equation specified above and $\Delta\, BRANDS_{it} = \gamma_0 + \gamma_1 \mathbf{FACTORS}_{it} + \gamma_2\, RETURN_{it} + \varepsilon_{3'it}$, where **FACTORS** include advertising expense, *ADV*, brand operating margin as reported by FW, *BR_MARGIN*, firm sales growth, *SALES_GRWTH*, measured as $(\text{sales}_{t-1}/\text{sales}_{t-(1+i)})^{1/i}$, where $3 \le i \le 5$ and sales are obtained form Compustat, and brand market share, *MKT_SHARE*, calculated as the weighted average of the firm's sales from brands in a given industry divided by sales of all brand sales in that industry, as reported by FW, with weights equal to the firm's sales relating to brands in a particular industry compared with total firm sales from brands.
All independent variables, except for *SALES_GRWTH* and *MKT_SHARE*, are deflated by beginning of period price.
YR_Y is an indicator variable that equals one if the observation is from fiscal year Y, and zero otherwise. Year-specific intercepts are untabulated.

on *BRANDS_PRD* is somewhat larger than on *BRANDS* in the OLS estimation, 0.34 versus 0.29. This increase in *BRAND*'s estimated coefficient is sufficient to prevent us from rejecting the null hypothesis that the coefficients on *BRANDS_PRD* and *BV* in Table 6, Panel B, are equal. Although failure to reject the null hypothesis is not strong evidence, it is evidence inconsistent with investors perceiving brand value estimates as significantly less reliable than other components of book value of equity.

Table 7 presents findings from using simultaneous estimation techniques to estimate the relation between returns and changes in brand values. The equation specifying changes in brand values is:

$$\Delta\, BRANDS_{it} = \sum_{Y=92}^{96} \gamma_{0Y} YR_{Yit} + \gamma_1 \mathbf{FACTORS}_{it} + \gamma_2\, RETURN_{it} + \varepsilon_{4it} \tag{4}$$

where **FACTORS** includes advertising expense, *ADV*, brand operating margin, *BR_MARGIN*, firm sales growth, *SALES_GRWTH* and brand market share, *MKT_SHARE*. All independent variables, except for *SALES_GRWTH* and *MKT_SHARE*, are deflated by market value of equity at the beginning of year t. We use the levels of these variables to explain annual changes in brand values because these variables change little year-to-year. Their primary role is to identify equation (4); we have no hypothesis relating to these variables.

The findings in Table 7 indicate that the Table 5 inferences relating to the significant positive relation between returns and changes in brand value estimates are not attributable to potential simultaneity bias. Specifically, the first set of results in Table 7 shows that our Table 5 OLS findings apply to the 404 firms for which we have complete data for estimating equation (4). More importantly, the second set of results shows that the coefficient on Δ*BRANDS_PRD* is significantly positive in the relation with contemporaneous returns. The coefficients on net income (change in net income) are significantly positive (insignificant) in both specifications.

5. Additional Analyses

5.1. Alternative Brand Proxies

The results in Table 4 indicate that FW brand value estimates are value-relevant, incremental to book value of equity and net income. The results in Table 6 indicate that much of the variation in the brand value estimates can be explained by variables that might be used to estimate brand values. Thus, to investigate whether the brand value estimates themselves provide power in explaining share prices incremental to these other variables, we estimate equation (1) after including the explanatory variables from equation (3) and interpret the additional variables as alternative proxies for brand values. Recall that these variables include advertising expense, *ADV*, brand operating, *BR_MARGIN*, firm sales growth, *SALES_GRWTH*, and brand market share, *MKT_SHARE*.

Table 8, Panel A, presents the results and reveals that *BRANDS* has a significantly positive relation with market value of equity, after controlling for these alternative brand value proxies (t-statistic = 3.22). Interestingly, the coefficients on all of the alternative proxies are insignificant, with the single exception of that on *SALES_GRWTH*, which is significantly positive, as predicted. These findings indicate that *BRANDS* reflects value-relevant information, not reflected in these alternative proxies.

Two of the variables in the Table 8, Panel A, estimation specification are obtained from FW and are not available in firms' published financial statements. To investigate the possibility that brand value estimates are proxies for value-relevant information already reflected in firms' financial statements, we estimate the relation using only financial statement variables. That is, we exclude *MKT_SHARE* and calculate *MARGIN* as the firm's gross margin, i.e., sales minus cost of goods sold. The findings, reported in Table 8, Panel B, indicate that *MARGIN* is significantly positively associated with market value of equity, incremental to the other included variables, as predicted. *SALES_GRWTH* also is significantly positively related, as in the Panel A specification. Interestingly, *ADV* has a significantly negative relation with market value of equity, after controlling for brand value estimates and the other potential brand proxies. This suggests that investors view as an economic expense the component of advertising expense that is orthogonal to the brand value estimate and other included variables. More importantly for our research question, the findings also indicate that, as predicted, the coefficient on *BRANDS* is significantly positive (t-statistic = 4.75). This finding again indicates that brand value estimates reflect value-relevant information not reflected in these financial statement amounts.

Table 8. Summary statistics from fixed year effects regression of market value of equity on brand value estimates, book value of equity, net operating income, and other potential proxies for brand values. Sample of firms with brand value estimates from 1991–1996 surveys, reported in *FinancialWorld* (1992–1997).

Panel A				Panel B			
Including *FinancialWorld* Variables				Financial Statement Variables			
Variable	Prediction	Coefficient	t-statistic	Variable	Prediction	Coefficient	t-statistic
BV	+	0.62	8.32	*BV*	+	0.43	5.82
NI	+	5.35	12.75	*NI*	+	4.71	11.92
BRANDS	+	0.24	3.22	*BRANDS*	+	0.24	4.75
ADV	+	0.25	0.55	*ADV*	+	−0.85	−1.93
BR_MARGIN	+	0.26	0.58	*MARGIN*	+	0.68	7.78
SALES_GRWTH	+	22.82	3.27	*SALES_GRWTH*	+	27.42	4.17
MKT_SHARE	+	7.89	1.40				
Number	487			*Number*	489		
Adjusted R^2	0.58			*Adjusted* R^2	0.62		

BRANDS is the firm's total value of brand names.
BV is book value of equity at fiscal year end.
NI is income from continuing operations.
ADV is advertising expense.
BR_MARGIN is the brand operating margin as reported by FW. *MARGIN* is the firm's total sales minus cost-of-goods-sold.
SALES_GRWTH is sales growth, measured as $(\text{sales}_{t-1}/\text{sales}_{t-(1+i)})^{1/i}$, where $3 \leq i \leq 5$, and sales are obtained from *Compustat*.
MKT_SHARE is brand market share, calculated as the weighted average of the firm's sales from brands in a given industry divided by sales of all brand sales in that industry, as reported by FW, with weights equal to the firm's sales relating to brands in a particular industry compared with total firm sales from brands.
Dependent variable is market value of equity measured at fiscal year end.
All variables, except for *SALES_GRWTH* and *MKT_SHARE*, are deflated by number of shares outstanding.
Fixed-effects refers to estimation with fixed-year effects. The year-specific intercepts are untabulated.

5.2. Analysts Earnings Forecasts

Brand values arise from the present value of future cash flows, or earnings, expected to be generated by the firm's brand names. Although FW uses historical earnings from a brand to calculate brand value estimates, FW incorporates expectations about the future earnings generating potential of the brand through the brand strength multiple. (See the Appendix for descriptions of the brand strength multiple components.) Because of the link between asset values and expected future earnings, we conduct three additional analyses based on equation (1) that investigate whether the brand value estimates capture brand values incremental to analyst earnings forecasts, a proxy for expected future earnings.

First, we include as an additional explanatory variable in equation (1) the mean analysts' long-term earnings growth forecast, which we obtain from *I/B/E/S* International, Inc. Second, we include as an additional explanatory variable earnings per share multiplied by the mean analysts' long-term earnings growth forecast. Third, we include as additional explanatory variables the mean analyst one- and two-year ahead earnings forecasts and the long-term earnings growth forecast multiplied by the two-year ahead earnings forecast.

Untabulated findings reveal that, although the coefficients on the analyst forecast variables often are significantly positive, as one would expect, in all three specifications the coefficient on *BRANDS* is significantly positive in the pooled and separate-year estimations. These findings suggest that the brand value estimates reflect value-relevant information beyond that reflected in expected future earnings as measured by analyst earnings forecasts.

5.3. Recognized Brand Assets

Thus far, we have implicitly assumed that sample firms do not recognize brand assets, which might not be the case for firms that acquire brands, e.g., in a purchase business combination. To investigate the effects on our inferences of this assumption, we obtain from the sample firms' financial statements disclosures about recognized brand assets. Untabulated findings reveal that of the 435 available firm-year financial statements, only 91, or 21%, relating to 35 firms, mention that recognized intangible assets include purchased brands. Only 59 or 14% of the firm-year observations disclose the recognized brand asset amount. Financial statements associated with more than three-quarters of firm-year observations, 344, do not mention brands in connection with recognized intangible assets.

Untabulated statistics also reveal that the amounts recognized by sample firms differ noticeably from the FW brand value estimates. For firms with available financial statements, the mean (median) ratio of recognized brand assets to FW brand value estimates is 0.12 (0.00), when we assign zero to recognized brand assets for firms not disclosing recognized brand assets. This ratio is particularly low when one considers the possibility that FW does not necessarily estimate values for all of a firm's brands. For the firm-year observations disclosing recognized brand assets, the mean (median) ratio is 0.56 (0.14), where the skewness is primarily attributable to one firm.[20]

We conduct two additional analyses to investigate the potential effects on our inferences of recognized brand assets. First, to the extent that brand assets are recognized by sample firms and, thus, included in *BV*, the coefficient on *BRANDS* in equation (1) represents the incremental coefficient on brand assets, relative to the coefficient on *BV*, not the coefficient on the asset itself. Thus, we estimate equation (1) after subtracting from *BV* recognized brand assets for firms that disclose recognized brand assets. Untabulated findings reveal that the coefficient on *BRANDS* is significantly positive, as predicted. We also estimate equation (1) after subtracting from *BV* goodwill and, for firms that disclose the recognized amount of brand assets, we also subtract recognized brand assets. We do this because it is possible that some firms recognize brands acquired in a purchase business combination as part of goodwill, not as a separate asset. Untabulated findings relating to this specification reveal that the coefficient on *BRANDS* is significantly positive, consistent with other specifications we report.

Second, we consider whether FW brand value estimates reflect brand values incremental to recognized brand assets. Although one can interpret equation (1) as providing this evidence, constraining the coefficient on recognized brands to equal that on other components of book value of equity potentially confounds the test. Thus, we estimate equation (1) after subtracting from *BV* recognized brand assets and including recognized brand assets as a separate explanatory variable. The untabulated findings reveal that the coefficient on recognized brand assets is insignificantly different from zero and the coefficient on *BRANDS* is significantly positive, as in Table 4. We also estimate this specification after subtracting from *BV* recognized brand assets and goodwill, and including the amount subtracted as an additional explanatory variable. The findings again reveal that the coefficient on recognized brand assets, including goodwill, is insignificantly different from zero and the coefficient on *BRANDS* is significantly positive.

5.4. Other Sensitivity Checks

We conduct several additional analyses to investigate the robustness of our findings. First, we examine the possibility that our results are driven by a small set of observations with a substantial level of brand values. To this end, we partitioned the sample into firms with ratios of brand values to total assets above and below the sample median. Untabulated results indicate that the association between brand value estimates and prices and returns are similar for the two subsamples.

Second, we investigate whether our inferences relate only to firms for which brands with values estimated by FW are large relative to the firms' operations. We investigate this by permitting the coefficient on *BRANDS* in equation (1) to vary for firms with ratios of brand sales per FW to total sales per Compustat above and below the sample median. Although the untabulated incremental coefficient for the above-median firms is positive, it is insignificantly different from zero, indicating that our findings do not relate only to firms whose brands represent a large fraction of their operations.

Third, we note that 68% of our sample firms have only one brand for which FW reports an estimated value. We investigate whether the relation between market value of equity and brand value estimates differs for these firms by permitting the coefficient on *BRANDS* in equation (1) to vary for firms with multiple brands. Untabulated findings indicate that both the base and incremental coefficients on *BRANDS* are significantly positive, indicating that the relation is significant for all firms, but stronger for firms with multiple brands. This finding is consistent with brand value estimates reflecting more value-relevant information for firms with multiple brands, perhaps because net income and book value of equity capture single-brand values more directly than multiple brand values.

6. Summary and Concluding Remarks

Although brand names are important intangible assets of many firms, U.S. GAAP does not permit firms to recognize internally developed brands as accounting assets. A major reason precluding accounting recognition is concern about whether brand values are reliably estimable. This paper provides evidence relating to the reliability of estimates of brand values by investigating whether share prices and returns reflect brand values estimated by *FinancialWorld* (FW), based on the methodology developed by Interbrand, Ltd., an established brand valuation consulting firm.

We use a sample of 1,204 brand value estimates collected from FW's annual surveys of brands relating to 1991 to 1996 fiscal years to test the joint hypothesis that brand values are relevant for equity valuation of firms owning brands and FW brand value estimates are sufficiently reliable to be reflected in share prices. Our tests are based on estimating the association between the FW brand value estimates and share prices, incremental to book value of equity and net income, and the association between year-to-year changes in the brand value estimates and annual returns, incremental to net income and changes in net income. We find consistent evidence that brand value estimates are significantly associated with equity market values in both specifications, providing evidence in support of our hypothesis.

Because brand value estimates could be, at least in part, determined with reference to equity share prices, we also estimate a system of simultaneous equations that treats the brand value estimates and market value of equity as jointly determined endogenous variables. Findings from estimating these equations provide strong evidence that our inferences are not attributable to simultaneity bias. That is, the brand value estimates are significantly positively related to share prices and returns, even after controlling for potential simultaneity bias. Findings from this analysis are inconsistent with investors assessing brand value estimates as significantly less reliable than other components of book value of equity.

The simultaneous equation analysis also shows that brand value estimates are, as predicted, significantly positively associated with advertising expense, brand operating margin, and brand market share, although, contrary to predictions, they are not significantly positively associated with sales growth. Thus, we also investigate whether the brand value estimates are significantly related to market value of equity incremental to these additional factors, which could be viewed as alternative proxies for brand value, and find that they are. Thus, brand value estimates reflect value-relevant information beyond that reflected in these alternative measures associated with brand value. Additional analyses reveal that brand value estimates also reflect value-relevant information beyond that reflected in recognized brand assets and analysts' earnings forecasts.

Because brand values likely are relevant to investors, finding that estimates of brand values are reflected in share prices and returns calls into question concerns that estimates of brand values are unreliable. Whether their reliability is sufficient to warrant financial statement recognition is left to accounting standard-setters to determine.

Appendix: Description of *FinancialWorld*'s Brand Valuation Methodology

FW draws heavily on a brand value methodology developed by Interbrand Ltd., which is a London-headquartered consulting firm. FW began reporting estimated values for a small number of high profile brands (such as Budweiser, Coca-Cola, Heinz, and Marlboro) in September 1992. Over time, FW has expanded its coverage to include more brands across a broad set of industries. Key factors that guide FW's addition or deletion of brands in their annual survey are readership interest in the brand as assessed by FW or Interbrand, and availability of data to estimate brand profit and brand strength. Relating to readership, for example, FW has increased its coverage of brands of information technology firms (e.g., America Online, Dell Computer, and Netscape) beyond well-established brands that were covered in the early surveys (e.g., IBM, Intel, and Microsoft). Relating to data availability, FW does not publish brand value estimates for brands for which FW does not believe it has sufficient reliable information. For example, values for brands owned by Mars, Inc. (e.g., M&M's, Snickers, and Uncle Ben's) are not reported by FW because Mars Inc. is privately held and has a reputation for minimal public disclosure of financial information. Similarly, FW makes no attempt to estimate brand values owned by privately held firms where FW believes the information available is reliable (e.g., the Levi's brand of Levi Strauss).

A brand value reflects the product of two factors: net brand-related profits and a brand strength multiplier. We describe each below.

A.1. Net Brand-Related Profits

Net brand-related profits is the estimated after-tax operating income of a brand minus what could be earned on a basic non-branded, i.e., generic, version of the product. FW estimates the worldwide operating income of the brand by extensive discussions with the brand-owner firm's securities analysts and by its own analysis of the firm's financial statements, including segment disclosures. FW estimates the earnings of a non-branded version of the product by estimating the amount of capital required to generate the brand's sales and assuming a generic version of the product would generate a 5% net pre-tax return on that capital. The excess of the brand's estimated after-tax profits over the generic product's estimated after-tax profits is net brand-related profits.[21]

A.2. Brand Strength

FW obtains brand strength multiples for each brand directly from Interbrand. The Interbrand model of brand strength has seven components (see discussion in Guilding and Moorhouse, 1992):

1. Leadership *(maximum 25 points)*: The brand's ability to influence its market. To achieve a high leadership score, a brand must be a dominant force in its sector with a strong market share.

2. Stability *(maximum 15 points)*: The ability of a brand to survive. Well-established brands that enjoy consumer loyalty will receive higher strength scores.

3. Market *(maximum 10 points)*: The brand's trading environment. Changes in market growth, market stability, or in the level of competition are important factors, as are opinions on supplier or customer (buyer) power and demand elasticity.

4. Internationality *(maximum 25 points)*: The ability of the brand to cross geographic and cultural borders. It is difficult to affect the internationality score by any significant amount over a short time horizon. Plans for international expansion or the withdrawal from specified markets will, however, have an impact on profitability. International brands are almost always more valuable than national or regional brands, especially because international brands usually benefit from marketing economies of scale and more robust sales, and because the brand is not dependent on one domestic market.

5. Trend *(maximum 10 points)*: The ongoing direction of the brand's importance to its industry. Unlike other dimensions of brand strength, trend can change dramatically over a short time period. Trend will not only affect brand strength, but also may well affect the ability of the brand to improve or maintain profitability. Trend analysis indicates a brand's ability to remain contemporary and hence retain profitability.

6. Support *(maximum 10 points)*: The effectiveness of the brand's communications. In the short-term, the level of support expenditures is an essential feature in the calculation of profitability. This support includes discretionary expenditures such as marketing support, which is made up of brand maintenance and brand development expenses. It is often difficult to determine a brand's support score because one needs to consider both quantity and quality of support.

7. Protection *(maximum 5 points)*: The brand owner's legal title. This factor is generally an opportunity to express doubts or concerns over a brand's relative level of protection, e.g., challenges to the trademark registration, rather than to appraise its absolute existence.

These components are weighted to develop a single brand strength measure, which ranges from 0 to 100. Each brand strength measure translates to a specific earnings multiplier—the higher the brand strength, the higher the multiplier. The brand strength multiplier can change each year, although the range remains similar from year-to-year. For example, in 1994 the range was 6 to 20 while in 1995 the range was 4.4 to 19.3.[22]

A.3. Illustrating the Interbrand Methodology

FW uses the Gillette brand name to illustrate its approach. In 1995 the Gillette brand was estimated to be worth $10.3 billion (FW, 1996):

> "The blades and razor brand had $2.6 billion in 1995 sales and $961 million in operating earnings. First, we estimated how much capital was employed to produce the brand. To do so, we first determined the median ratio of capital employed to company sales for each industry. In the personal-care category, this was 0.38, or $38 of capital to produce $100 in sales. We estimated this ratio by the brand sales to estimate the capital employed to produce the brand. For Gillette this came to $988 million ($2.6 billion times 0.38).
>
> "A generic brand on average should have a 5% profit on the capital employed to produce a product. So we multiplied this 5% by the capital employed to produce the brand, and we arrived at $49 million for Gillette.
>
> "After subtracting this $49 million from the brand's $961 million in earnings, we got the earnings that can be attributed to the Gillette brand name—$912 million. Keep in mind that we use the two-year weighted average of the earnings attributed to the brand.
>
> "We then applied the maximum corporate tax rate for the country where the brand's parent company is located (35% for U.S. companies) to the two-year earnings average. For Gillette the calculated net income attributable to the brand was $575 million.

"The final step was to multiply the brand's after-tax earnings figure by its strength multiple. Such multiples, in 1995, range from 4.4 to 19.3. For Gillette, one of the most prestigious names in the personal-care industry, this multiple was an impressive 17.9. The final brand value is $10.3 billion."

Acknowledgments

We appreciate the helpful comments and suggestions by participants at the 1998 *Review of Accounting Studies* Conference, especially Jim Ohlson, the discussant, and workshop participants at the University of Alabama and Georgia State University, Baljit Sidhu, and an anonymous reviewer. We thank the editors of *FinancialWorld* for helpful discussions, and *I/B/E/S* for use of analyst earnings forecast data. We also appreciate the research assistance of Hung-Ken Chien. Mary Barth and Ron Kasznik appreciate funding by the Financial Research Initiative, Graduate School of Business, Stanford University.

Notes

1. Brand values also potentially are relevant to evaluating the performance of brand managers because the single most important asset a brand manager must manage is the brand itself. This study's motivation relates to external financial reporting and, thus, we do not focus on brand manager performance evaluation. See Foster and Gupta (1994) for a discussion of research challenges in this area.
2. Annual reports to shareholders of several of our sample firms contain statements highlighting their focus on brand management. For example, Time Warner states "We believe that the surest way to create value for our shareholders is to develop, extend, and enhance the global brands that are Time Warner's alone" (1995 Annual Report).
3. FW articulates similar criticisms of U.S. GAAP when presenting their annual survey of brand value. The following quotation is illustrative: "Given the large and growing importance of brand equity, it is high time that the accounting profession took a second look at the topic. FW maintains that brand value can indeed be measured and that, in general, it does not depreciate over time like a factory or machine. . . . In FW's opinion, the conventions of historical cost introduce more distortions than they avoid, particularly in the field of brand equity" (1991 survey, FW, 1992).
4. For example, in the 1995 survey, FW (1996) reports value estimates for 14 Philip Morris brands, e.g., Marlboro, Kraft, Maxwell House, Miller, and Kool-Aid, the aggregate value of which is $65.663 billion. The largest among these are Marlboro and Kraft, with estimated values of $44.614 billion and $5.742 billion, respectively.
5. Our sample does not include privately held or non U.S. firms for which Compustat data are unavailable, even though FW reports estimates of brands for several such firms.
6. One reason for lack of two consecutive years of brand value estimates is the increase in FW's brand coverage over time. Another is that FW ceased reporting brand value estimates for 63 brands, most of which FW dropped after only one year of coverage, perhaps because of large decreases in estimated brand value.
7. Because FW focuses its reporting on brands with large estimated values, use of brand value estimates available in three consecutive years likely biases the graph against brands with large decreases in estimated brand value.
8. The returns analysis in Section 3.2 is designed to investigate whether these year-to-year changes in brand value estimates reflect changes in brand values.
9. See Section 5.3 for additional analyses relating to the possibility that book value of equity of some sample firms includes the cost of acquired brands.
10. Reliability is a matter of degree. Whether an estimate possesses sufficient reliability for accounting standard-setters to consider it reliable enough for financial statement recognition is a judgment for them to make. We provide evidence on the extent of reliability, not conclusions about whether the estimates are reliable "enough" for recognition. Comparison of the coefficient on the brand value estimates with that on book value of equity provides some evidence on how the reliability of the estimates compares with that of recognized amounts.

11. Our inferences are unaffected by using share prices three months after year end.
12. Under this interpretation, Ohlson's (1995) model also suggests including in equation (1) the annual change in *BRANDS*, Δ *BRANDS*, consistent with viewing Δ *BRANDS* as an "as if" component of net income. Untabulated findings from including Δ *BRANDS* as an additional explanatory variable in equation (1) indicate that although its coefficient is significantly positive, as one might expect, its inclusion has little effect on the coefficients on the other variables. Note also that equation (1) is analogous to Ohlson (1995), equation (7), which is based on a particular linear information dynamics for net income. If net income does not follow this dynamic, then growth and/or expected future earnings are potential omitted variables. We include growth in the specification in Table 8 and report in Section 5.2 findings from additional analyses that consider analysts' forecasts of future earnings. In both cases, our inferences regarding *BRANDS* are unaffected.
13. Our inferences are unaffected if we use the amount reported in the prior year to calculate change in brand value. Our inferences also are unaffected if we include in equation (2) the change in Δ *BRANDS*, although the associated data requirements result in loss of a substantial number of observations.
14. We define sales growth using Compustat rather than FW data because of data limitations. Our inferences regarding the value-relevance of brand value estimates are unaffected by using a one-year sales growth measure based on FW reported brand sales, although doing so substantially reduces the sample size. Our inferences also are unaffected by using Compustat data for all variables, and to using one-year lagged, rather than contemporaneous, advertising expense.
15. Including sales growth and brand market share as explanatory variables in equation (3) with other variables on a per share basis implicitly assumes that all variables are devoid of scale. To ensure our inferences are unaffected by this assumption, we estimated equation (3), using ordinary least squares (OLS) and as part of the simultaneous system, where the share-deflated variables are instead deflated by sales, which effectively is the deflator for *SALES_GRWTH* and *MKT_SHARE*. The untabulated findings are similar to those we report in Table 6, except that the insignificantly negative coefficient on *SALES_GRWTH*, reported in Panel A, is significantly negative in the revised specification.
16. The Z1-statistic is $(1/\sqrt{T})\sum_{j=1}^{T}(t_j/\sqrt{k_j/(k_j-2)})$, where T is the number of years, t_j is the t-statistic, and k_j is the degrees of freedom for year j (see Healy, Kang and Palepu, 1987). The Z2-statistic is (mean t)/(std deviation t/$\sqrt{(T-1)}$) (see White, 1984, and Bernard, 1987).
17. We use the term significant to denote p-values less than 0.05. Untabulated findings reveal that including *BRANDS* in equation (1) reduces the estimated coefficients on both *BV* and *NI*, by 9% and 11%, respectively. Our inferences are unaffected by estimating equation (1) using sales as a deflator, and undeflated, and including either number of shares outstanding or sales as an additional explanatory variables (Barth and Kallapur, 1996). All of our inferences are unaffected by using White (1980) heteroscedasticity-consistent standard errors to calculate test statistics.
18. Inspection of the untabulated separate-year regressions reveals that the difference between the coefficients on *BRANDS* and *BV* is decreasing over the sample period. In the 1993, 1994, 1995, and 1996 regressions, the difference is 0.79, 0.29, 0.11, and 0, respectively. Untabulated regressions that also include Δ *BRANDS* reveal that the coefficient on Δ *BRANDS* is significantly smaller than that on *NI* in the pooled regression and in all separate-year estimations. Unlike the coefficient on *BRANDS*, this difference in coefficients is not shrinking over time, suggesting Δ *BRANDS* is estimated with more error than is *BRANDS* (Barth, 1994).
19. Note that the effectiveness of the two-stage estimation depends, in part, on whether the first-stage regression explains a significant portion of the variation in *BRANDS*. The untabulated adjusted R-squared of the first-stage regression of *BRANDS* on all of the exogenous variables is 0.57, suggesting the exogenous variables explain a substantial portion of the variation in brand value estimates.
20. For firms disclosing that recognized intangible assets include brands, but not disclosing separately the brand amount, we treat total intangible assets as if they relate to brands.
21. Prior to 1994, FW used the most recent year's brand operating income to calculate brand values. Starting with the 1994 survey (FW, 1995), it uses a two-year weighted average of the earnings attributed to the brand, with the most recent year weighted twice as much as the previous year. FW uses this averaging to prevent brand values from varying widely because of economic or short-term industry fluctuations that do not reflect variations in the value of the brand itself. Nonetheless, our separate-year estimation results reveal no discernible temporal pattern.
22. We reviewed the Letters to the Editor of *FinancialWorld* subsequent to each annual survey to identify any specific criticism of the FW brand valuation methodology. The few letters that were published did not take

issue with the methodology. For example: “I have sent your article on brands to our clients. It is important reading for all of us”—Chief Executive Officer (CEO), J. Walter Thompson.

Capital markets research and accounting standard setting

Philip Brown[a], Bryan Howieson[a]

[a]*Department of Accounting and Finance, University of Western Australia, Western Australia* 6907

Abstract

Accounting academics and practitioners have been known to question whether accounting research is as efficacious as it might be. This paper focuses on capital markets-based research in accounting and how its potential contribution to the wider regulatory process can be realised more fully. Examples used are: research on corporate regulation; the move to 'harmonise' accounting standards; accounting for R&D; accounting for goodwill; and equity accounting.

Key words: Capital markets-based research; Accounting standards; Standard-setting

JEL classification: G14, G18, M40

1. Introduction

Many papers discuss the alleged gap between accounting research and accounting practice (see, for example, Schipper, 1994; Beresford and Johnson, 1995; and Howieson, 1996). In this paper, we adopt a similar theme devoted to understanding and closing the gap between 'accounting research' and 'accounting practice'. Like Leisenring and Johnson (1994, p. 74), respectively Vice Chairman and Research Manager of the U.S. Financial Accounting Standards Board (FASB), we take the narrower view that 'accounting practice' means 'accounting standard setting'. Similarly, we limit our comments on 'accounting research' to capital markets-based research in financial accounting. Limiting our comments to capital markets-based accounting research is not to

---

An earlier version of this paper was presented at a plenary session of the 1997 Annual Conference of the AAANZ, Hobart, Tasmania.

deny there are many other, important ways in which the gap between accounting research and accounting standard setting can be narrowed. For example, Beresford and Johnson (1995, p. 115) refer to the FASB working with the American Accounting Association's (AAA) Accounting, Behavior and Organisations Section to develop a research agenda of projects that would interest standards-setters.

Capital markets-based research in financial accounting is more than 30 years old and it continues to thrive, with good reason. Typically, capital markets-based accounting research investigates the association between accounting information and key capital market variables, such as the subject company's share price, or the rate of return on its shares over some time period, or their systematic risk. An example would be to see how well share rates of return are predicted by EPS calculated by the cost method of accounting for investments, compared with the equity method.

In this paper we first discuss in general terms how capital markets-based research can contribute to standard setting. We follow this review with a discussion of the comparative strengths of Australasian researchers in capital markets. Then, to illustrate some of the possibilities, we look at five specific research opportunities, namely: (1) the 'new mood' in corporate regulation in Australia, covering the economic consequences of corporate regulation, including accounting standards, and the uniquely Australian Continuous Disclosure regime; (2) the move to 'internationalise' or 'harmonise' accounting standards; (3) accounting for R&D; (4) accounting for goodwill; and (5) equity accounting. Having canvassed these topics we then suggest means by which capital markets research can be made more effective for standard setting and we finish with some overall conclusions.

2. Can capital markets-based research contribute to standard setting?

We begin with the question, is capital markets-based research ever likely to be of any great interest to standard setters? Some commentators say that, if there is a role, it can only be quite limited, and they note the following limitations.

First, in the early 1970s a series of papers pointed out, quite correctly, that standard setters face an *economically* impossible task because accounting standards affect interested parties in various ways, with both 'winners' and 'losers' in the wealth stakes. Pareto optimality requires that at least one party be better off and none worse off, which is a seemingly impossible ideal to achieve with an accounting standard, given the number of informational and contractual arrangements that rely on accounting numbers. We believe, however, that society expects more of its standard setters. They cannot simply shrug their shoulders and walk away from the task just because it is, in a formal sense, economically impossible. Further, because financial accounting standard setters stress the informativeness of accounting measures, especially to the residual risk bearers, accounting researchers can at least try to help them out, for instance by saying something about the valuation implications of alternatives under consideration.

Second, there is the empirical evidence that suggests accounting information is of limited relevance even to residual risk bearers. Lev's much cited 1989 paper made that point very clearly. Lev defines the 'quality' of earnings by its explanatory power (r^2) in the returns-earnings relation. He concludes that the quality of reported earnings is low, with r^2 in the returns-earnings relation typically being of the order of 5%. Interestingly, Lev also spells out a challenging research agenda, focused on the 'quality' of accounting information. Since Lev's paper, a great deal of effort goes into improving explanatory power, including:

(1) relating returns to earnings levels and changes, both theoretically (for example, Ohlson, 1995; Ali and Zarowin, 1992) and empirically (for example, Easton and Harris, 1991);

(2) separating accruals and cash flows into their components, on the grounds that they differ with respect to their valuation implications;

(3) fitting non-linear models, to allow for the transitory nature of extreme values of earnings, and employing different estimators, for example to mitigate measurement error bias in the Earnings Response Coefficient;

(4) widening the returns-earnings window, so that it covers multiple years (but doesn't that beg the fundamental accruals question, implied by the accounting period convention?);

(5) fitting price-to-book models, such as that used by Landsman (1986) to study defined benefit pension assets and liabilities and since then adopted and adapted in a variety of contexts.

Third, externalities can complicate how we interpret the results of capital markets studies and thereby limit their relevance to standard setters. In particular, consider the implications of the information transfers literature that were first referred to by Foster (1981) and later by Schipper (1990), whereby the benefits of information generated by the reporting firm are seen to spill over to other firms in the same industry; how can we factor those effects into the cost-benefit equation of an accounting standard? Given Lev's (1989) conclusion, that earnings explains relatively little of the cross-sectional variance in the reporting firm's returns, it is perhaps fortuitous that the information transfers literature suggests accounting-induced externalities are of a 'second order of smallness'.

Fourth, Skinner's (1996) observations are sobering. He comments on two studies reported in the *Journal of Accounting and Economics* in 1996. In one study, Venkatachalam (1996) investigates the value-relevance of banks' derivatives disclosures provided under FAS119 and finds that the fair values of derivatives are value-relevant. In the other, Aboody (1996a) investigates whether investors incorporate the value of a firm's outstanding employee stock options (ESOs) into its stock price. He finds that options that are not yet fully-vested on balance increase the stock price (because their incentive effects outweigh the expected costs of dilution), while in-the-money options that are already fully vested are a net cost to shareholders. Moreover, investors appear to value vested ESOs by marking them to market. Correspondingly, the FASB's method of calculating compensation expense has no explanatory power beyond the options' fair value. Skinner argues that, as interesting as these and similar papers may be, how we interpret their results depends on our beliefs about the sophistication of market participants: can the marginal investor (that is, the 'user') in fact value complex financial instruments, reconstruct the financial statements, derive the financial ratios, and select and fit the econometric models that are employed at 'the cutting edge' of capital markets-based financial accounting research?

Fifth, as Schipper (1994) points out, researchers and standard setters have different incentives. If so, why should we expect a close commonality of interests? For their part, standard setters face judgmental issues, like: when should an item be recognised or disclosed, and how should it be measured? They must decide an issue ex ante, that is, before the standard is set. They want research that is available 'now', that comprehensively addresses the entire issue and is conclusive. And they emphasise the answer to the question, not the research process. Schipper notes that, in contrast to the standard setters, capital markets researchers (as we use that term) face an ex post empirical question. For instance, is an item that is currently recognised, or disclosed in some way, value-relevant? Further, their research is time consuming, incremental, inconclusive (because of its incrementalist nature), and it emphasises the research process as well as the question.

So for all these reasons (the impossibility of Pareto optimality, the weak explanatory power of accounting data, externalities, research based on overly complex models and a mismatch of regulators' and researchers' incentives), some would say that capital markets research has little to do with standard setting in practice.

On the other hand, others would say that there is a standard setting role for capital markets-based research, but the opportunity has not been realised as fully as it might be. For instance, the FASB's Leisenring and Johnson (1994, pp. 74–79) claim there simply is not enough '*good*' accounting research. They distinguish between 'research and scholarship' and 'writing and publishing', with the majority of accounting academics being unproductive as researchers. They report that an internal FASB study revealed 87% of U.S. college and university level accounting academics had not published a single paper in any of six leading accounting scholarly journals in six years (1987–1992). The Mathews Committee report of 1990 (vol. 2, Table 3.12B, p. 35) contains a similarly unflattering view of the research productivity of Australian university-level accounting academics, 58% of whom had not published even one refereed article in 10 years.

This pessimistic view of the past is not just from the FASB or a governmental inquiry. Two highly accomplished researchers, Holthausen and Palepu (1994) claim accounting researchers have not done a thorough job of documenting the extent to which accounting standards either:

(1) provide new value-relevant information to investors;

(2) or affect a firm's access to capital markets;

(3) or stifle innovation;

(4) or reduce the cost of obtaining information;

(5) or make information available more uniformly to market participants.

We, however, take a more optimistic view of the future. We believe that there is a role for properly executed capital markets research and that accounting researchers should try to fill it more effectively.

3. Why the optimism?

We have several grounds for suggesting that capital markets research can contribute to accounting standard setting. First, there is no shortage of research questions. Standards setters are active and the research questions they generate are becoming more challenging. We illustrate some of these research questions in the fourth section of this paper. Second, there are steady improvements in the quality of our inputs into the research process. The improvements reflect the higher quality of the research training that is now available in our universities in recent years, combined with the increased research experience of their academic staff. Other initiatives are also leading to better trained researchers, such as the AAANZ's doctoral consortium and doctoral colloquium.

Recent years have given accounting researchers access to higher quality data as computerised databases become increasingly available. We will mention just a few:

(1) Connect 4 which publishes data from Australian annual reports and prospectuses on CD-ROM;

(2) the Securities Industry Research Centre of Asia Pacific (SIRCA's)

infrastructure initiative which provides intraday, high frequency data from Australasian equity and derivatives markets. This database will be extended to financial statement data on overseas stock and futures markets and the over-the-counter market;

(3) several overseas-based data services are now available in Australasia. They include the I/B/E/S earnings forecasts, Standard & Poor's Compustat and Global Vantage databases, Bloomberg, Datastream, Financial Times, and Reuters.

Some research will always require painstaking hand collection. One example is Cotter's (1996) careful work on specific provisions in banks' trust deeds, but the data sources mentioned above can help. Ready availability of data does, of course, expose us to competition from academics in other countries.

Better research methods are another way quality has improved. For instance, better research frameworks have been developed as outgrowths of Ohlson's extensive work on the relations between accounting earnings, book values and stock prices. A second example is the evolution of Landsman's (1986) initial study of pension plan assets and liabilities via the 'balance sheet' approach. Papers such as these lead to alternative ways to fit the data. Technological change also brings great benefits to researchers. There are now more user-friendly computer packages and the internet vastly improves communication and helps overcome the tyranny of distance.

A third reason for being optimistic about the future is that output barriers to research effort are being broken down by the ready availability of publication outlets. It is still true to say that it may be tougher if a researcher targets only, say, *The Accounting Review*, *Journal of Accounting and Economics* or the *Journal of Accounting Research*. To be published in these journals, a 'local' paper may be best motivated in terms of not only what it adds to the literature, but also what special or unique insights can be gained from Australasian data. Nevertheless, the growth in the number of journals makes it easier to publish than it would otherwise have been. Zeff (1996) reports that the number of 'academic research journals in accounting, edited in the English language' grew from 17 in 1980 to 42 by 1988 and 77 by mid-1996. Of the 77, nine are either wholly or partly 'editorial residents' of Australia or New Zealand (Zeff, 1996, Exhibit II, p. 170). As well as the more traditional academic journals, among Zeff's 77 are various outlets for high quality 'applied' or 'professionally oriented' research, such as the *Australian Accounting Review*, which aims to be 'the major forum in Australia for the explanation and discussion of developments in the discipline and practice of accounting'.

Another exciting development is the rapid spread of electronic publishing. One example is the Accounting Research Network (ARN), which references an ever-increasing number of working and accepted papers. The Australian Graduate School of Management is studying the feasibility of electronic publishing, focused on the *Australian Journal of Management*. Although established hard-copy journals, such as *Accounting & Finance* or *The Accounting Review*, add the solid imprimatur of their review process, we might ask at what cost? In the information age, time to market is becoming increasingly critical in the academic world as well. The significance of electronic publishing can only grow.

Consider, for example, the importance of publishing a department or school's working papers on the web. Although it is easy to do, there is a need for caution. The credibility of a department or school's working papers has to be earned. For some institutions that has been done already, through years of striving for research excellence and publishing in high quality journals. For others it may mean departmental or school quality assurance measures are necessary before working papers are posted 'officially' on the web.

4. Some relevant research questions

Given our optimism (because of many questions, better inputs and fewer output restrictions), where can accounting researchers of capital markets help close the gap? We address this question in this section of the paper. What follows is a brief canvassing of five research areas, where capital markets-based research could lead to better informed decisions in the standards arena. Our comments are not a review of what is currently being done. Rather, they seek to illustrate what can be done.

4.1. Corporate regulation

Our first area of potential research questions is prompted by the 'new mood' in corporate regulation, which in Australia may be interpreted as a shift to de-emphasise a legal mind-set in favour of a microeconomic approach. One item on the Australian corporate regulation agenda is a sharper focus on the economic consequences of accounting standards. One of the first regulatory moves of the Howard Government was to shift responsibility for corporate law from the Attorney General's portfolio to that of the Treasurer. An outgrowth of this change was the announcement in March 1997 of a review of the Australian Accounting Standards Board.[1] Since that announcement, various proposals have surfaced to revamp the standards setting process, to focus on the costs and benefits of accounting regulation, and even to provide sunset clauses for accounting standards.[2] These proposals culminated in the release of Paper No. 1, *Accounting Standards* (CLERP 1) of the Corporate Law Economic Reform

[1] See *Chartac,* 28 March 1997.

[2] See *Legislative Instruments Bill 1997*; refer *Chartac* #245, 9 May 1997, p. 4.

Program. In that Paper, the Federal Treasurer proposed that the existing standard setting arrangements will be replaced by an Australian Accounting Standards Committee (AASC) which will be under the supervision of a Financial Reporting Council (FRC).[3] These developments provide research opportunities to explore the consequences and implications of various institutional structures for accounting standard setting.

The uniquely Australian Continuous Disclosure regime is an example of how regulation creates such an opportunity. In September 1994 the Corporations Law was amended to give legislative backing to the Australian Stock Exchange's (ASX's) listing rule 3A(1), which requires listed companies to notify the ASX promptly when a price sensitive development occurs. The legislation, which has few carve-outs (or exceptions), ushered in what is known as 'enhanced' or 'continuous' disclosure. The legislation provides for a review of its effectiveness to be commenced within 18 months, which is a relatively short time for corporations and markets to adjust. We should pause and ask, how might one measure such legislation's 'effectiveness'? A careful study of the parliamentary and community debate reveals that it largely rests upon an *unstated* proposition: 'that the imposition of statutory civil and criminal sanctions will alter the way in which the management and/or directors of listed firms will make decisions relating to corporate disclosures, especially the decision to voluntarily (that is, irregularly) disclose "value relevant" information'. This quote is from a study by Brown, Taylor and Walter.[4] They look for evidence of improved market efficiency in: an increased frequency of price-sensitive announcements by listed firms; analysts' forecasts that are more accurate and reflect a greater degree of consensus; stock prices reflecting news more rapidly; fewer major share market 'surprises'; and lower share price volatility. The evidence found by that study is mixed, most probably because, as the authors argue, the post-enhanced disclosure time period available for their study was too short. We mention this example because a similar approach may be applicable when researching the economic consequences of other financial market regulation, such as accounting standards.

4.2. International harmonisation

A second area to mention is the push to 'harmonise' accounting standards. Globalisation of financial markets (from both supply and demand viewpoints) explains much of the interest in international harmonisation. Michael Sharpe, ex-Chairman of the International Accounting Standards Committee (IASC)

---

[3] See the *Australian Financial Review*, 9 September 1997, p. 3. Also see Corporate Law Economic Reform Program (1997).

[4] See Appendix 6, p. 2 of the CASAC Report.

and both a former Partner of Coopers & Lybrand and a Director of the ASX, takes the view that the 'main goal… is to bring about complete unification of the world's accounting systems: uniformity between International Accounting Standards and the national standards of all countries',[5] an objective that has far-reaching implications.

To appreciate the potential research opportunities a few background comments are helpful. Users of financial statements (that is, suppliers of capital or traders in secondary markets) and preparers (that is, the demanders of capital) have incentives to understand international differences in performance reporting, because the cost of becoming informed, or of price protection strategies to overcome a lack of information, will drive up the cost of capital. In this context, Saudagaran and Biddle (1992) ask whether a firm's decision to list on a particular foreign exchange is influenced by its financial disclosure requirements. From a study of 302 internationally traded firms in 1987, and changes in listing between 1981 and 1987, they conclude that 'stringent disclosure levels could reduce access to foreign capital and foreign investment opportunities' (p. 106). Some investment institutions (that is, users) attempt to contain those costs by developing 'translators' that convert financial statements prepared under one set of GAAP to another, with somewhat less than overwhelming success (see, for example, Choi and Levich, 1991). Baumol and Malkiel (1993) claim that income tax complexities make the task well nigh impossible, anyway. Despite these 'challenges', Barth, Brown and Clinch are currently attempting to develop computer algorithms to translate Australian financial statements into their U.K., U.S. and Japanese GAAP equivalents.

In August 1996 the ASX announced a one million dollar levy on listed entities over two years to fund a specific Australian/IASC harmonisation project. The project is being undertaken by the AASB and AARF.[6] The ASX set up a monitoring panel to oversee the project, the members being Robert Nottle (ASX), Bruce Brook (Group of 100) and Brigid Curran (Coopers & Lybrand).[7] Further impetus for the project came in April 1997, when the Wallis Inquiry into the Australian Financial System suggests in its twelfth recommendation that 'The Australian Accounting Standards Board should, where practicable, seek to harmonise Australia's accounting standards with international standards.' It was this recommendation that resulted in the proposals contained in CLERP 1. This paper not only advocates the creation of the FRC and the AASC,[8] but as part of its proposal no. 2 it submits the

[6] See the AARF's newsletter, *The Standard*, December 1996, for more details.

[7] As an aside, it is an interesting question as to whether the composition of the oversight committee represents an example of regulatory 'capture'.

[8] See footnote 3.

suggestion that:

> 'From 1 January 1999, the AASC should issue identical exposure drafts of standards for public comment to those issued by the IASC with the objective that final standards issued by the AASC would be consistent with Australian law and be the same as those issued by the IASC, unless the Government, upon advice from the FRC, determines that to do so would not be in Australia's best interests.' (Corporate Law Economic Reform Program, 1997, p. 28).[9]

Various benefits are claimed for the harmonisation project, including increased investment, greater market liquidity and simpler and less costly financial statements. Parker (1997) summarises some of these alleged benefits as:

- 'to enhance Australia's ability to compete in the global market place'.
- 'The ASX considered that if Australian companies complied with the IASC Accounting Standards, then increased investment would flow to Australia'.
- 'The major beneficiaries, in the short term, of the Australian/IASC Harmonisation program are the Australian multinational companies. The costs in staying up to date with different accounting rules in different reporting regimes and producing various sets of general purpose financial reports for various jurisdictions in which they operate will be reduced. Foreign entities seeking listing on the ASX will not be significantly affected as they are permitted to list and report on the basis of IASC Standards or their equivalents'.

Peirson and McBride (1996) produce a similar list of alleged benefits:

- 'Harmonisation would allow investors in international capital markets to have access to better quality information and international investment would be expected to be encouraged as a result'.
- 'International harmonisation of accounting standards would simplify the reporting requirements for multinational companies and hence would reduce the cost of complying with financial reporting requirements'.

In an article in *Business Review Weekly* (26 August, 1996) it was stated that '(m)any large companies produce second sets of accounts in accordance with' U.S. GAAP.

---

[9] The Federal Government has since indicated that the deadline of 1 January, 1999 is 'effectively conditional' on the FRC advising the Government that the full adoption of IASC standards is in the best interests of Australia. The Government's view is that this advice is unlikely to be forthcoming before the proposed adoption date. See the *Australian Financial Review*, 3 December 1997, p. 27.

Despite these claims, one wonders just how widespread the costs and benefits are. As part of her on-going postgraduate research, Tarca (1997) reports on a survey of Australian companies listed on overseas stock exchanges that raises doubts about the extent of any direct benefits to Australian companies. According to information provided by the ASX, at January 1997, 107 ASX-domiciled companies were listed on at least one overseas stock exchange and, with multiple listings, total listings were 154. The breakdown of these 154 listings by country is as follows:

- New Zealand, 53
- U.S., 32
- U.K., 23
- Other Europe, 20
- Canada, 15
- Asia, 10
- Africa, 1.

Tarca's (1997) review of the various reporting requirements reveals the following:

- U.S.: New York, Midwest: the U.S. Securities and Exchange Commission (SEC's) Form 20-F which requires a reconciliation to U.S. GAAP, filed (16 companies); NASDAQ, ADR: financial statements prepared according to Australian GAAP are sufficient (16 companies).
- Canada: financial statements according to Canadian GAAP are filed.
- all others (107 companies): financial statements prepared according to Australian GAAP are sufficient.

In the light of this preliminary data, for those affected by overseas requirements, the cost of complying with more than one set of accounting standards is hard to gauge. An additional complexity of course is the question, what costs are relevant? This aside, Chan and Seow (1996) report that the cost of a major U.K. or Japanese company complying with U.S. GAAP is of the order of one million U.S. dollars.

Incidentally, any uncertainty about the cost of harmonisation is not confined to preparers and users of the financial statements of multinationals. Under Watts and Zimmermans' (1979) characterisation of accounting academics as agents in the market for excuses, we ourselves might well face an uncertain future. If International Accounting Standards were imported and adopted wholesale in lieu of the local product as the ASX is alleged to advocate,[10] there would be much less demand for our research services. The accounting standard

[10] See 'Secret ASX Moves to Derail Standards Review', *Chartac,* 1 August 1997, p. 1.

setting industry might soon take a quite different form from the process and players we know today, and it bears watching closely.

A worry some people, including the FASB, have expressed in the past is that the IASs are too permissive and thereby diminish the quality of accounting reports.[11] On the other hand, if IASs do offer more choice, who is to say that firms and their stakeholders won't benefit from the freedom? It should also be noted that the IASC adopted in March 1996 an accelerated work program to issue or re-issue more rigorous standards in a set of core areas. The International Organization of Securities Commissions (IOSCO) 'agreed that successful completion of IASC's current work plan … will allow IOSCO to consider endorsing International Accounting Standards for cross-border capital raising and listing purposes in all global markets'.[12] The IASC was hoping to complete this task by March 1998.

A number of recently published papers deal with the relations between capital market variables and accounting information across countries. For instance, Harris, Lang and Möller (1994) find that the German and U.S. investment markets adjust for relative differences in their respective accounting standards. Amir, Harris and Venuti (1993) compare the value-relevance of U.S. with non-U.S. GAAP financial statements, using a self-matching design, of multiply-listed firms that were required to reconcile their domestic GAAP financials to their U.S. GAAP equivalents and to file their reconciliations with the U.S. SEC, using its Form 20-F. They find that differences in accounting standards for goodwill, asset revaluations and income tax are priced by the equity market. However, there is no share market reaction on the 20-F filing date, suggesting the market has reconstructed the differences for itself.[13] Other Form 20-F-based studies are conducted, by Barth and Clinch (1996) and Chan and Seow (1996). The latter study finds that foreign companies' earnings are more closely related to U.S. stock market prices if they are *not* translated into U.S. GAAP. We expect that the number of such papers will continue to grow; for instance, 'internationalisation' is the key theme for the 1998 *Journal of Accounting and Economics* and *Journal of Accounting Research* conferences, thereby guaranteeing a flow of such papers, at least in the short term.

[11] For instance, it has been reported that 'Warren McGregor, AARF executive director, believes the IASC is putting a likely endorsement of IOSCO [the International Organisation of Securities Commissions] at risk by adopting a 'true and fair' override in a standard on the presentation of financial statements.' *Chartac*, 29 August 1997, p. 6.

[12] See *IASC Insight*, September 1996, p. 9.

[13] Rees and Elgers (1997) extend Amir et al.'s work by analysing the initial registration statements. They conclude (p. 126): 'the value-relevant information captured in the reconciliation is fully impounded in (stock) prices prior to its disclosure.'

Given the interest in harmonisation, there will be greater research payoffs to Australasian researchers in areas where our data provide us with a natural comparative advantage, in terms of their richness or fineness, relative to data elsewhere. One obvious example is mark-to-market accounting, including asset revaluations (see, for example, Easton et al. 1993; and Barth and Clinch, 1996). Two other topics where we have a comparative advantage are accounting for research and development expenditures (R&D) and goodwill.

4.3. Research and development

The third area we review is accounting for R&D. By way of background, a story in the *Australian Financial Review* (22 May 1997, p. 11) notes that 'The Securities Institute of Australia (has) argued that Australia should move towards U.S. accounting standards, which it says are recognised as world's best practice'. It is of course arguable that U.S. GAAP is indeed world best practice. For example, Alford et al. (1993, p. 184) conclude that 'accounting earnings from Australia, France, the Netherlands, and the United Kingdom are more informative or more timely than U.S. accounting earnings'. Even if we concede that, collectively, U.S. GAAP are world's best practice, they are not necessarily the best on all counts. The FASB's Leisenring is quoted by *Chartac* (11 April 1997) as saying that 'non-U.S. standards in many ways are superior'. There are at least two areas where the superiority of U.S. GAAP is strongly contestable, asset revaluations and accounting for R&D.

In the U.S., accounting for R&D has been researched closely over the last decade, particularly by Shevlin (1991) and Lev and Sougiannis (1996).[14] The relevant U.S. standard is FAS2. Before FAS2, R&D capitalisation was permitted under some circumstances but since 1975 FAS2 requires immediate write-off, thereby effectively enforcing a 'coarseness' on U.S. R&D data. An interesting research question is this: does the Australian accounting requirement to capitalise R&D costs that are recoverable 'beyond any reasonable doubt' provide value-relevant information beyond the requirement to report total R&D costs (AASB 1011.31) ? In other words, does the added 'fineness' of the Australian accounting standard, which requires R&D costs to be partitioned into those that do and those that do not meet the recoverable amount test, result in information that seems more useful to shareholders? Australian researchers [15] have a comparative advantage over U.S. researchers (but maybe

[14] Shevlin studies the valuation implications for the general partner of its option to exploit technological developments under R&D limited partnership agreements. Lev and Sougiannis document that R&D expenditures impact on future earnings and present equity values, despite the fact that R&D does not create an asset in U.S. accounting terms.

[15] See, for example, Abrahams and Sidhu (1997) for some recent research.

not over our colleagues elsewhere, since capitalisation is not uncommon in other countries).

Within Australia, accounting practice has always been variable. McGregor (1980) reports widespread deficiencies in R&D reporting practices in the 1970s. A June 1996 study by the ASC of accounting for R&D reports that the majority of the 20 surveyed companies that deferred R&D costs in 1994/95 made inadequate disclosures.[16] It also reports that companies were moving from selective capitalisation (as required under AASB 1011) to immediate write-off. The ASC report concludes that AASB 1011 needs immediate revision and spells out areas where disclosure could be improved. The report goes on to note that international accounting standards permit direct write-off as an alternative to selective capitalisation. It then recommends that any revision of AASB 1011 should aim to ensure that it is 'compatible with principal overseas R&D accounting standards, e.g., the U.S. standard which prescribes all R&D costs are to be written off as incurred' (p. 5).

It is far from obvious, given the capital market evidence, that the move to direct writeoff could possibly be a move in the right direction. The ASC's reference to U.S. standards appears enough to persuade at least one major Australian industrial company to adopt direct write-off. This is what AWA Ltd says in its 1996 annual report: 'the Directors have considered the recommendations of the Australian Securities Commission and changed the accounting policy of the economic entity to accord with international best practice and write off research and development costs as incurred'. Of course, given AWA's recent financial history, there could be other forces at work too.

4.4. Goodwill accounting

The fourth area we review is accounting for goodwill. Australia may be fertile ground in which to investigate goodwill issues because of its history of changing accounting standards. We suggest three research questions to do with goodwill:

(1) Is reported goodwill value-relevant; and if so, how does its 'value per dollar of asset' compare with other assets, and in particular, with identifiable intangibles?

(2) Do some countries' standards for goodwill disadvantage their firms when they compete internationally, as business often claims? James (1997) seeks to address this question.

[16] Ryan and Heazlewood (1997, pp. 100–101) report 56% of 150 companies disclosed R&D costs in their 1996 annual reports. Nine companies are classified as apparently not complying with AASB 1011.

(3) Given the recent controversy on how to amortise goodwill, is there any evidence from the capital market to support the revision of AASB 1013 to impose the straight line method, thereby prohibiting the inverse sum-of-the-years'-digits (ISOYD) method, or any other cost allocation method for that matter?

Much of the relevant research to date is reviewed by Clinch (1995). He notes that the question of whether goodwill is value-relevant can be answered from any one of several approaches. For example, is the carrying value of goodwill correlated with the market value of shareholders' equity (MVE)? Or, is goodwill amortisation expense correlated with stock returns? With respect to the first approach, whether the balance sheet value for goodwill is positively associated with the MVE, overall the answer is yes but there is no clear association for manufacturing firms (see Chauvin and Hirschey, 1994). Moreover, the association for goodwill is weaker than the association for other intangibles (Chauvin and Hirschey, 1994; Muller, 1994).

One interesting research issue is whether this result is driven by greater measurement error in goodwill. Goodwill is by construction affected by any measurement error in every other item associated with an acquisition. We do know that goodwill interacts with identifiable intangibles; for example, the *Business Review Weekly* speculated in 1996 that Fosters Brewing would 'deal with' $359m goodwill on acquiring Mildara Blass by revaluing its brand names (22 July, 1996, pp. 75–76). If there is an interaction, why should we not, then, have a standard on identifiable intangibles, given we have one for goodwill? Evidence on interactions between accounting for goodwill and for identifiable intangibles may have been helpful during the debate on the ill fated ED 49, *Accounting for Identifiable Intangible Assets*.

With respect to the second approach to studying the capital market relevance of goodwill (that is, via the returns-earnings relation), it is unclear whether goodwill amortisation expense is associated with share returns. There are inconsistent findings from the two approaches (that is, the balance sheet approach versus the returns-earnings relation) which limit the usefulness of the research to standard setters. However, the news is not all bad. Rather, it leaves the door open for further research, to resolve the inconsistency.

A second research question on accounting for goodwill is whether some companies suffer a competitive disadvantage because of the goodwill standard. Choi and Lee (1991) study U.K. versus U.S. acquirers of U.S. targets. U.K. firms can take a direct write-off and thereby avoid the periodic amortisation charge that U.S. companies must book (and almost all of them do). They find that U.K. acquirers paid higher takeover premiums. These two same authors also study acquisitions by U.S., Japanese and German bidders and find that U.S. firms paid lower premiums (Lee and Choi, 1992). Similarly, Hong et al. (1978) and Davis (1990) find higher share returns over the acquisition period for firms that use the purchase method (and thereby recognise goodwill on acquisition) than firms which use the pooling method (no goodwill).

Australia may be a very good site for pursuing research on this question, of competitive advantage (or otherwise). There have been changes in the Australian goodwill standard over time, and there probably is enough takeover activity to be able to meaningfully compare, say, the premiums paid by Australian, U.K. and U.S. bidders with each other and over different standards regimes. James (1997) is engaged in research which goes some of the way in this regard.

The third goodwill research question relates to the issue of the choice of methods of amortisation. Did the Australian standard setters overreact in the light of the available evidence? Before banning alternative methods of amortisation, it might have been helpful to have some evidence on how users viewed the methods. At this point in time, we simply do not know. Moreover, it would be quite difficult to get reliable evidence, because very few Australian companies used the ISOYD method (Brown, 1995).

4.5. Equity accounting

Equity accounting is the last area we mention by way of illustrating potentially useful research questions. It is helpful to focus on the background to ED 71, *Accounting for Investments in Associates*. Gordon and Morris (1996) provide a useful account. Equity accounting seems to have been re-instated on the standard-setting agenda in 1994, apparently on the initiative of the Group of 100, Peter Day (he was, at that time, AASB Chairman), and the ASC's then front-line accountant, Stuart Grant, all of whom were to some extent concerned that Australian practice was out of line with practice overseas. ED 71 was issued and since then, the re-introduction of equity accounting has slipped relatively quietly into place. Leo (1996) gives a progress report on submissions on ED71 as at July 1996. He reports there were 30 submissions up to then,[17] of which 29 supported the standard. Is the lack of 'fuss' because equity accounting's benefits relative to the cost method can be argued easily, either by appealing to classical 'dividend irrelevance' theory (signalling issues should be largely absent in cases where the investor has significant influence and equity accounting applies), or say, by some eclectic mixture of 'matching', 'timing', 'contracting efficiency' and 'opportunism' arguments, or on the grounds of international harmonisation?[18]

The Second Corporations Law Simplification Bill Exposure Draft (issued

[17] A total of 31 submissions were finally received.

[18] Miller and Leo (1997) discuss the impact of harmonisation on the equity accounting debate in Australia.

June 1995) proposed to remove the so-called legal impediment to recognising equity accounting in the body of financial statements. As Gordon and Morris describe it (1996, p. 166), the impediment arose from a legal interpretation that, under the Companies Act, group profit should be confined to the profit of the holding company and its subsidiaries; or, in other words, the investor's share of the profits of companies that were not its subsidiaries must be excluded from the investor's profit figure. The Second Corporations Law Simplification Bill, which would have removed the claimed impediment was delayed, but the ASC used its administrative powers to clear the way for an early introduction.[19] The Australian Shareholders Association (ASA) objected to the ASC's move, not because the ASA was opposed to equity accounting as such, but because it claimed there were two standards, the real standard and a 'Clayton's standard'.[20]

What evidence do we have on the relevance of equity accounting to the shareholders of the investor? One piece of evidence is a study by Ricks and Hughes (1985) who examine the stock market behaviour of U.S. firms at the time of four key events in the Accounting Principles Board's equity accounting deliberation process around 1971, and also the market's reaction when firms whose earnings were affected by the new standard first reported those effects. Ricks and Hughes find no unusual stock market reaction to any of the four events in the lead up to the standard but they do find a significant stock market reaction when the results of switching from cost to equity accounting were first reported by affected firms. They attribute the stock market reactions to new information content from the adoption of equity accounting. Recontracting costs are discounted because they are said to be negligible.

Given the limited evidence, there are research opportunities for Australian researchers here (see, for example, Czernkowski and Loftus, 1997). Indeed, there may be an opportunity for an unusual experiment. Could one investigate whether the quality of footnote disclosure may have exceeded that of recognition during the time that equity accounting was effectively relegated to the footnotes? Such research is not without its problems because, as Bernard and Schipper (1994) caution, researching recognition versus disclosure issues via capital markets relations is extremely difficult.[21] There is no conclusive evidence that recognition and disclosure have the same pricing implications; although it is usually assumed by researchers (and by quite a few practitioners, for that matter) that the implications are identical. A view often expressed by regulators is that managers who are inclined to engage in unacceptable

[19] See the *Australian Financial Review*, 10 June 1997, p. 24.

[20] See the *Australian Financial Review*, 17 June 1997, p. 26.

[21] See also Aboody (1996b).

practices behave differently when their activities are public knowledge and it matters little how that knowledge is gained.

By way of illustration, one very difficult research design issue is how to interpret the coefficient of a typical 'balance sheet equation' approach to demonstrating value-relevance, as in say Landsman's (1986) study of pension funds (which are much the same as Australian defined benefit superannuation funds). Landsman's dependent variable is the MVE. His explanatory variables are the book values of on-balance sheet assets and liabilities, and the estimated values of off-balance sheet pension plan assets and liabilities. The hypothesised relation is fitted by OLS regression. Suppose the estimated coefficients of the on- and off-balance sheet assets are statistically different. Bernard and Schipper (1994) then ask the question, what can we safely conclude? Any measurement error in the explanatory variables will bias the coefficient estimates. Almost certainly some explanatory variables are omitted ($r^2 < 1$), so it cannot be concluded that the disclosed item (pension assets or liabilities) is itself informative, even if the coefficient is statistically significant. This is a manifestation of the correlated omitted variables problem. Even if we avoid these two matters, we do not know whether market agents are biased in their assessments, or acting irrationally in some other way. Further, they may be unbiased, but behave rationally, discounting the disclosed item because it is known with less precision (which is why it is disclosed and not recognised).

5. Crossing the great divide

What processes can be implemented so that where academics can help, they are more effective and the gap between research and practice can be narrowed? A closely related question is, if standard setters would welcome help ex ante, how can academics be more proactive, in relation to issues likely to arise in our part of the world?

One action that could be undertaken is that Australasian academics and practitioners could try to predict the next item to surface on standard setters' agendas. This is being done in the United States, where the FASB has attempted to institute an 'early warning system', to promote timely ex ante research (see Beresford and Johnson, 1995, p. 116). Topics identified so far include footnote disclosures and reporting environmental liabilities. Perhaps Australian accounting academics can work with the AARF, ASC or ASX to have them do likewise?[22]

One of the simplest ways to help bridge the gap would be to engage in 'U.S. or U.K. watching'. Beresford and Johnson (1995) make a number of useful

[22] The AAANZ has instituted a study leave register, available to a number of Australian regulatory bodies, of accounting academics wishing to work on topical accounting problems. The register is maintained by the AAANZ Vice President-Practice.

suggestions, about processes, that bear repeating, albeit in a localised form. First, standard setters do, in fact, appreciate academics' analytical skills, and so academics should not be shy in volunteering them. Second, academics can communicate their views in various ways, such as by making written submissions on exposure drafts. Many academics can and do assign 'draft a submission to the AASB/PSASB' as a task for their students, but relatively few make their own submissions. United States academics, for instance, averaged 4.4 submissions (median equals 2) over 148 documents preceding FAS Numbers 1–117 (Tandy and Wilburn, 1996, Table 3). Australian academics do somewhat better. We recently reviewed tabulations for 13 Australian exposure drafts issued since 1979. The median number of submissions from academics is six compared with a median from all sources of 53. Another written submission could be what Leisenring and Johnson call a 'thought piece' (1994, p. 78): a 'carefully argued position that uncovers logical flaws or shortcomings in previously held views'. Thought pieces 'can provide insights that are every bit as powerful as any other piece of research and scholarship'. We ask the question: is every submission always to be seen as 'lobbying'? It carries the negative connotation of trying to persuade the decision maker to adopt a position that advantages the submitter, thereby suggesting that such practice by accounting scholars is somehow *infra dig*.

A third vehicle for bridging the gap is by publishing scholarly papers. These are beneficial because leading accounting journals are monitored by regulators' staff, or by those commissioned by the regulators to write discussion papers. However, it must be acknowledged that scholarly articles are not written in a style that is used by practitioners; we write for our intended audience. As mentioned previously, it should not be overlooked that some journals *are* designed to bridge the gap, and they can be influential.

We must also acknowledge that worthwhile and important links now exist between academics and standard setters. For instance, distinguished academics (such as Bob Walker, Malcolm Miller, Jayne Godfrey) have served on the AASB or its predecessor, the Australian Standards Review Board. There are many other valuable links with the AARF, as well. The discussion papers by Hancock (1990), on financial reporting by financial intermediaries and accounting for financial instruments, and by Howieson (1997), on accounting for investment properties, are examples of other means of being involved. Further, academics serve on many professional committees, and contribute to continuing education programs.

That said, we would also like to encourage the Australasian standard setters to harness the *research* expertise more widely, as the FASB has done in recent years. For example, since 1991 the FASB has promoted Financial Reporting Research Conferences which are held annually at a major university. These conferences are sponsored by the American Accounting Association and are also supported by major accounting firms. They bring together members of the AAA, the FASB, SEC representatives, public accountants, corporate accountants and financial analysts. The Accounting Standards Forums which have been held at the beginning of each of the last three AAANZ conferences are somewhat similar in their aims. These forums are organised by the Accounting Standards Interest Group, with the assistance of the Australasian standard setters. The theme of the 1997 Forum was 'harmonisation with international accounting standards' and it included representatives of academics, accounting regulators such as members of the Urgent Issues Group, AASB, AARF, NZ Accounting Standards Board and Bob Sweiringa who, until recently, was a member of the FASB.

As an example of how successful these interactions can be, consider the FASB's research roundtable presentation on executive stock option valuation. The roundtable presentation was a one-day meeting attended by academics and others with valuation expertise (for example, investment bankers). The discussion between the various parties prompted further academic research and assisted the FASB in its deliberations. Indeed, some papers have since been published (see, for example, Hemmer et al., 1995).

Finally, there may be a role for a local equivalent of the AAA's Financial Accounting Standards Committee, which the FASB's former Chairman, Beresford, describes as very helpful. That committee routinely makes submissions to the FASB and it could serve as a model for formal interaction between Australasian academics and standard-setters.

6. Conclusions

We have reviewed a number of issues associated with the relation between capital markets research and accounting standard setting. Unlike some commentators, we are naturally optimistic about the future of this line of research and its contribution to accounting practice.

We supported our optimism by illustrating various topics to which capital markets research can contribute to standard setters' understanding and deliberations. One has only to look at the published evidence to see that there is a strong and continuing interest in capital markets research. For instance, in the editorial to the May 1997 edition of the *Journal of Accounting and Economics* there are some interesting numbers on the breakdown, by subject matter, of articles published in that journal since 1979. The totals, excluding book reviews, are as follows:

- between 1979 and 1986, a total of 78 articles were published, of which 23, or 29.5%, were empirical capital markets studies

- between 1987 and 1991 there were 86 in total of which 25, or 29.1%, were empirical capital markets studies

- and from 1992 to 1996, of the 122 articles published, 42 (34.4%) were empirical capital markets studies.

We hope that we have demonstrated that there is no lack of suitable research questions. We encourage accounting academics (and standard setters) to continue to explore the potential of capital markets research to inform and further our understanding of financial accounting practice.

Accounting earnings and firm valuation: the French case

Pascal Dumontier
Ecole Supérieure des Affaires
Réal Labelle
Ecole des Hautes Etudes Commerciales

ABSTRACT

Considering that the level of the association between stock returns and accounting earnings provides a measure of the extent to which earnings summarize the information which is useful for firm valuation, this paper analyses the contemporaneous association between stock returns and earnings changes or earnings level of individual French stocks and portfolios for periods of one, two and five years between 1981 and 1990. The empirical findings are as follows. (a) Stock returns are more linked to earnings changes than to earnings levels indicating that earnings provide more information about changes in firm value than about firm value. (b) Earnings prepared in accordance with the French accounting principles are not less value-relevant than those prepared in accordance with US or UK GAAP. (c) A cross-sectionally and time-aggregated data procedure provides a large increase in the explanatory power of earnings for returns which is consistent with a noise-in-earnings effect probably induced by accounting measurement and valuation principles and with a recognition lag effect due to the fact that value-relevant events are not integrated into earnings exactly when they occur. These two effects are shown to be the major causes of the low association between earnings and returns generally observed in studies based on short period data for individual stocks.

1. INTRODUCTION

Several functions are commonly assigned to accounting. One of them is the provision of useful information to enable investors to value securities and make rational investment decisions. Among all accounting data, earnings are probably the ones investors study with the greatest scrutiny. As mentioned by Beaver (1989), ‘No other figure in the financial statements receives more attention by the investment community than earnings per share. This relationship between accounting earnings and security prices is probably the single

Address for correspondence
Pascal Dumontier, Ecole Supérieure des Affaires, BP 47 – 38040 Grenoble, cedex 9 – France. E-mail: dumontie@esa.upmf-grenoble.fr

 0963–8180

most important relationship in security analysis, and its prominence is reflected in the attention given to price–earning ratios.'

The price–earning association has received considerable attention in empirical accounting research since the seminal work of Ball and Brown (1968) which shed light on the informational perspective of accounting data. In their footsteps, numerous papers in the accounting literature have examined the association between accounting earnings and security prices behaviour.[1] The current study is intended to contribute to this line of research by analysing the contemporaneous association between stock returns and earnings of French firms over several periods in order to assess to what extent accounting data published by these firms reflect factors incorporated in stock prices. Following Beaver *et al*. (1980), Collins and Kothari (1989), Easton and Harris (1991) or Strong (1993), this paper focuses on the sole role of earnings without considering the usefulness of any other financial statement items for valuation purposes.[2]

Considering that the level of the association between stock returns and accounting earnings provides a measure of the extent to which earnings summarize the information which is useful for firm valuation, this paper has several purposes. First, empirical tests are performed in order to investigate whether earnings are statistically related to returns. Inasmuch as two measures of earnings (the level of earnings and the first difference in earnings) are generally assumed to be both relevant for evaluating the return–earnings association, this paper uses a rigorous likelihood ratio test to determine empirically which of these two variables has the highest explanatory power for stock returns. Although both variables appear to be statistically linked with stock returns, the results suggest that the earnings-level variable performs better than the earnings changes one in explaining returns. Second, since empirical tests of the return–earnings association based on annual returns and earnings for individual stocks exhibit a remarkably low explanatory power of earnings for returns which can be attributed to a noise-in-earnings bias and to a recognition lag bias, the paper proposes a data aggregation approach to circumvent these biases. The evidence indicates that this procedure strengthens the return–earnings association. Last, a short comparative analysis of the results obtained for France with those obtained in other countries is conducted in order to estimate the value-relevance of earnings prepared in accordance with the French accounting standard setting.

The paper is organized as follows. The next section presents some theoretical justifications for the existence of an association between security prices and accounting earnings and it examines the literature which has tested this relationship. Section 3 describes the sample and provides details on the research design. Sections 4 and 5 present empirical results from individual and aggregated data. The last section is devoted to concluding remarks.

2. PREVIOUS RESEARCH ON THE RETURN–EARNINGS ASSOCIATION

Theoretical justifications of the return–earnings association

Several models motivating association studies have been proposed in the literature. A first approach assumes that firms' market value is related to their book value. Accordingly, any change in the book value (which is equal to retained earnings because of the clean surplus condition) should be linked to a change in stock prices:[3]

$$\Delta P_{it} = \Delta BV_{it} + u_{it} = EPS_{it} - D_{it} + u_{it} \tag{1}$$

where ΔP_{it} = change in market value per share of firm i at time t; ΔV_{it} = change in book value per share of firm i at time t; $EPS_{it} - D_{it}$ (earnings per share minus dividend per share) = retained earnings of firm i at time t; u_{it} = error term.

Dividing (1) by $P_{i,t-1}$ and rearranging shows that returns are related to contemporaneous earnings levels normalized by the beginning of period stock price:

$$\frac{\Delta P_{it} + D_{it}}{P_{i,t-1}} = \frac{EPS_{it}}{P_{i,t-1}} + u'_{it} \tag{2}$$

While the book value approach stipulates that firms trade at a given market-to-book ratio, other models assume that value is measured by the earnings figure. These models are based on three critical links: a link between security prices and future dividends, a link between future dividends and future earnings and a link between future earnings and current earnings.[4] If the market value per share of firm i at time t reflects the present value of its expected future dividends, if these dividends are linked to earnings and if current earnings provide information about future earnings, then the firm's stock price (P_{it}) should be related to its earnings per share (EPS_{it}) and price changes should be a function of earnings changes:

$$\frac{P_{it} - P_{i,t-1}}{P_{i,t-1}} = \phi\left(\frac{EPS_{it} - EPS_{i,t-1}}{P_{i,t-1}}\right) \tag{3}$$

Ohlson (1991) proposes an analysis which explains why and how contemporaneous earnings levels and earnings should be both related to stock returns. His model shows that in a certainty setting returns should relate to earnings levels. Under uncertainty, earnings changes are shown to explain returns as well as contemporaneous earnings.

A survey of the empirical evidence of the return–earnings association

Empirical tests of equations (2) and (3) aim at measuring the relation between a stock price variation for a given period and an accounting measure of earnings generated during the same period. Following the book value approach which results in equation (2), stock returns (R_{it}) are regressed on *earnings levels* (EPS_{it}) deflated by the beginning of period share price:

$$R_{it} = \alpha_0 + \alpha_1 \frac{EPS_{it}}{P_{i,t-1}} + \upsilon_{it} \tag{4}$$

Following equation (3) and the approach of earnings as a measure of value, stock returns are regressed on *earnings changes* (ΔEPS_{it}) deflated by the beginning of period share price:[5]

$$R_{it} = \beta_0 + \beta_1 \frac{\Delta EPS_{it}}{P_{i,t-1}} + w_{it} \tag{5}$$

The strength of the association between earnings and stock returns is given by the coefficients of determination (R^2) of the regression models. Those are generally taken as a measure of the degree to which earnings provide relevant information concerning firm performance because of their ability to reflect value-relevant items incorporated in stock prices. The slope coefficients α_1 or β_1, frequently defined as the earnings response coefficients, measure the effect of one franc of earnings or earnings changes on stock prices.

As outlined by Lev (1989) or Cho and Jung (1991), the R^2's obtained in most studies by regressing annual security returns on annual earnings or earnings changes are very low. They rarely exceed 10%. In the US, Beaver *et al*. (1980) find an average R^2 of 7% for their year-by-year regressions of individual securities. Average R^2 coefficients obtained by Collins and Kothari (1989) or Livnat and Zarowin (1990) are respectively 6.9% and 5%. In the US, the earnings level variable appears to perform better than the earnings changes variable. Easton and Harris (1991) or Kothari (1992) observe that the average R^2 obtained with earnings levels is greater than the one obtained with earnings changes: 7.5% instead of 4% for Easton and Harris, 15% instead of 11% for Kothari. In the UK, Strong's results (1993) provide a contrast with those in the US since he finds an average R^2 of 13% for the earnings changes variable but only 9% for the earnings level one.

The above studies link annual earnings to contemporaneous annual stock returns. Indeed, most of the return–earnings analyses use yearly data, probably because they are in time with the period covered in annual reports. However, the choice of the one-year horizon may not be optimal in testing this relationship because stock price changes may be associated in a given period with events that have not met the conditions for accounting recognition, but that will be captured in subsequent periods' earnings. In order to reduce the bias due to the lag between the period in which value-relevant events occur and the period in which these events are integrated into earnings, Lev (1989), Warfield and Wild (1992), Easton *et al*. (1992) or Dechow (1994) examine whether a longer time horizon can significantly improve the return–earnings association. Their results show that the correlation between earnings and returns improves with increases in the time interval under consideration. Lev's model R^2 is 3% for a one-year interval and 35% for a five-year interval. Warfield and Wild obtain R^2's of 2.1%, 9%, and 39.8% depending on whether they use quarterly, annual or four-year data, respectively. For exactly the same time periods, Dechow's R^2's are respectively 3.24%, 16.2% and 40.26%. Easton *et al*. observe the same phenomenon: the longer the time interval, the higher the explanatory power of earnings for returns. Their average R^2 varies from 5% for one-year return to 15% for two-year returns, 33% for five-year returns and 63% for ten-year returns.

While empirical tests use accounting earnings, models of the return–earnings association refer to a theoretical economic income. Reported earnings significantly differ from this economic income and are therefore subject to measurement errors which might result from the numerous conventions that underly accounting principles or from financial reporting manipulations. Grouping is an efficient procedure commonly used to reduce this well-known problem which causes a downward bias in the estimated regression coefficients. Beaver *et al*. (1980) show that such a procedure leads to a real improvement in correlations compared to those not using portfolios. They observe R^2 coefficients which vary from 7% to 55%, 72% and 82% depending on whether they use individual stocks or whether they group these stocks into 100, 50 or 25 portfolios.

3. SAMPLE SELECTION AND RESEARCH DESIGN

Sample selection

The study covers a ten-year period from 1981 to 1990. The sampled firms meet two conditions: they are all listed on the Paris Stock Exchange during the whole period of interest and their accounting figures are available for each year of the study in the 'Desfossé' directory which contains financial statements of the firms listed on the French stock market. The market data (stock prices, dividends and adjustment factors) come from the 'Association Française de Finance-SBF' data bank. All earnings, dividends and prices are adjusted for stock splits and stock issues.

This selection results in a sample which includes the *same* 117 firms for any of the years under consideration. This restriction comes from the time aggregation procedure used in section 5, which imposes the earnings variables of each firm to be available for each year under study. This constraint is likely to bias the sample which therefore mainly includes large surviving firms. However, since the impact of this possible survivor bias on results is hard to determine *a priori*, it is supposed to be negligible following in this (Collins *et al*., 1994).

Research design

In order to determine whether the earnings level variable and the change in earnings one are value-relevant because of their ability to explain French firms stock returns, the two univariate regressions (4) and (5) are run.[6] Each regression model is estimated both for each year between 1981 and 1990 and for the pooled cross-section and time-series sample.

Since the analysis of the return–earnings association is primarily aimed at determining whether the factors that explain returns during a given period of time also explain earnings related to the same time interval, following Beaver *et al*. (1980) or Kothari and Zimmerman (1995) return intervals align exactly with the period to which the earnings figures relate, i.e. the accounting year. Accordingly, no attempt was made to include earnings' preliminary announcement dates in the period over which returns are calculated even if, as shown by Collins and Kothari (1989), this might have improved the results by increasing the degree of association between returns and earnings.[7]

When the absolute value of earnings per share or earnings changes per share deflated by initial stock prices happens to be greater than one, it is considered as an outlier and it is not taken as such in the statistics. In these cases, stock returns and deflated earnings were deleted from the sample.[8] These outliers are due to the fact that the market value of some companies is close to zero while their earnings (levels or changes) are significantly positive or negative. The exclusion of these extreme obervations is consistent with a similar practice in previous research.[9]

Market efficiency and return–earnings studies

Since this study uses stock prices as a benchmark to assess whether earnings provide a relevant measure of firm value, it relies heavily on the efficient market hypothesis in the sense that stock prices are assumed to be good estimates of this value. If prices significantly deviate from fundamentals because investors do not take into account all relevant information concerning future cash flows, then stock returns will be inadequate to judge the relevance of earnings for valuation purposes. With regard to the French stock market efficiency, the empirical evidence described by Hawawini (1984) is highly supportive.[10] Indeed, empirical tests conducted in France suggest that publicly available information concerning firms' future cash flows is instantaneously and fully reflected in prices as suggested by the efficient market hypothesis. Consistent with these findings, this study assumes that stock prices in France reflect information as efficiently as prices in countries where similar studies have previously been conducted. Stock prices are therefore considered as an appropriate benchmark to evaluate earnings' ability to reflect firm value.

4. THE RETURN–EARNINGS ASSOCIATION BASED ON ANNUAL DATA FOR INDIVIDUAL STOCKS

Regression results

The results from the two univariate regressions (4) and (5) for one-year time horizon are reported in Table 1. The first column reports results of the regression using earnings level (henceforth model 1). The second column reports results of regression using earnings changes (henceforth model 2).

The evidence indicates that security returns are significantly associated with earnings level as well as with earnings changes. The slope coefficients from model 1 and model 2 pooled regressions are statistically significant at the 1% level. As expected, each year's coefficients exhibit positive signs. Model 1 yields an average earnings response coefficient estimate of 1.38. Concerning model 2, this estimate comes to 0.98. Model 1 and model 2 pooled cross-sectional and time-series coefficients are also positive. They equal, respectively, 1.70 and 1.21. However, the association between returns and earnings is highly variable over time. Model 1 earnings response coefficients vary from 0.72 to 2.43. Concerning model 2, they fluctuate between 0.27 and 1.94. All the return–earnings studies show the same variation in earnings response coefficients. This non-constancy of earnings coefficients surely limits the operational implications of these studies since, as mentioned by Lev (1989), 'if earnings are to be useful in predicting future returns, the form of the return–earnings relationship should exhibit a certain degree of stability over time'. However, this instability of earnings coefficients does not affect the credibility of results, first, because the return–earnings theoretical models do not stipulate any permanence of these coefficients and, second, because the link between returns and earnings depends on the current and future economic conditions which are supposed to vary through time. Therefore, the temporal variation in regression coefficients should be the rule rather than the exception.[11]

The relative explanatory power of earnings level and earnings changes for stock returns

Theoretically, as has been shown previously, earnings level and earnings changes are both supposed to be related to stock prices, so that these two

Notes: In columns 1 and 2, figures in parentheses denote t-statistics (* significant at $\alpha \leq 0.01$). In column 3, ΔR^2 refers to the difference between model 1 and model 2 R^2's. Figures in parentheses denote the Z-statistic from Vuong's likelihood ratio test (* significant at $\alpha \leq 0.01$).

variables are set up as competing measures to explain stock returns. Therefore, it is an empirical question to determine which variable performs better. Since the measure (either the level of earnings or the change in earnings) that has the highest association with returns can be considered as the most value-relevant one, the comparison of model 1 and model 2 R^2's is of special interest to assess the most useful variable for valuation purposes.

The results in Table 1 indicate that the level variable is more strongly correlated with stock returns than the changes one. The pooled cross-sectional and time-series models exhibit a greater R^2 for earnings level (21.4%) than that for earnings changes (12.9%). The average R^2 of the earnings level model comes to 18.5% instead of 15% for the earnings changes model. The R^2 from the earnings level model is greater than that from the earnings changes model in all but three years. Last, the annual regression coefficients are statistically significant in each of the ten years for the earnings level model and only in seven out of the ten years for the earnings changes model.

In order to formally determine whether the levels of earnings are more value-relevant than the first differences in earnings because they exhibit a stronger association with stock returns, the third column of Table 1 presents the results of a likelihood ratio test developed by Vuong (1989).[12] Vuong's Z statistic indicates which of the competing variables (earnings level or earnings changes) has relatively more explanatory power for stock returns. A positive (negative) Z statistic implies that the residuals of the earnings changes' regression are larger (smaller) than those from the earnings level one, which means that the earnings level model 1 explains more (less) of stock returns than the earnings changes model 2.

Concerning the regressions using the pooled sample of all firm-year observations, Vuong's Z statistic rejects model 2 in favour of model 1 at the 1% level. Concerning the annual cross-sectional regressions, Vuong's statistic comparing earnings level to earnings changes is not significant in all but three years. However, in these cases, the earnings changes variable is rejected in favour of the earnings level one at the 1% level in two out of the three years.[13] In accordance with Easton and Harris (1991) or Kothari (1992) in the US and contrary to Strong (1993) in the UK, these findings suggest that for France the earnings level model performs better than the earnings changes one indicating that, in compliance with the book value approach, earnings provide more information about changes in firm value than about firm value.

Differences in the return–earnings association between France and Anglo-Saxon countries

This study is not primarily aimed at comparing the return–earnings associations between US (or UK) and non-US (or non-UK) generally accepted accounting principles such as in Amir *et al*. (1993), Harris *et al*. (1994), Bandyopadhyay *et al*. (1994) or as in Chan and Seow (1996). However, since the strength of the return–earnings association (as measured by R^2's) provides insights into the value relevance of earnings, the comparison of R^2 coefficients reported in Table 1 with those generally obtained in the UK or in the US is of special interest to evaluate the ability of the French accounting system to provide relevant figures for firm valuation.[14]

One could expect the explanatory power of earnings for returns to be lower in France than in the US or in the UK for at least three reasons. First, in the UK or in the US, as in most countries influenced by the English common-law system, accounting practices traditionally rely on professional judgement. This permits discretion in the preparation of financial statements as long as they provide a 'true and fair view' of firms' position. By contrast, in France, because of the influence of the Roman codified system, accounting rules are provided by a national accounting plan defined by government-run committees. This implies a high level of standardized practices that can be in opposition with the true and fair view approach.[15] To the extent that the adoption of this approach is expected to provide more value-relevant accounting figures, the association between earnings and stock prices should be higher in the US or in the UK than in France.

Second, while the alignment of financial accounting with tax accounting is very low in the UK or in the US, the tax system has a strong influence on accounting rules and practices in France since the figures in the financial accounts form the basis for those in the tax accounts.[16] This might tend to lead firms to systematically adopt tax-minimizing reporting techniques so that earnings may not reflect economic reality, which is supposed to lower the return–earnings association.

Third, because firm financing is mainly provided by widely dispersed small shareholders in the US or in the UK, the accounting systems strongly focus on profit measures. In France, ownership being largely in the hands of family members or banks that have direct access to internal financial information and firms relying heavily on debt financing, the accounting principles mostly focus on reporting to creditors.[17] This may reduce the relevance of accounting numbers for shareholders and their association with share prices.

Contrary to expectations, earnings prepared in accordance with the French accounting principles do not appear to be less value-relevant than those of US or UK companies. R^2 values reported in Table 1 are similar or even a little higher than those observed in the US or in the UK.[18] Model 1 and model 2 pooled regressions R^2's are, respectively, 21.4% and 12.9%, the average R^2's of model 1 and model 2 are equal, respectively, to 18.5% and 15%. Recall that the model in the US Easton and Harris (1991) find pooled regressions R^2's of 7.5% for the earnings level model and 4% for the earnings changes, while in the UK Strong (1993) obtains pooled regressions R^2 values of 9% and 13% for the same models. Consequently, despite the strong influences of the legal system and of the taxation system in France, evidence suggests that the French accounting practices perform at least as well as accounting practices applied in the US or in the UK for valuation purposes.

5. THE IMPACT OF DATA AGGREGATION ON THE RETURN–EARNINGS ASSOCIATION

The weak contemporaneous return–earnings association displayed in the previous section may originate from the presence of value-irrelevant noise in earnings and from a recognition bias due to a lag between the period in which value-relevant events occur and the period in which they are integrated into earnings. If such is the case, correcting for the effects of value-irrelevant noise and recognition lag should increase the explanatory power of earnings for returns. Data aggregation is an appropriate procedure to circumvent these effects since cross-sectional aggregation should diversify value-irrelevant noise away, while temporal aggregation should increase the percentage of value-relevant events recognized in both earnings and returns.

Cross-sectional aggregation and value-irrelevant noise

Reported earnings are often viewed[19] as the sum of a value-relevant component and a noise component which is irrelevant in explaining stock returns and thus induces a measurement error in the independent variable, biasing the regression estimates. If the value-irrelevant noise is not significantly correlated across firms, while value-relevant earnings are positively cross-sectionally correlated because, for instance, of the simultaneous impact of economy-wide factors on all firms, then aggregating across firms should reduce the variance of the noise component relative to that of the value-relevant component and improve the return–earnings association.

Temporal aggregation and recognition lag

While stock prices are affected by economic events as soon as they occur because investors' future cash flows expectations are then modified, earnings recognition must await compliance with accounting recognition criteria. This often tends to delay the incorporation of major events into financial statements so that current earnings do not recognize all of the current period's economic events. Some of them will be captured only in future periods' earnings, when the conditions for accounting recognition will be satisfied. Consequently, the low contemporaneous return–earnings explanatory power generally observed might originate from a lag between the period in which value-relevant events occur and the period in which they are integrated into earnings because of accounting recognition rules. If such is the case, the return–earnings association should improve as the horizon under consideration increases since the longer the time horizon, the higher the number of economic events recognized in both earnings and returns. In other words, in as much as earnings for long periods are less subject to the effects of recognition lag, aggregating earnings and returns over long periods should increase the correlation between earnings and returns.

Regression results based on cross-sectionally aggregated data

In order to circumvent the measurement error in the earnings variable by diversifying value-irrelevant noise away, regression models 1 and 2 are tested using a portfolio aggregation procedure. Stocks in the sample are classified into portfolios including five firms each. As the sample contains 117 firms, 23 portfolios are created. Each year the highest stock return security and the lowest one are excluded from the test. Since grouping mitigates the measurement error problem only if the grouping variable is uncorrelated with the error, the sample securities are ranked according to their returns. Indeed, returns are assumed to be uncorrelated with the measurement error in earnings as rational investors are supposed to be uninfluenced by fluctuations in reported earnings due to noise.

Results based on portfolio returns for annual data are reported in Table 2. These results provide evidence of the presence of noise in earnings that causes a downward bias in the regression estimates based on individual stocks, since the aggregation procedure increases significantly earnings response estimates and leads to a real improvement in correlations compared to those not using portfolios. Concerning model 1, the average regression coefficient is 1.93 for portfolios instead of 1.37 for individual stocks. The pooled regression coefficient comes from 1.70 with individual stocks to 2.34 with portfolios. Concerning model 2, the impact of grouping on earnings coefficients is still more significant: the average and pooled regression coefficients are, respectively, 3.42 and 3.52 for portfolios instead of 0.97 and 1.21 for individual stocks.

Cross-sectional aggregation yields a serious improvement in explanatory values. Comparing the R^2's of individual stocks with those of portfolios shows a significant increase of the explanatory power of earnings for returns. The average R^2's come from 18.5% to 45.1% for model 1 which represents a 143.8% increase. It comes from 15% to 32.4% for model 2 which represents a 116% increase. The earnings level pooled regression R^2's vary from 21.4% to 26.6%, while the earnings changes time-series and cross-sectional pooled R^2's increase from 12.9% to 14.7%. These findings, supported by Vuong's statistics reported in the third column of Table 2, confirm

Table 2 Regressions of portfolio returns on earnings level and earnings changes for one-year periods

	Model 1: earnings level			*Model 2: earnings changes*			*Model 1 vs model 2*

Figures in parentheses denote the *Z*-statistic from Vuong's likelihood ratio test (* significant at $\alpha \leq 0.01$).

that for France the earnings level variable performs better than the earnings changes one for explaining stock returns.

Regression results based on time-aggregated data

In order to reduce the potential bias due to the recognition lag and to detect the impact of the time period on the explanatory power of earnings for returns, two- and five-year security returns are regressed against two- and five-year earnings levels or earnings changes, in accordance with model 1 and model 2. Long period stock returns (R_{iH}) and long period earnings (EPS_{iH})[20] are then computed as follows:

$$R_{iH} = \prod_{t=1}^{H} (1 + R_{it})^{t-1}$$

$$EPS_{iH} = \sum_{t=1}^{H} EPS_{it}$$

where $R_{it/H}$ = rate of return of firm i during year t or during period H (H is successively equal to two and five years), $EPS_{it/H}$ = earnings per share of firm i during year t or period H.

Table 3 reports a significant increase in earnings response coefficients with temporal data aggregation. The average coefficient of model 1 varies from 1.37 for one-year intervals to 1.67 for two-year intervals and to 2.51 for five-year intervals.[21] The average coefficient of model 2 increases from 0.97 to 1.56 depending on whether one-year or two-year intervals are used. As cross-sectional data aggregation, temporal aggregation does not reduce the instability of parameter estimates over time. Model 1 earnings response coefficients vary from 0.72 to 2.43 for one-year intervals, from 0.72 to 3.03 for two-year intervals and from 1.35 to 3.61 for five-year intervals. This instability is still higher for model 2 coefficients since they fluctuate between 0.27 and 1.94 for one-year intervals or between 0.67 and 2.76 for two-year intervals.

R^2 coefficients in Table 3 substantiate the hypothesis of an increase in correlations as the length of the time intervals increases. R^2's of both models are strongly affected by changing the time interval. Concerning model 1, the pooled cross-sectional and time-series regression based on five-year data yields an R^2 of 42.5% which represents a 98.6% increase in comparison with the R^2 for annual periods. This increase is also evident in the individual R^2's. They vary from 5.5% to 48.8% for one-year return periods, from 7.8% to 55.5% for two-year intervals and from 30.1% to 62% for five-year intervals. They average 43.6% for five-year periods instead of 30.4% and 18.5% for two- and one-year periods. Concerning model 2, the correlation between returns and earnings changes also improves as the return interval expands: average R^2 coefficients are, respectively, 15.1% and 27.6% for one- and two-year intervals, the pooled cross-sectional and time-series regression based on five-year data yields an R^2 of 38.6% which represents a 199.2% increase in comparison with the R^2 for annual periods.

These results support the hypothesis that annual earnings do not provide a sufficient summary measure of all value-relevant events observed by investors. Because of accounting recognition criteria, some of them will be recognized as earnings after the return period and conversely earnings will include events integrated into prices prior to the period under consideration. This suggests that the return–earnings association based on short period data might be improved by introducing additional financial variables. These variables should be selected on the basis of their ability to provide information about value-relevant events ignored by earnings.

Table 3 Regressions of individual stock returns on earnings level and earnings changes for five-year periods

	Model 1: earnings level		
Years	α_0	α_1	R^2
1981–85	81.43 (2.67)*	2.66 (7.04)*	30.1%
1982–86	167.71 (3.82)	3.61 (9.52)*	43.7%
1983–87	90.78 (2.29)	2.06 (7.84)*	34.9%
1984–88	84.31 (2.19)	2.41 (9.92)*	46.1%
1985–89	67.55 (1.83)	2.99 (13.76)*	62.1%
1986–90	17.55 (1.13)	1.35 (9.64)*	44.5%
All	82.15 (5.51)	2.56 (22.81)*	42.5%
	Model 2: earnings changes		
Years	β_0	β_1	R^2
1986–90	57.15 (4.28)	1.29 (8.54)*	38.6%

Note: *t*-statistics are provided in parentheses (* significant at $\alpha \leq 0.01$).

Regression results based on cross-sectionally and time-aggregated data

In order to correct both biases due to value-irrelevant noise in earnings and to recognition lags, the return–earnings regression models 1 and 2 are run with cross-sectionally and time-aggregated data.

Results in Table 4 are based on portfolio returns for five-year intervals. They show that temporal and cross-sectional data aggregation significantly strengthens the explanatory power of earnings for returns by diversifying value-irrelevant noise away and by reducing the lag between the period in which value-relevant events occur and the period in which they are integrated in earnings. Model 1 individual R^2's based on five-year portfolio data average 84.6% instead of 43.6% for five-year individual stock data or 18.5% for one-year individual stock data. Model 2 pooled regression R^2's increase from 12.9% for one-year individual stock data to 52.5% for five-year portfolio data. These results demonstrate that correcting both for recognition lag and for noise in earnings enhances the return–earnings association.

Table 4 Regressions of portfolio returns on earnings level and earnings changes for five-year periods

	Model 1: earnings level		
Years	α_0	α_1	R^2
1981–85	50.23 (2.33)	3.24 (11.25)*	85.7%
1982–86	175.12 (4.48)	3.61 (9.47)*	81.1%
1983–87	74.17 (4.48)	2.21 (8.91)*	78.9%
1984–88	51.2 (1.67)	2.84 (13.52)*	89.3%
1985–89	60.85 (2.17)	3.09 (15.68)*	92.1%
1986–90	−10.64 (0.58)	1.85 (9.27)*	80.3%
All	67.01 (3.94)	2.80 (19.31)*	73.0%

	Model 2: earnings changes		
Years	β_0	β_1	R^2
1986–90	55.26 (3.06)	2.59 (4.82)*	52.5%

Note: *t*-statistics are provided in parentheses (* significant at $\alpha \leq 0.01$).

6. CONCLUDING REMARKS

This paper analyses the contemporaneous association between stock returns and earnings changes or earnings level of individual French stocks and portfolios for periods of one, two and five years in order to test the ability of earnings to summarize the information which is relevant for valuation purposes (i.e. the information the market found relevant when it became available). The evidence suggests that earnings level and earnings changes are both relevant for explaining stock returns, but the level variable seems to perform better than the changes one in explaining returns, indicating that earnings are more linked with changes in firm value than with firm value.

The tests indicate that a cross-sectional data aggregation procedure yields a large increase in the explanatory power of earnings with respect to returns. This is consistent with the cross-sectionally uncorrelated noise-in-earnings hypothesis. This suggests that the weakness of the association between returns and accounting figures, usually observed in studies based on individual firms, is largely due to a noise-in-data problem probably induced by accounting measurement and valuation principles or by manipulation of reported figures. The results also support the recognition lag hypothesis since expanding the period in which the value-relevant events are recognized as earnings enhances the return–earnings association. This suggests that the return–earnings association based on yearly observations might be improved by including accounting figures other than earnings in order to take into account value-relevant events which are not recognized in the earnings of the period under consideration.

Finally, in addition to serving an aim of their own, the results reported in this paper tend to prove that the French accounting standard setting allows an association between stock returns and earnings which is similar to the one observed in most countries, in particular in the US or in the UK where most studies of this kind are frequently conducted. Accordingly, while differences exist, French accounting practices are not less efficient for valuation purposes than those prevailing in these countries.

ACKNOWLEDGEMENTS

We wish to thank Ollivier Tamarasco who gave us access to the AFFI-SBF data bank of French stock returns. We are particularly grateful to anonymous referees for their relevant suggestions. The helpful comments of Michel Albouy, Bernard Colasse, Pascal Louvet and workshop participants at ESA-Grenoble, Paris-Dauphine and the University of Dijon are gratefully acknowledged. However, all remaining errors are our own responsibility.

NOTES

1 For an analysis of association studies, see Atiase and Tse (1986) and Brennan (1991).
2 Results obtained by Ou and Penman (1989), Martikainen (1993) and Lev and Thiagarajan (1993) show that several financial statements of selected items contribute significantly to the association with security returns beyond the contribution of net earnings alone.
3 For a discussion of the book value (or clean-surplus) model see, for instance, Easton and Harris (1991), Ohlson (1991), Brennan (1991), Lyon and Schroeder (1992) and Strong (1993).
4 See for instance Atiase and Tse (1986), Collins and Kothari (1989) and Strong (1993).
5 As shown by Christie (1987), scaling accounting variables by beginning-of-period prices improves the specification of the tests.
6 Following Easton and Harris (1991), it might have been interesting to test a multivariate model including both earnings levels and earnings changes. Unfortunately, this analysis was not possible because of strong collinearity between variables: the correlation coefficients between the level variable and the changes variable vary from 43% to 77% depending on the year under consideration.
7 Collins and Kothari (1989) experimented several return intervals commencing with different months into the fiscal year. On the basis of maximizing the R^2, they showed that a fifteen-month interval beginning in August of the preceding year is optimal. However, as mentioned by Lev (1989), no theoretical or institutional reason was provided to justify this 'optimal' return interval.
8 Such deletions are very rare. They concern seventeen earnings changes (1.6% of the observations) and nine earnings levels (0.77% of the observations).
9 For instance, Easton and Harris (1991) or Strong (1993) delete observations of earnings deflated by stock prices which exceed 150% in absolute value to avoid undue influences of extreme observations. For the same reason, Collins *et al.* (1994) truncate their earnings growth variable to −200% or +200% when the growth rate exceed 200% in absolute value. Kothari and Zimmerman (1995) exclude the largest and the smallest 1% of their observations.
10 Empirical results supporting the French capital market efficiency can also be found in Dumontier (1985), Hamon and Jacquillat (1992), Hachette (1994), Mai and Tchéméni (1997).
11 The reasons for the instability of earnings coefficients are not examined here because they are beyond the scope of this paper.
12 For a discussion of Vuong's likelihood ratio test, see Dechow (1994: Appendix 2).
13 The same conclusion can be drawn from results reported in Table 2 which are based on portfolios instead of individual stocks.
14 The results obtained for France are compared to those obtained only in the US or in the UK mainly because these are the countries where most similar studies have been conducted.
15 See Most (1984) and Walton and Scheid (1987).
16 See Frylender and Pham (1996).
17 See Nobes (1991).
18 There is no reason to believe *a priori* that differences in R^2's between France and the US (or the UK) are only due to the possible survivor bias mentioned previously.
19 See for instance Beaver *et al.* (1980) or Lev (1989).

20 In order to take into account the fact that dividends may be paid during the time horizon under consideration, Easton *et al*. (1992) propose to adapt the raw return performance index and the earnings variable as follows:

$$\text{Adjusted stock performance index} = \frac{P_T - P_0 + \sum_{t=1}^{T} D_t(1 + R_t)^{T-t}}{P_0}$$

where

$$\text{Adjusted earnings variable} = \frac{\sum_{t=1}^{T} EPS_t + \sum_{t=1}^{T} D_t(R_t)^{T-t}}{P_0}$$

where

$$\sum_{t=1}^{T} D_t(1 + R_t)^{T-t}$$

is the future value of dividends reinvested at the risk-free rate R_t, P_0 is the beginning-of-period stock price, P_T is the end-of-period price. However, this procedure is not used here since Easton *et al*. show that it has no significant impact on their results.

21 Complete results for two-year intervals are not included in the paper; they can be obtained from the authors by request.

Corporate Disclosure Policy and Analyst Behavior

Mark H. Lang
University of North Carolina at Chapel Hill
Russell J. Lundholm
University of Michigan

ABSTRACT: This paper examines the relations between the disclosure practices of firms, the number of analysts following each firm and properties of the analysts' earnings forecasts. Using data from the *Report of the Financial Analysts Federation Corporate Information Committee* (FAF Report 1985–89), we provide evidence that firms with more informative disclosure policies have a larger analyst following, more accurate analyst earnings forecasts, less dispersion among individual analyst forecasts and less volatility in forecast revisions. The results enhance our understanding of the role of analysts in capital markets. Further, they suggest that potential benefits to disclosure include increased investor following, reduced estimation risk and reduced information asymmetry, each of which have been shown to reduce a firm's cost of capital in theoretical research.

Key Words: *Financial analysts, Discretionary disclosure, Analysts' forecasts, Capital markets.*

Data Availability: *The FAF data used in this study are available from the authors on request.*

I. INTRODUCTION

Financial analysts are an integral part of the capital market, providing earnings forecasts, buy/sell recommendations and other information to brokers, money managers and institutional investors. Much of the information analysts use in their evaluations is

provided directly by the firm.[1] Although all publicly traded firms must meet minimum disclosure requirements set by the SEC, firms vary substantially in the amount of additional information they provide to the capital markets. Even for mandatory disclosures, such as those found in annual financial statements, firms have substantial discretion in the informativeness of the disclosures and the amount of detail provided.[2] Discretion in disclosure is even more pronounced for press releases and direct contact with analysts. In this paper, we investigate the association between disclosure practices and the number of analysts following the firm and the properties of their forecasts. We document significant associations and interpret those associations to suggest that analysts respond to firms' disclosure practices. Our conclusions suggest that firms can attract analysts, improve the accuracy of market expectations, reduce information asymmetries and limit market surprises by adopting more forthcoming disclosure practices. Although not addressed directly by this study, theory indicates that such results may be associated with a lower cost of capital for firms adopting those strategies.

We use data from the FAF Report (1985–89) as a comprehensive measure of the informativeness of a firm's disclosure policy.[3] In the FAF report, analysts evaluate the complete range of a firm's disclosures, summarizing their evaluations by a score in each of three categories: annual published information, other published information (including quarterly filings, press releases and proxy statements) and investor relations. Our dependent variables are the number of analysts following the firm and the accuracy, dispersion and variability of their forecasts. We control for other variables that previous research has shown to be related to our variables of interest and find that, within their industry, firms with more forthcoming disclosure practices have a larger analyst following, more accurate analyst earnings forecasts, less dispersion among individual analyst forecasts and less volatility in forecast revisions. In addition, these results hold after controlling for potential simultaneity between firms' disclosure choices and analysts' following.

Overall, our results indicate that company-provided disclosure is an important determinant of analyst following and the characteristics of their forecasts. In addition, our finding that more analysts follow firms with more informative disclosure practices is consistent with the notion that firm-provided information is not a substitute for analyst services. Finding greater consensus among analysts for firms with more informative disclosure practices suggests that different analysts make different forecasts primarily because of differences in non-firm-provided information, rather than differences in interpretation of common information.

Nichols (1989) and Schipper (1991) suggest that the behavior of analysts provides insight into the activities and beliefs of investors that cannot be observed directly. To the extent that analysts may be viewed as either representing or influencing investor beliefs, our results also provide insight into the effect of disclosure on investor following and the characteristics of their

[1] Based on surveys of financial analysts, Lees (1981) finds their sources of information, in order of importance, are: (1) interviews with company executives, (2) 10-Ks and other reports to the SEC, (3) annual and interim stockholders' reports, (4) management forecasts (if disclosed), and (5) formal presentations by company executives. Knutson (1992) also argues that companies are a primary source of information for analysts and identifies various communication channels.

[2] As an example, firms have discretion in the number of segments they report, how they aggregate operations into segments and whether they include segmental data in quarterly reports.

[3] We use the term "disclosure policy" to refer to the overall informativeness of a firm's discretionary disclosures, as measured by their score in the FAF Report. The FAF Report (1985–89) measures "the firm's effectiveness in communicating with investors" and the extent to which the firm provides information "so that investors have the information necessary to make informed judgments" across all types of disclosure. Section IV contains a more complete discussion of the data.

beliefs.[4] The effects of enhanced disclosures are of interest to accounting professionals who are involved in preparing and attesting to firm-provided disclosures, corporate managers and regulators. Benefits described by the AICPA Special Committee on Financial Reporting (AICPA 1993), and echoed by investor relations authors Marcus and Wallace (1991) and Mahoney (1991), include reduced uncertainty, lower information asymmetry among stock market participants, fewer extreme earnings surprises and greater investor following. Theoretical research echoes similar benefits to disclosure, including increased investor following (Merton 1987), reduced estimation risk (Barry and Brown 1985), and reduced information asymmetry (Glosten and Milgrom 1985), each of which reduces the cost of capital. Our results suggest that increased disclosure is associated with increases in analyst following and forecast accuracy, reductions in forecast revision volatility and dispersion and which hence, may reduce the cost of capital.

In the next section we discuss the related literature, and in section III we present our hypotheses. In section IV, we present the data and empirical analysis and, in section V, summarize our results and conclusions.

II. RELATED LITERATURE

Our research is related to two streams of the extant literature: (1) research on determinants of analyst following, and (2) research on the determinants of forecast accuracy and dispersion. Most of the empirical research on the determinants of analyst following focuses on firm characteristics other than disclosure policy. In a cross-sectional study, Bhushan (1989) finds that the number of analysts following a firm is increasing in firm size, institutional ownership, and return variability. In a time-series study, O'Brien and Bhushan (1990) find that analyst following increases when a firm's return volatility has declined, increases more for firms with smaller prior analyst following, and increases more for firms in industries with more stringent disclosure requirements and increasing numbers of firms. Brennan and Hughes (1991) find that analyst following is greater for firms with lower share prices after controlling for size, return variability and past returns, and that the number of analysts increases after a stock split. Perhaps closest to our study, Byrd et al. (1993) document a short-term increase in analyst following after CEO presentations to analyst societies and Healy et al. (1994) find that firms in the top quintile of FAF ratings' changes over a 12-year period experience a significant increase in their analyst following, although the firms in the bottom quintile of ratings' changes do not experience a significant decrease in their analyst following. Healy et al. (1994) also find that the firms in the top quintile of FAF ratings' increases are more likely to experience management changes, undertake major business restructurings, access capital markets, repurchase stock and announce stock splits, making it difficult to attribute the increase in analysts solely to the increase in disclosure.

Although there is substantial literature on the properties of analyst forecasts (see Brown et al. 1985 and Brown 1993 for reviews), relatively few papers consider how discretionary disclosure affects analysts' forecasts. Baginski and Hassell (1990) and Jennings (1987) provide evidence that analysts revise their forecasts in response to management earnings forecasts, and Williams (1996) suggests that the magnitude of the adjustment is a function of the usefulness of

---

[4] Survey evidence in SRI International (1987) suggests that analyst reports are a primary source of information to buy-side investors, and Marcus and Wallace (1991) argue that analysts are an important source of information for individual investors, either directly or through brokers. This view underlies the use of analyst expectations as a proxy for investor expectations in a large body of capital markets research (see Brown (1993) for an overview).

managements' previous forecasts. Similarly, Waymire (1986) finds that the accuracy of analyst earnings forecasts increases slightly after a management earnings forecast is released. While management earnings forecasts have the advantage of being concrete disclosure events, the FAF data represent a more comprehensive measure of firm disclosure by incorporating important aspects of disclosure which are difficult to quantify (e.g., new product announcements, management discussion and analysis, qualitative discussions with management) and reflect the perceptions of some of the primary users of financial statement data.[5] As an alternative to management earnings forecasts, Kross et al. (1990) use inches of print in the *Wall Street Journal Index* to test whether the accuracy of analyst forecasts increases as the amount of media coverage increases. However, media coverage captures the impact of exogenous events and editorial policy as well as the effect of disclosure policy.[6]

III. HYPOTHESES

We focus on two aspects of analysts' behavior—their choice of which firms to follow as measured by the number of analysts providing earnings forecasts for a firm, and characteristics of their earnings forecasts as measured by the forecast accuracy, the degree of dispersion among forecasts and the variability of forecast revisions during the year.[7]

Disclosure and Analyst Following

In Bhushan (1989), the equilibrium number of analysts is determined by the intersection of the aggregate demand and supply curves for analyst services. The model describes how various firm characteristics affect the intersection of these curves and, consequently, the equilibrium supply of analysts. Applied to our study, the issue is how firm-provided information affects the supply and demand for analyst services.

If it is less costly to receive information from the firm than to acquire it independently from other sources, increased disclosure will shift the analyst supply curve to the right, increasing aggregate supply. All else equal, this effect increases the equilibrium number of analysts.[8] The effect of additional disclosure on the demand for analyst services depends on the role that analysts play in the capital market. If analysts are primarily *information intermediaries*—the principle flow of information goes from the firm to the analysts, who process the information and transmit

[5] It is not clear whether management earnings forecasts are representative of other types of disclosure. The *ex post* accuracy of earnings forecasts is publicly validated or refuted in relatively short order while the validity of other types of disclosure is not as easily assessed. As a result, managers perceive more legal risk associated with earnings forecasts than with other types of disclosure (Lees 1981). Skinner (1994) suggests that concern about potential litigation creates incentives to issue earnings forecasts preempting bad earnings news; however, incentives for "softer" disclosure which is not validated as quickly or precisely are not as clear.

[6] In terms of mandatory disclosures, Brown and Han (1992) find that the consensus of analyst long-range forecasts increases around earnings announcements, and Swaminathan (1991) finds that consensus increases following the adoption of segmental reporting requirements. Baldwin (1984) finds that analysts' forecast accuracy increases for multisegment firms after the adoption of segmental reporting requirements. Brown and Rozeff (1979) find that analyst forecasts of annual earnings become more accurate following interim accounting reports, and Critchfield et al. (1978) find that forecast accuracy increases through the fiscal year but the dispersion among analysts' forecasts remains unchanged. Finally, Brown et al. (1987) show that forecast accuracy (relative to a random walk) is positively associated with firm size and negatively associated with the dispersion of analyst forecasts.

[7] By focusing on earnings forecasts, we ignore other functions of analysts such as issuing buy/sell recommendations and generating trades. It is unclear how analysts weight these different activities, but we assume that the choice of which firms to cover and what to forecast for earnings is a significant part of their job.

[8] In an investor relations context, Nichols (1989) describes how a lack of disclosure leads to a low supply of analyst services. He quotes Robert Dunlap of Irving Trust, "I don't follow Pullman because they won't tell you enough about their business to allow you to get a handle on it.... If they change and become more open with the street, there is no doubt that I'd take more of an interest in Pullman."

it to the capital market—then an increase in firm-provided information means the analyst has a more valuable report to sell. In this case, increased disclosure increases aggregate demand for analyst services. This effect in isolation will increase the equilibrium number of analysts.[9] Consistent with this prediction, the analyst community has consistently come out in favor of increased firm-provided disclosure.[10]

However, if analysts are primarily *information providers* who compete with firm-provided disclosures made directly to investors, then an increase in firm-provided information will substitute for the analyst report. In this case, increased disclosure reduces the aggregate demand for analyst services. This effect in isolation will decrease the equilibrium number of analysts.

In sum, increased firm-provided disclosure is expected to increase the supply of analyst services, but it may either increase or decrease the demand for analysts, so the net effect depends on the relative importance of these potentially competing forces. An observed negative relation between disclosure levels and the number of analysts implies that analysts are primarily information providers, and firm-provided disclosure is a substitute for their services.[11] An observed positive relation implies that either analysts are primarily information intermediaries or else, if they are information providers, the effect of reduced information production costs outweighs the effect of reduced demand.

Since the direction of the effect of disclosure on analyst following is unclear, we test the following non-directional hypothesis (stated in the null form):

H1: The number of analysts following a firm is unrelated to the informativeness of the firm's disclosure policy.

The direction of causality between a firm's disclosure level and the number of analysts is debatable. Specifically, an observed positive relation could reflect either the fact that analysts are attracted to firms which disclose more or that analysts are able to apply pressure on firms which they follow for other reasons to increase their disclosure levels. Evidence presented in Section IV suggests that the direction of causality runs from disclosure policy to analyst following.

Disclosure Policy and Forecast Characteristics

In addition to affecting the number of analysts following the firm, additional disclosure is likely to affect the properties of analysts' earnings forecasts. We consider three characteristics—forecast dispersion, accuracy and volatility.

Dispersion

The effect of increased disclosure on the dispersion of analyst forecasts depends on whether differences in forecasts are due to differences in information or differences in forecasting models. If analysts have a common forecasting model and observe the same firm-provided disclosures but possess different private information, they will place less weight on their private information as the informativeness of firm-provided disclosure increases, increasing the consensus among their forecasts. Alternatively, if analysts have the same firm-provided and private information but

[9] Fishman and Hagerty (1989) and Merton (1987) make similar predictions for investor following. In these models, investors can only follow a limited number of firms and prefer to follow firms that provide the most valuable information.

[10] Knutson (1992) and AICPA (1993), for example, discuss analysts' positions on increased disclosure.

[11] To the extent that firms have an incentive to increase analyst following (as they would in Merton (1987) and Fishman and Hagerty (1989)), it may seem unlikely that they would engage in discretionary disclosure that reduces analyst following. However, as discussed in the introduction, other incentives for disclosure exist (e.g., reductions in information asymmetry, risk, earnings surprises, etc.) which would be balanced in determining disclosure policy.

differ in the weights they place on components of firm-provided disclosure in forecasting earnings, additional disclosure may increase the dispersion of analyst forecasts.[12]

Therefore, an observed negative relation between disclosure and forecast dispersion implies that analysts differ primarily in their private information. Observing a positive association implies that analysts have different forecasting models, so they draw different conclusions from the same observed disclosures and, as the disclosures become more precise, their forecasts become more dispersed. Since the direction of the effect of disclosure on dispersion in analyst forecasts is unclear, we test the following non-directional hypothesis (stated in the null form):

H2: The dispersion of analysts' earnings forecasts is unrelated to the informativeness of a firm's disclosure policy.

Accuracy

The likely relation between disclosure and forecast accuracy is more clear. To the extent that firm-provided disclosure is informative about future earnings, analysts' forecast accuracy will increase with the informativeness of a firm's disclosure policy. Although a firm's disclosures may be useful to analysts without providing information about next period's earnings, it is difficult to imagine scenarios (short of fraudulently misleading disclosures) in which additional disclosure systematically reduces the accuracy of analysts' earnings forecasts. However, the strength of the relation between firm-provided disclosures and the accuracy of analysts' forecasts is an empirical issue. This leads to the following hypothesis:

H3: The accuracy of analysts' earnings forecasts is positively associated with the informativeness of a firm's disclosure policy.

Revision Volatility

The volatility of forecast revisions in the time period leading up to an earnings announcement is likely to be reduced by a more forthcoming disclosure policy. In assessing the informativeness of a firm's disclosure practice, the FAF considers the timeliness of information releases and firms that disclose information on an ongoing basis are judged to have more informative disclosure practices than those that withhold information until a mandatory disclosure is required. Over time, events occur with implications for the firm's future earnings. The firm has the option of disclosing them as they occur (with analyst revisions made after each announcement) or waiting and disclosing them all at once (with only one analyst revision). The latter will result in more extreme expectation revisions when the information is disclosed. The notion that more timely disclosure may be valuable in reducing the magnitude of forecast revisions is consistent with Mahoney (1991) who argues that disclosure is beneficial, in part, because it reduces the incidence of significant surprises for investors and analysts.[13] Our fourth hypothesis (stated in alternate form) is:

H4: The volatility of analyst earnings forecast revisions is negatively associated with a firm's disclosure policy.

---

[12]Harris and Raviv (1993) and Kandel and Pearson (1995) present models in which investors differ in their interpretation of publicly-disclosed data, and in which additional disclosure can result in divergence of beliefs.

[13]Mahoney (1991) states that "surprises are anathema to analysts and investors, and thus to investor relations practitioners as well. They are to be avoided. How? By keeping analysts and investors informed..."

IV. EMPIRICAL ANALYSIS

Disclosure Data

The informativeness of firms' disclosures is measured by FAF ratings. The analysis in the FAF Report (1985–89) is conducted by industry-specific subcommittees composed of leading analysts and contains evaluations of the informativeness of a firm's disclosures along three dimensions: annual published information, quarterly and other published information, and investor relations and related aspects.[14] The assessment factors include both the content of a firm's disclosure and its timeliness. Briefly, in the "Annual Published Information" category, analysts assess the clarity and candor of the financial highlights and president's letter, the amount of detail about the corporate officers, the corporation's goals and product and geographic segments, and the overall level of detail in the financial statements and footnotes. In the "Quarterly and Other Published Information" category, analysts consider the depth of coverage in quarterly reports and the availability and timeliness of other written material, such as press releases, proxy statements, summaries of the annual meeting proceedings and presentations to analyst groups, and statistical supplements. In the "Investor Relations" category, analysts assess how knowledgeable and responsive the company contact is to analyst questions, the accessibility of management and their candor in discussing corporate developments, and the frequency and content of presentations to analysts.

The industry subcommittees meet first to agree on the firms to be reviewed and the criteria and weights to be applied in evaluating companies in the industry. The larger firms in the industry are generally reviewed, and the set remains relatively constant over time. Individual committee members later complete evaluations of each firm, which are returned to the subcommittee chairperson. The subcommittees generally meet a second time to summarize the scores, prepare a written explanation and decide whether to recommend any companies for an "Award for Excellence in Corporate Reporting." Each subcommittee report is reviewed by the Corporate Information Committee for consistency and fairness, and a final report is prepared containing a detailed evaluation of each firm. The evaluation assigns a score in each category and a total company score which is a weighted combination of the three category scores. The report is mailed to all the firms surveyed, the FASB, the SEC and other interested parties. In many cases, the subcommittee meets individually with company representatives to discuss the results.[15] A typical year's report covers 460 firms in 27 industries, with an average of 13 analysts in each industry providing the evaluations.

Our primary sample of FAF ratings is taken from the 1985–89 FAF reports. For the investor relations, other publications and total score categories, we use these data as our measure of disclosure that took place during the company's fiscal year. However, the annual report is not

[14]A comparison of the analysts included on the subcommittees with those selected for the *Institutional Investor* All-American Research Team (1988) suggests a substantial overlap. For example, in 1988, 3 of the 5 airline subcommittee analysts and 10 of the 18 chemical subcommittee analysts were members of the 1988 All-American Research Team. In discussions with analysts, a primary motive for serving on a subcommittee is visibility and an indication of status in the analyst community.

[15]The stated goal of the evaluation process is to measure the forthcomingness and effectiveness of communicating with investors. The FAF's "Checklist of Criteria for Evaluating Financial Communications Effort" emphasizes that the evaluation is based on communication with both analysts and shareholders. However, since the evaluation is conducted by analysts (although both the buy and sell sides are included), the criteria may reflect the effectiveness in communicating with analysts more than with investors. Given that our dependent variables are based on analyst followings and characteristics of their forecasts, a disclosure measure which focuses on the ability of disclosure to satisfy analysts' needs is appropriate.

released until after the company's fiscal year end, so for this disclosure category we use the FAF annual report ratings from 1984–1988, matching the analyst dependent variables for a fiscal year to the lagged disclosure data.[16] Descriptive statistics on the disclosure data are based on 1985–1989.

The FAF data represent a cross-section of industries, including service, manufacturing, financial, transportation and extraction.[17] Because approximately nineteen percent of the industry subcommittees (covering 38 percent of the firms) report only the overall company scores, the composition of the sample varies depending on whether the total score or individual category scores are used.[18] Re-estimating the results for the total score variable including only those industries with complete data on each of the disclosure components yields similar conclusions to those reported.

Although disclosure policy is likely to be correlated across the three categories, we include each separately, as well as the total score, because firms may vary in their choice of disclosure media and because the effect of disclosure policy may vary by the media employed.[19] For example, because much of the disclosure included in the investor relations category is targeted specifically at analysts, this category may have the most influence on the willingness of analysts to follow the firm but, to the extent that periodic press releases are important sources of information on material developments for the firm, the other publications category may be a more important determinant of forecast accuracy.

The FAF data contain a potential sample of 751 firms (732 with COMPUSTAT data) that are rated in at least one of the five FAF reports during 1985–1989. In total, there are 2272 firm-years in the sample, with each firm evaluated approximately three times in the five year period. Panel A of table 1 provides descriptive statistics for the three category scores and the total company score as a percentage of total available points. As seen in the table, each category has considerable variation; the difference between the 1st and 99th percentiles is highest for the investor relations variable (75 percent) and lowest for the annual report variable (58 percent), which may suggest that firms can more clearly differentiate their investor relations efforts than their annual report disclosures, perhaps because annual reports are more closely regulated.

A primary advantage of the FAF data is that the scores capture all aspects of disclosure which are viewed as important by analysts rather than focusing on a single aspect, such as the existence of a management earnings forecast. Further, the scores quantify qualitative disclosure (e.g., management's discussion and analysis) and disclosure which may not have been reflected in published financial statements or the media (e.g., conference calls to analysts). In addition, the measures are prepared by analysts who are primary users of financial statements, are familiar with the firms' disclosures through their use of them during the year and invest substantial time and effort in preparing the FAF reports.

A potential problem with the FAF data is that the scores reflect analysts' perceptions of firms' disclosure policies rather than the disclosure policies themselves. However, the FAF is clearly aware of this possibility and the FAF's evaluation process is specifically designed to enhance the objectivity of the evaluations in several ways. First, only summary measures for a subcommittee

[16] For example, we use the 1988 FAF annual report score and 1989 FAF investor relations, other publications and total scores as explanatory variables for 1989 analyst following and forecast characteristics.

[17] See table 1 in Lang and Lundholm (1993) for a summary of industries.

[18] Most prominently, the banking industry provides 20 percent of the total score observations, but this industry subcommittee does not report individual category scores. As a result, the banking industry affects the analysis of total scores, but not the individual disclosure categories.

[19] Marcus and Wallace (1991) and Mahoney (1991) discuss the relative advantages and disadvantages of various disclosure media.

TABLE 1
Descriptive Statistics for the Raw FAF Disclosure Scores, Analyst Dependent Variables and Control Variables

Panel A: Disclosure Variables

			percentile				
Variable	*n*	*mean*	*1%*	*25%*	*50%*	*75%*	*99%*
Annual Report	1324	.73	.37	.64	.75	.83	.95

Investor Relations	1392	.74	.25	.64	.77	.87	1.00
Total Score	2272	.70	.32	.62	.72	.80	.95

Panel B: Dependent Variables

			percentile				
Variable	*n*	*mean*	*1%*	*25%*	*50%*	*75%*	*99%*
Number of Analysts	2175	17.6	2.4	9.9	16.7	24.3	39.8
Standard Deviation of Forecasts	2141	.014	.001	.003	.005	.010	.150
Accuracy	2164	–.042	–.619	–.025	–.008	–.003	.000
Revision Volatility	2211	.010	.000	.001	.002	.005	.137

Panel C: Control Variables

			percentile				
Variable	*n*	*mean*	*1%*	*25%*	*50%*	*75%*	*99%*
Market Value ($ millions)	2215	2438	33	433	1072	2538	20794
Std(Return on Equity)	2022	.021	.001	.005	.015	.028	.111
Return-Earnings Correlation	1952	.316	–.590	.090	.360	.590	.895
Earnings Surprise	2166	.076	.000	.009	.019	.044	.842
Percentage New Forecasts	2169	.267	.102	.208	.263	.318	.457

The four disclosure variables are the analysts' ratings of disclosure from the FAF report measured as the percent of possible points received in each category. The dependent variables, percentage of new forecasts and earnings surprise are all calculated from the IBES Summary Tape. Other control variables are from COMPUSTAT. In total there are 751 firms with at least one year of FAF data during the years 1985 through 1989.

are presented, thereby reducing the opportunity for individual analysts to curry management's favor by providing a more positive evaluation than is warranted. Second, a primary motive for having subcommittee members meet both before and after the evaluation process is to reduce subjectivity and ensure that all members use the same basic criteria in their evaluations. Further, because each subcommittee report includes a written justification of each firm's score, and the report is frequently presented to the firm orally, subcommittee members cannot capriciously make their evaluations. Finally, the Corporate Information Committee's review of the subcommittee reports helps ensure fairness and consistency.

Because each industry is evaluated by a different set of analysts, we industry-adjust the dependent and independent variables. Therefore, the tests explain intra-industry variation in the number of analysts and their forecast properties by the intra-industry variation in the disclosure and control variables. This approach controls for potential cross-industry variation in scores due to differences in subcommittee composition, but ignores cross-industry variation in scores due to legitimate differences in disclosure policy across industries. The results for measures that are not industry-adjusted are consistent with those reported in the paper.[20]

Dependent Variables

All analyst data are taken from the IBES Summary Tape. The four dependent variables we consider are:

Number of Analysts	=	the number of analysts providing an annual earnings forecast;
Std. Dev. of Forecasts	=	the inter-analyst standard deviation of forecasts deflated by stock price;
Forecast Accuracy	=	the negative of the absolute value of the analyst forecast error, deflated by stock price (i.e., $-(\lvert EPS_t - AF_t \rvert)/P_t$, where EPS_t, AF_t and P_t are earnings per share, the median analyst forecast of earning per share and price per share in period t, respectively); and
Revision Volatility	=	the standard deviation of the changes over the fiscal year in the median forecast from the preceding month, deflated by the stock price as of the beginning of the fiscal year.

We deflate the forecast measures by the stock price to facilitate comparisons across firms. We define forecast accuracy as the negative of the (scaled) absolute forecast error so that more accurate forecasts are represented by higher values. The revision volatility measures the smoothness with which analysts' expectations change during the period.[21]

We are interested in assessing the impact of disclosure generally, rather than at a particular announcement date. Further, there is no single time during the year when one would expect investor relations or other publication disclosures to have the most significant effect on analysts. Even though the annual report is issued at a single point in time, it is difficult to identify the date

[20]A related concern is that the individual analysts in a subcommittee may vary across years so that scores may not be strictly comparable across years. The FAF formalizes the evaluation process in part to mitigate such variation. To the extent that it remains, it will add noise to the disclosure variables. Results are consistent when estimated on a year-by-year basis, suggesting that variation in committee composition over time is not of serious concern.

[21]Disclosure policies might also affect the bias in analyst forecasts. For example, analysts might bias earnings forecasts to reward firms who were particularly forthcoming. However, Lang and Lundholm (1993) provide evidence that positive forecast errors are associated with more disclosure. Although this result could imply that analysts bias their forecasts downward for firms who disclose more, a more likely explanation is that firms are more willing to report good news than bad news.

on which the annual report information reaches the market, and the informativeness of the annual report will influence the forecast accuracy and other variables over the entire year. Consequently, the number of analysts, the standard deviation of forecasts and the forecast accuracy are computed as the simple average of the measure across the twelve monthly reporting periods on the IBES tape during the company's fiscal year. Revision volatility is computed as the standard deviation of forecast changes over the twelve months of the fiscal year. Each dependent variable is based on forecasts of annual earnings made during the fiscal year to which the forecasts pertain.[22] As a practical matter, results are robust to changes in the period over which the dependent variables are measured and are very similar using measures computed based on data for a single month computed at fiscal year-end or at six months prior to fiscal year-end.

Panel B of table 1 reports descriptive statistics on the dependent variables. The median firm-year in the sample is followed by 16.7 analysts, has a standard deviation of forecasts equal to 0.5% of its share price, has an analyst forecast error that is 0.8% of its share price and a standard deviation of forecast revisions equal to 0.2% of its share price. Each variable also exhibits considerable variation across the sample, as evidenced by the inter-quartile ranges.

Control Variables

The hypothesized relations between disclosure and the analyst variables are based on the assumption that other variables are held constant. In practice, however, other factors are likely to vary systematically with both the dependent variables and disclosure scores, creating the possibility of an omitted/correlated variable problem. For example, firm size has been shown to be related to both the number of analysts and a firm's FAF disclosure score. If we did not control for firm size in the regression, a significant relation between the number of analysts and disclosure could be observed even if size were the true explanatory variable. Therefore, in addition to simple correlations, we also estimate multiple regressions including five control variables which prior research suggests may affect analyst following and forecast properties, and may be correlated with the variables of interest.

For the analyst-following regression, we include firm size, the standard deviation of return on equity and the historical returns-earnings correlation as control variables. Bhushan (1989) and Brennan and Hughes (1991) provide empirical evidence of a positive association between the number of analysts following a firm and both firm size and performance variability. Waymire (1986) and Lang and Lundholm (1993) suggest that firm size and performance variability are also likely to be correlated with disclosure policy. King et al. (1990) argue that analyst following is likely to be positively associated with returns-earnings correlation because it is easier to predict future stock price based on earnings forecasts for those firms. Lang and Lundholm (1993) document a negative correlation between the level of return-earnings correlation and the firm's disclosure level, with the interpretation that a low returns-earnings correlation indicates that earnings does a relatively poor job of capturing valuation-relevant information, so additional forms of disclosure are necessary.

[22] For example, the number of analysts following a December 31 year-end firm for the 1985 observation is computed as the sum of the number of analysts providing forecasts of 1985 annual earnings at the IBES reporting date for each of the months January through December 1985, divided by 12. As a result, forecasts of 1985 earnings made prior to the announcement of 1984 results may not be strictly comparable with those made later in the year because, for example, some analysts may only begin forecasting 1985 earnings when 1984 results are known. However, the predicted relation between disclosure and analyst behavior holds regardless of whether the forecast variables are measured before or after 1984 results are announced.

The control variables for the number-of-analysts regressions, computed from COMPUSTAT, are:

Market Value	=	the market value of the firm's equity at the beginning of the fiscal year;
Std. Dev. of ROE	=	the historical standard deviation of return on equity computed over the preceding ten years; and
Return-Earnings Correlation	=	the historical correlation between annual returns and earnings computed over the preceding ten years.

We also include the preceding control variables in the regressions examining the forecast dispersion, accuracy and revision volatility. Firm size, returns-earnings correlation and standard deviation of ROE are likely to affect forecast characteristics because, as argued above, they affect analysts' incentives to gather information about the firm and, consequently, are likely to affect their forecast characteristics.[23]

In addition to the control variables listed above, we include additional control variables, earnings surprise and the percent of new forecasts, in our forecast characteristic regressions. The earnings surprise, measured as the random walk forecast error deflated by price, controls for the fact that forecast characteristics are likely to be affected by the magnitude of the earnings information to be disclosed. Consider a firm's introduction of a major new product. Realized earnings are likely to deviate substantially from expected earnings, consensus among analysts is likely to be low, and there are likely to be significant revisions in analyst forecasts. Inclusion of a measure of earnings surprise as an independent variable should control for such factors.

The percentage of new forecasts mitigates the possible effect of stale IBES forecasts. Analyst forecasts which were not updated in a given month are still included in IBES's computation of summary statistics on analyst forecasts, and it is not possible to determine whether the forecast was not revised because it still reflected the analyst's best estimate or because the analyst opted to not reestimate earnings. As a partial control for cross-sectional differences in the staleness of forecasts, we include the average monthly percentage of new forecasts for the year. Controlling for the percentage of new forecasts should reduce any systematic variation across observations in the IBES forecast characteristics which is due solely to differences in the proportion of recently revised forecasts.[24]

We define earnings surprise and percent new forecasts as follows:

Earnings Surprise	=	the absolute value of the difference between the current year's earnings per share and last year's earnings per share, divided by the price at the beginning of the fiscal year; and
Percent New Forecasts	=	the number of forecasts revised during the month plus the number of first-time forecasts issued during the month divided by the number of forecasts at the month-end, averaged over the twelve months in the firm's fiscal year.

[23]We also performed three specification checks for alternative control variables in the number-of-analysts regressions. First, we included the number of institutional investors and the percent of shares outstanding held by institutions in 1987, reflecting Bhushan's (1989) evidence that analyst following is increasing in institutional ownership. Second, we included the firm's share price, based on Brennan and Hughes' (1991) result that the number of analysts is higher for firms with lower share prices. Finally, we included the other three dependent variables as independent variables in each regression. The results are not sensitive to any of these variations.

[24]We have also conducted the analysis for the quartile of observations with the highest percentage of new forecasts (where staleness should be less of an issue) and find consistent results. However, the possibility of stale forecasts cannot be dismissed entirely.

Panel C of table 1 presents descriptive statistics on the control variables. The sample firms are generally large, as indicated by a median firm-year market value in excess of $1 billion; however, market value ranges from $33 million in the 1st percentile to over $20 billion in the 99th percentile.[25] For the median firm-year, the standard deviation of return on equity is 1.5%, the earnings/returns correlation is 36.0%, the absolute value of the change in earnings per share from the previous year is 1.9% of the share price, and 26.3% of the forecasts are new each month.

Simple Correlations

Because we do not predict a particular functional form for the relation between the dependent and independent variables, we base our analysis on ranked data. We rank the dependent and independent variables within their industry-year and convert the ranks to percentiles: (rank – 1)/(number of firms – 1). The conversion yields the percentile of the firm's rank within its industry-year, so the lowest-ranking firm receives a zero and the highest-ranking firm receives a one.

Table 2 presents correlations between pairs of independent variables after they have been converted into percentiles. As one would expect if firms coordinate disclosure policy across media, the three disclosure categories are positively correlated at levels ranging from 0.46 to 0.83. Disclosure categories have correlations that are considerably less than one, suggesting that different categories may capture different aspects of disclosure. The correlations among the control variables are relatively low, ranging from 0.28 to –0.25, as are the correlations between the disclosure variables and the control variables, suggesting that multicollinearity among disclosure and control variables is not likely to be a significant issue in the multiple regressions. As reported in Lang and Lundholm (1993), firms with higher disclosure scores are generally characterized by larger market values, lower standard deviations of past return on equity, and lower past return/earnings correlations. Further, higher disclosure scores are associated with a larger proportion of forecast revisions, suggesting that a more forthcoming disclosure policy is associated with more frequent forecast revisions.

Table 3 presents simple correlations between pairs of analyst variables, and between pairs of analyst variables and independent variables. Panel A displays the associations of primary interest in this study, the relations among analyst following and forecast characteristics and the disclosure variables. The associations are consistent across all three disclosure categories, with correlations significant at the 0.01 level. The number of analysts is positively correlated with the informativeness of a firm's disclosure practices, and firms with more informative disclosure practices have less dispersion in analyst forecasts, the forecasts are more accurate, and there is less volatility in the sequence of forecast revisions.

Table 3, panel B reports the correlations between the analyst variables and the control variables. The number of analysts is most closely associated with market value (0.70). The standard deviation of forecasts and the revision volatility are both highly positively correlated with the earnings surprise and the standard deviation of past return on equity suggesting that, for firm-years with high past and present uncertainty, there is more dispersion and volatility in analysts' forecasts. Similarly, forecast accuracy is negatively correlated with earnings surprise, suggesting that analysts are less accurate when there has been a significant change from last period's earnings.

[25]Because the sample firms are large on average, care should be taken in generalizing the results to other populations. Marcus and Wallace (1991) and Mahoney (1991) suggest that, because of the competition for analyst attention and limited alternate sources of information, disclosure policy is likely to have a greater impact for small firms than for large firms.

Revision Volatility	–.197	.764	–.670	
	.0001	.0001	.0001	

All variables are computed by ranking the unranked variables in table 1 within their industry-year and converting the ranks to percentiles: (rank – 1)/(number of firms – 1). Listed below each correlation is the p value. The number of observations ranges from 1047 to 2125.

Table 3, panel C reports the correlations between the dependent variables. The highest correlation is between forecast revision volatility and standard deviation of forecasts (0.76) suggesting that forecast revisions tend to be more volatile in cases in which there is less consensus among analysts. Forecast accuracy is positively correlated with the number of analysts, possibly because the median forecast becomes a more accurate estimator as the number of observations increases.

Given the relatively high correlations among the analyst following and forecast characteristic variables, the control variables and the disclosure variables noted above, inference drawn from the simple correlations may be misleading. Specifically, our interest is in the marginal effect of disclosure on analyst following and forecast characteristics. In the next section, we assess the marginal effect of disclosure holding other variables constant.

Regression Results

Table 4 reports the results of regressions of the number of analysts on the control and disclosure variables.[26] With respect to H1, results for the total score category indicate a significant relation between disclosure policy and analyst following, suggesting that analyst following is a function of disclosure policy.[27]

To test whether each category has explanatory power incremental to that in the other categories, we estimate the regression including all three categories together. The collinearity among the disclosure variables discussed earlier can result in inflated sampling variances and unstable coefficient estimates. Nevertheless, when all three components of disclosure are included, coefficients on both the other publications and investor relations categories are significantly positive, while the coefficient on the annual report variable is insignificant.[28] The significant positive coefficients for the investor relations and other publications variables are consistent with Lees' (1981) survey finding that analysts rely heavily on direct contact with firms and with the notion that, although the securities laws prohibit disclosure of material nonpublic information to selective subsets of the analyst population, a firm's willingness to communicate with analysts is an important factor in their willingness to follow a firm.[29] The significant result when the annual report variable is included separately and the correlations across disclosure categories suggest that increased disclosure in the annual report is part of an overall disclosure strategy that increases analyst following. However, the fact that annual report loses significance when all three categories are included indicates that the other disclosure variables capture the

[26]Iman and Conover (1979) provide a discussion of rank regression. This ranking mechanism produces larger differences between percentiles for small industries than for large industries. For example, in an industry with only two firms, one will have a disclosure score of 1.0 and the other of 0.0 where, if those firms were in an industry with many firms, their values would probably be less extreme. As a result, observations in industries with fewer firms will tend to have slightly higher variances. We have re-estimated the regressions with unranked data and with data ranked across all firms (not adjusted for industry) with similar results to those reported in the paper, suggesting that this effect does not affect our conclusions.

[27]Significance levels should be interpreted with caution because some firms are included in the analysis for consecutive years, which may induce auto-correlation in the residuals. We have conducted specification checks which take first order auto-correlation into account with very similar results. As a more extreme check, we also conducted the analysis using only one observation per firm with very similar results. A firm appears in our sample on average three times, so at most the number of independent observations is overstated by a factor of three, causing the t-statistics to be overstated by at most a factor equal to the square root of 3. Unless otherwise stated, we refer to a result as "significant" if the p-value for a two-tailed test is less than 0.01.

[28]Collinearity between disclosure categories is an issue in all of the sets of regressions which follow. In every case, each disclosure category is statistically significant with a consistent sign in explaining forecast characteristics when included alone, but generally one or more are not significant when the other categories of disclosure are included.

[29]The fact that the coefficient on the total score is higher than that on any of the components reflects the fact that the relation tends to be stronger for the industries for which the subcommittees did not provide scores for the individual disclosure categories (principally banking).

TABLE 4
Regression of the Number of Analysts Following the Firm on Disclosure Scores and Control Variables

$$\textit{Number of Analysts} = \alpha + \beta_1 \textit{Annual Report} + \beta_2 \textit{Other Publications} + \beta_3 \textit{Investor Relations} + \beta_4 \textit{Total Score} + \beta_5 \textit{Market Value} + \beta_6 \textit{Standard Deviation of ROE} + \beta_7 \textit{Return-Earnings Correlation} + \varepsilon$$

α	β_1	β_2	β_3	β_4	β_5	β_6	β_7	N	R^2
0.11				0.17	0.66	–0.01	–0.02	1868	0.52
(6.2)				(10.1)	(38.6)	(–0.8)	(–1.5)		
0.17	0.02	0.07	0.10		0.59	–0.05	–0.06	998	0.45
(6.1)	(0.8)	(2.3)	(3.5)		(23.0)	(–1.8)	(–2.7)		

Regressions are estimated using ordinary least squares, with all variables ranked and then computed as percentiles within the industry-year. T-statistics are noted in parentheses below each coefficient estimate. Annual Report, Other Publications, Investor Relations and Total Score are the annual report, other publications, investor relations and total score, respectively, based on the FAF scores for each category of disclosure. Number of Analysts is the average number of analysts on IBES providing an estimate of annual earnings over the 12 months of the company's fiscal year. Market Value is the market value of outstanding equity at the beginning of the fiscal year. Standard Deviation of ROE is standard deviation of net income divided by shareholders' equity and Returns-Earnings Correlation is the correlation between annual returns and earnings, each calculated over the 10 years prior to the observation. N is the number of observations and R^2 is the adjusted R^2 for the regression.

effect of the disclosure strategy, and the score for the annual report does not have incremental explanatory power.[30]

The positive relation between the number of analysts and the FAF scores suggests that firm-provided disclosures complement rather than substitute for analyst activities. Consequently, information intermediation (processing firm-provided information) appears to be a significant aspect of the analyst function in capital markets. As argued earlier, if analysts were primarily information providers—in competition with firm disclosures provided directly to investors—then more firm-provided disclosures should diminish the value of analyst services and the number of analysts following the firm.

The coefficient on firm size is positive and significant, consistent with the results reported by Bhushan (1989). The standard deviation of past return on equity and the correlation between annual returns and earnings are significantly negative in the regression including all three categories of disclosure separately but are not significant in the regression including only the total disclosure score, providing weak evidence that analysts are more likely to follow firms with low performance variability and firms for which earnings are not highly correlated with returns. The negative coefficient estimate for performance variability in the regressions including all three

[30]The fact that we measure analyst following as an average over 12 months while the annual report is released at one point in time may bias against results for the annual report variable. However, results are not sensitive to time period over which the analyst-following variable (or other analyst variables) are measured.

categories of disclosure is consistent with that documented by Bhushan (1989) and Brennan and Hughes (1991), but the negative association between analyst following and the return-earnings correlation runs counter to the intuition from King et al. (1990) that the incentives for private information acquisition will be greater when the returns-earnings correlation is high. The explanatory power of the regressions is substantial, with an adjusted R^2 of 0.52 for the regression including the total score and 0.45 for the regression including all three of the disclosure categories.

Direction of Causality

Our hypotheses assume firms choose their disclosure policies partly to influence the activities of analysts. Thus, we view the informativeness of disclosure as "causing" the observed level of analyst following. It is possible, however, that the direction of causality is the opposite (i.e., a larger analyst following causes the firm to increase its disclosures) or that analyst following and the informativeness of disclosures are simultaneously determined by other exogenous variables.

One approach to investigating the direction of causality is to examine the association between changes in disclosure scores and changes in the lead and lag number of analysts. There are several problems with this approach. First, while the FAF attempts to maintain consistency from year to year, the evaluation process is designed to make comparisons among firms at a point in time, rather than comparisons of the same firm through time. The composition of the industry subcommittees and the specific criteria and weights vary from year to year, so changes in disclosure scores may reflect changes in subcommittees or criteria over time. Second, the disclosure policy of a firm and the number of analysts following it are likely to change only slowly over time because of the fixed costs to a firm of substantially changing disclosure policies or the fixed cost to an analyst of adding or deleting a firm. Therefore, we include changes computed over time periods of up to four years. However, because a given firm may have been evaluated in only a subset of the sample years, the number of observations for longer intervals is significantly reduced.

We compute the rank-order correlations between changes in disclosure scores and changes in both lead and lag analyst following. The change in lead (lag) analyst following is the change in the number of analysts following the firm computed over the time period following (preceding) the period over which the change in disclosure is computed. If changes in the number of analysts following the firm *precede* changes in disclosure policy, then the correlation between changes in disclosure and changes in the lagged number of analysts should be positive; if changes in the number of analysts *follow* changes in disclosure policy, then the correlation between changes in disclosure and changes in the lead number of analysts should be positive. As seen in table 5, all but one of the correlations for the lagged number of analysts are negative (although many are not significant), rejecting the hypothesis that changes in the number of analysts precede changes in disclosure. In addition, all the correlations for the lead number of analysts are positive, (although only a subset are significant) supporting the hypothesis that changes in the number of analysts follow changes in disclosure. Although a chronological ordering of events does not conclusively establish causality, these results provide limited evidence that disclosure policy changes cause changes in the number of analysts; we observe no evidence that causality runs in the opposite direction.

An alternate approach is to estimate a simultaneous equations model to investigate whether a firm's disclosure score and the number of analysts following the firm are jointly determined by a set of exogenous variables. The simultaneous equations approach potentially controls for bias in the OLS estimates when the error term is correlated with the independent variables, as is the case when a truly endogenous variable is treated as an exogenous (independent) variable. To implement this model, we estimate a first stage regression of FAF scores on a set of instrumental

ΔAnnual Report, ΔOther Pubs, ΔInvestor Relations and ΔTotal Score are the changes in the annual report, other publications, investor relations and total disclosure scores from the FAF data. Δ in lead 1 # of analysts and Δ in lag 1 # of analysts are the changes in the number of analysts over the period following and over the period preceding the window over which the change in disclosure scores is computed respectively. The window over which both variables are computed is noted at the top of each panel.

variables; we then use the predicted value from this regression in place of the actual disclosure score in the number-of-analysts regression. Whether the coefficient estimates from this approach are more or less biased than the OLS estimates depends on whether the instrument variables are indeed exogenous (i.e., independent of the error term) and the portion of the variation in disclosure score that is captured in the first stage regression (Bound et al. 1993). In the context of our analysis, the difficulty is identifying instrumental variables that are highly correlated with FAF scores, but are uncorrelated with the error from the number of analysts regression.

Our source of instruments is Lang and Lundholm (1993), who model disclosure scores as a function of the firm's structural environment (market value and standard deviation of past return on equity), performance (market-adjusted returns and analysts' earnings forecast errors) and activity in the public capital market (security offering in the current or following two years). While the explanatory variables are statistically significant, the resulting first-stage regressions have very low adjusted R^2s, ranging from 0.05 to 0.09, which suggests that significant measurement error may have been introduced in the first stage of the analysis.

To assess statistically whether the two equations are simultaneously determined, we apply the Hausman test (Hausman 1978). We regress the number of analysts on the exogenous variables (i.e., the control variables), the instrument for disclosure score (i.e., the predicted value from the first-stage regression) and the actual disclosure score. If the disclosure score is truly exogenous, the coefficient on the instrumented disclosure score will equal zero. The results from this test fail to reject the hypothesis that the coefficient is zero for all four disclosure score variables, suggesting that simultaneity is not an issue. The p-value for two-tailed t-test is 0.19 for the annual report, 0.18 for other publications, 0.62 for investor relations and 0.77 for the total score.

Results from estimating the second-stage regressions using the instruments estimated in the first stage (not reported) are consistent with those reported earlier. While the statistical significance of the disclosure scores is reduced somewhat relative to the results in table 4, all remain significant at less than the 0.10 level. The reduced significance may reflect the effects of simultaneity, but it also likely reflects the low R^2 in the first-stage regressions.

In summary, the analysis for number of analysts suggests a significant relation between the firm's disclosure policy and the number of analysts following the firm. Further, there is limited evidence that changes in firms' disclosure policies cause changes in analyst following; there is no evidence of the opposite direction of causality.[31]

Forecast Dispersion and Disclosure

Table 6, panel A provides evidence on H2 with respect to the relation between forecast dispersion and disclosure. In the regression including the total disclosure score, the coefficient on the total score is significantly negative, suggesting that more forthcoming disclosures decrease dispersion among analyst forecasts. This result is consistent with additional disclosure reducing the divergence of beliefs across analysts by increasing the precision of their shared information. In the regression including all three categories of disclosure, coefficients on both the annual report and investor relations variables are significantly negative, but the other publications variable is not significant.

The relation between the standard deviation of analyst forecasts and market value is negative, indicating that analyst dispersion is lower for larger firms. The relations between the standard

[31]We do not control for simultaneity of other dependent variables because forecast characteristics in a given period are unlikely to affect contemporaneous disclosure ratings (e.g., firms are unlikely to increase disclosure because analyst forecasts are very accurate). It is possible that analysts' perceptions of disclosure are affected by forecast characteristics, but the FAF designs the evaluation process to mitigate this bias.

Panel C: Volatility of Forecasts Revisions

α	β_1	β_2	β_3	β_4	β_5	β_6	β_7	β_8	β_9	N	R^2
0.24				–0.09	–0.21	0.12	0.02	0.23	0.45	1858	0.41
(11.0)				(–5.1)	(–10.8)	(6.6)	(1.0)	(12.0)	(24.5)		
0.33	–0.03	0.01	–0.10		–0.27	0.12	0.02	0.19	0.44	994	0.42
(9.9)	(–1.1)	(–0.4)	(–3.4)		(–9.9)	(4.5)	(1.0)	(7.6)	(17.5)		

Panel title indicates the forecast characteristic dependent variable in the regression. Regressions are estimated using ordinary least squares, with all variables ranked and then computed as percentiles within the industry-year. T-statistics are noted in parentheses below each coefficient estimate. N is the number of observations and R^2 is the adjusted R^2 for the regression.

deviation of forecasts and the standard deviation of past ROE, the past returns-earnings correlation, earnings surprise and the percentage of new forecasts are all significantly positive, suggesting that the dispersion among analysts is higher when the past earnings series is volatile and strongly related to past returns, and when there is a large earnings surprise and frequent forecast revisions. The proportion of variation explained in the regressions is substantial, with adjusted R^2s of 0.38 for the regression including total score and 0.42 for the regression including all three disclosure categories.

Forecast Accuracy and Disclosure

Table 6, panel B presents results from the regressions of forecast accuracy on the disclosure scores, providing evidence on H3. The coefficient on the total disclosure score is significantly positive when it is included as an explanatory variable, confirming that firm disclosure is an important determinant of the accuracy of analyst forecasts. When all three disclosure categories are included, coefficients on both the other publications and investor relations categories are significantly positive, consistent with the notion that ongoing communication with companies is an important source of information to analysts in forecasting earnings.

Accuracy is positively associated with market value, suggesting that analysts' forecasts are relatively more accurate for larger firms. The coefficients on the standard deviation of past return on equity are negative but insignificant. The standard deviation of past forecasts was significantly negatively correlated with accuracy in the simple correlations, so it appears that inclusion of other measures of uncertainty such as earnings surprise and market value have rendered this variable insignificant. Coefficients on the earnings-return correlation, earnings surprise and percent of new forecasts are generally significantly negative, suggesting that forecasts tend to be less accurate in cases when there is a large earnings surprise, when analysts are frequently revising their forecasts and when the past association between returns and earnings is low. The significant negative coefficients on the percent of new forecasts suggest that its inclusion is, at best, a partial control for stale forecasts. The regression explains a significant proportion of the variation in forecast accuracy, with adjusted R^2s of 0.38 for both the regression with total score and the regression including all three categories of disclosure.

Volatility of Forecast Revisions and Disclosure

Table 6, panel C presents evidence on H4 from the regression of forecast revision volatility on disclosure scores. The coefficient on the total score is significantly negative when it is included in the regression. When all three disclosure categories are included, only investor relations is significant, consistent with the notion that a firm can reduce the likelihood of large revisions in analysts' expectations through its investor relations effort.

The volatility of forecast revisions is decreasing in market value, suggesting that there are fewer extreme expectation revisions for large companies. The relation between variability of forecast revisions and the standard deviation of past ROE, earnings surprise and percentage of new forecasts are all positive, suggesting that revisions in expectations tend to be volatile when there is a large earnings surprise, there are frequent forecast revisions and the past earnings series is volatile. The coefficient on the correlation between returns and earnings is insignificant, suggesting that the past relation between returns and earnings is not a significant determinant of forecast revision volatility. The explanatory power of the regressions is high, with adjusted R^2s of 0.41 for the regression with the total disclosure score and 0.42 for the regression including all three categories of disclosure.

V. CONCLUSIONS

The results of this paper indicate that, after controlling for size, the earnings surprise and other attributes of the information environment, firms with more forthcoming disclosures in their industry have a greater analyst following, more consensus among analysts' earnings forecasts, more accurate forecasts and less variable forecast revisions. Of the three categories of disclosure considered, investor relations is consistently a significant determinant of analyst behavior even after controlling for other categories of disclosure, confirming existing survey and anecdotal evidence that direct contact with the company is a primary source of information for analysts.

Overall, these results are consistent with the view that more forthcoming disclosure policies, particularly in the investor relations area, attract more analysts, either because these disclosures increase the demand for analyst reports or because they reduce analysts' costs of supplying them. The fact that an increase in firm-provided information increases analyst following suggests that analysts are not in direct competition with firm disclosures provided directly to investors. The results are also consistent with the view that analysts possess both firm-provided and privately-acquired information, but that increases in disclosure and timeliness reduce the weight analysts place on other information in their forecasting models and smooth the forecast revision process by expediting the resolution of uncertainty.

To the extent that the behavior of analysts captures that of investors more generally, these results are consistent with motivations for disclosure given in the investor relations literature and have implications for management as it sets disclosure policy, for the SEC and Congress as they establish securities laws and for the FASB as it proceeds with its project on "Disclosure Effectiveness." While there has been a great deal of discussion about the costs of increased disclosure, potential benefits have received less attention.[32] Although the evidence is indirect, this study finds relationships between firms' disclosure policies and factors that have been linked to a reduced cost of capital. The results for analyst following suggest that firms that disclose more have a larger pool of potential investors; the results for forecast accuracy suggest that their investors have more accurate beliefs about future performance; the results for forecast dispersion suggest that there is less asymmetry in investors beliefs about their performance; and the results for revision volatility suggest that investor expectations about their earnings change more smoothly over the year.

[32]The FASB laments in SFAS No. 1 that, "the benefits from financial information are usually difficult or impossible to measure objectively, and the costs often are."

GREG CLINCH

Accounting Measurement and Capital Markets Research

Measurement of financial statement elements is a fundamental concern of financial accounting.

The difficulty experienced in seeking consensus on the many accounting measurement questions suggests that no single perspective is likely to provide all of the answers. Nevertheless, there is reason to expect that capital markets research has the potential, at least, to shed some light on accounting measurement issues. In particular, the importance of capital market participants as a class of financial statement users suggests that studying their behaviour (indirectly) through various market metrics is a promising research direction. And the large volume of capital markets research suggests also the potential to inform the many debates surrounding a wide range of accounting measurement questions.[1]

Despite this initial promise, my main conclusion is that the contribution of capital markets research to our understanding of measurement questions to date has been quite modest. In particular, the present "state of the art" in capital markets research allows conclusions concerning whether a particular accounting number measures *something* that is relevant to investors, but little more. Questions concerning precisely what is being measured by the accounting number, whether the measurement object is a suitable target in the first place and how well it is being measured are not yet easily addressed using capital markets-based research approaches. Although this is a disappointing conclusion, I suggest that it reflects an early stage of development in the research literature rather than an inability *per se* to address these questions successfully. In light of recent and continuing theoretical advances relating accounting (and other) information to capital market outcomes, I remain optimistic that a capital markets research perspective has more to offer in the future.

There are at least two broad questions relating to accounting measurement that are important to address:

1. For a specific financial statement element, what is the appropriate object of measurement? For exam-

Numerous controversies — from goodwill amortisation to the appropriateness of fair value accounting — illustrate both the importance of measurement questions, and the difficulty often encountered in devising accounting measurement "solutions" that are widely accepted. This paper discusses what might be learned about accounting measurement questions from the perspective of capital markets-based research. While this field of inquiry is not well developed, there are indications that further research from the capital markets perspective could provide useful conclusions about accounting measurement.

ple, in the case of non-current assets is the "preferred" approach to measure the assets at cost, cost after deducting suitable charges for amortisation (ie, amortised cost), amortised cost subject to an impairment test, market value, value in use, or some other alternative?

2. Given a specific measurement object, how should the object be measured and what are the properties of alternative measurement approaches or estimates? For example, if amortised cost is chosen as the appropriate object for measurement, what amortisation method will result in a "better" measure? Or, if an impairment test is viewed as appropriate, should it be subject to a discounted or non-discounted realisable value benchmark?

The first question relates in part to whether a proposed and (typically) unobservable object for measurement is likely to be relevant to financial statement users, including investors. How well, or reliably, the object is measured by a particular set of measurement rules is the target of the second question.[2] The issue addressed in this paper is to what extent capital markets-based accounting research can assist in answering these questions.

Broadly defined, capital markets-based research investigates various aspects of the operation of capital markets, including the role of differing market structures, the behaviour of market participants and the role of information in the market. A large subset of capital markets research investigates the association between various dimensions of market activity — such as share prices, volume of trade and bid-ask spreads — and specific information available to market participants.[3] It is built on the assumption that observable market activity reflects the aggregation of individual market participants' investment and trading decisions. More specifically, to the extent that investors employ accounting information in their investment and trading decisions, it is assumed that this is (potentially) detectable in market-wide indicators such as share prices. Under this assumption, the association between share prices (or other market indicators) and accounting information might be used to infer market participants' perceptions of the properties of accounting measures — including their relevance and reliability.

IT IS BUILT ON THE ASSUMPTION THAT OBSERVABLE MARKET ACTIVITY REFLECTS THE AGGREGATION OF INDIVIDUAL MARKET PARTICIPANTS' INVESTMENT AND TRADING DECISIONS.

Since the research focuses primarily on one class of financial statement user — investors — and the interests of differing classes of users need not agree, it cannot fully answer the two accounting measurement questions above. In particular, it is not able (or designed) to answer prescriptive questions requiring the balancing of different interests. However, it can potentially provide input that is important in addressing these issues, particularly given the importance attached to investors as a major class of financial statement users.

WHAT MIGHT BE LEARNED FROM THE CURRENT STATE OF CAPITAL MARKETS RESEARCH?

The example of non-current asset measurement and some of the related capital markets research can provide a useful illustration of the issues for at least two reasons:

- The appropriate measurement of non-current assets remains an unresolved question, with various measurement bases such as unamortised cost (with and without impairment tests), voluntary revaluations and sometimes fair values being allowed or required in different regulatory jurisdictions.
- There is a reasonable, and growing, body of capital markets-based research related to this question — much of it quite recent.[4]

The research indicates that for most major classes of non-current assets, firms' market values appear to be positively associated with asset carrying values measured at cost, at revalued amount, and where available fair value. However, it is not yet clear which (if any) of the asset measurement approaches is more strongly associated with firms' values, and whether this varies between asset classes.[5]

In terms of the two measurement questions posed above, the mere association between share values and asset carrying amounts provides only a little guidance. The first question, regarding what is an appropriate measurement object for non-current assets, is not answered at all since an association between firm market values and the various measurement alternatives alone implies nothing about any benefits to investors of such an association. There are several reasons for this.

First, an association need not mean that investors actually use the information in making their investment and trading decisions; it may simply reflect some common information with other accounting (or non-accounting) measures that are used by investors.[6] In these circumstances, the specific accounting measure might be removed with little or no impact on investor welfare. Second, an association with firm values need not mean investors are made better (or worse) off, even if the information is being used by investors. This is a long and well established result in the research literature relating to the economics of information.[7] Finally, the fact that the research indicates that alternative measurement bases (eg, cost or revalued amount) are all associated with firm market values does little to help choose *among* the bases. However, the observed associations do suggest a minimal conclusion: that each of the measurement bases reflects *something* that is relevant to investors. If the measurement bases reflected no useful information, it is unlikely they would be associated with investors' decisions and reflected in share price.

The second measurement question, regarding the reliability of accounting measures, also receives only a modest answer: associations between firm market values and accounting measures such as amortised cost or revalued amount suggest that the accounting measure in question is sufficiently reliable for the measures to reflect *something* of potential interest to investors. However, identifying precisely what is being measured remains elusive. This is because the reason the accounting measure is associated with price is typically not explicitly described (or tested) in the research. In particular, it is possible for the accounting measure to reflect information very different from that implied by the particular measurement object.[8] This makes inferences about measurement properties less clear.[9] Also, comparing measurement properties (such as reliability) across competing accounting measures is difficult.[10]

In summary, the inferences presently available from capital markets-based accounting research regarding accounting measurement questions are quite limited. Certainly the existence of an association between firm market values and an accounting measure suggests the measure is relevant and reliable enough in reflecting some (unstated) aspect of companies' activities of interest to market participants for the association to be detectable. However, assessing levels of relevance or reliability, and comparing these across competing measures with any great confidence is not yet possible.

WHAT IS NEEDED TO EXTEND THE INFERENCES AVAILABLE?

The minimal inferences presently available from capital markets research regarding accounting measurement questions are hardly satisfactory. However, I believe these inferences can eventually be extended in future research, particularly regarding the properties (eg, reliability) of specific accounting measures.

The inability of capital markets research to determine appropriate measurement objects — eg, whether assets should be measured at amortised cost, revalued amount or on some other basis — is not surprising. Such a question is prescriptive, and requires agreement on what are appropriate objectives for financial reporting and how conflicting interests among financial statement users, preparers and other interested parties are to be balanced.

In contrast, the second measurement question, regarding the properties of particular accounting measures, is potentially well suited to capital markets research approaches since it is essentially a descriptive question. The failure to make much progress with this question in capital markets research is not because of the nature of the question, but because of a lack of ingredients necessary to properly address the question. In particular, the major deficiency is the unavailability of sufficiently developed theory linking observable capital market indicators (such as market value) with information available to investors. Instead, almost all research has avoided specifying this link, leading to the limited inferences discussed earlier.[11]

Despite this shortcoming in existing research, there have been recent theoretical developments in at least two areas that will assist future capital markets research into accounting measurement properties:

- The model by Ohlson (1995) and subsequent refinements, in, for example, Feltham and Ohlson (1995), provide a framework linking measurement properties of accounting numbers and share valuation. The model has focused on aggregate accounting numbers such as a firm's net book value and earnings and how they can be linked to firm values. However, it provides the foundation for potential future extensions based on specific financial statement elements.
- Recent research using rational expectations models of capital markets has begun to investigate accounting questions such as the impact of international accounting harmonisation (eg, Barth, Clinch and Shibano 1999 and Huddart, Hughes and Brunnermeier 1999), and the impact of recognition and disclosure (eg, Barth, Clinch and Shibano 2000) on the operation of capital markets. Although this research does not directly address the accounting measurement questions discussed in this paper, it does incorporate measurement issues in the models developed.[12] This is a potential precursor to future research directed specifically at accounting measurement questions relating to particular financial statement elements.

Each of these approaches potentially provides the foundation for future research linking measurement properties of accounting numbers with market activity, although from differing modelling perspectives.[13] The challenge is to further develop the models at the level of specific financial statement elements. This will allow the theories to specify more precisely how measurement properties of specific accounting measures will be reflected in capital market activity.[14] Only then will there be a sufficient basis for extending the inferences regarding accounting measurement from a capital markets-based research perspective. Otherwise, the contribution of the research to answering measurement questions in accounting is likely to remain modest.

Greg Clinch is professor of accounting in the Australian Graduate School of Management, Universities of New South Wales and Sydney. *The author thanks Baljit Sidhu and Malcolm Miller for helpful comments on an earlier draft.*

NOTES

1 I do not here attempt to provide a comprehensive review of capital markets-based research in financial accounting generally, or even the majority of research related to measurement questions. Instead, I focus on a small number of relevant research papers to illustrate some of the issues involved and questions raised. For more comprehensive reviews of the relevant literature, together with a discussion of implications for standard setting, see, for example, Barth (2000) or Brown and Howieson (1998).

2 This approach places specific meanings on "relevance" and "reliability" — terms used frequently to describe desirable attributes of accounting measurements. In particular, I employ relevance as a property of the underlying object being measured — eg, if the object could be measured without error would it be relevant to investors' trading and investment decisions — and reliability as a property of the actual outcome of a set of measurement rules applied to estimate the object. These meanings do not necessarily accord perfectly with those used or implied elsewhere.

3 Although I restrict my attention here to accounting-related information, the research literature is much broader than this. Accounting measures that have been investigated using capital markets-based approaches range from broadly defined performance measures such as earnings numbers (eg, Ball and Brown 1968) to specific elements of financial statements such as capitalised R&D expenditure (eg, Abrahams and Sidhu 1998). For broad surveys of this literature see, for example, Lev and Ohlson (1982), Brown (1994), Barth (2000) and Holthausen and Watts (2000).

4 For example, recent capital markets-based research relating to asset revaluations includes Easton, Eddey and Harris (1993), Easton and Eddey (1997), Barth and Clinch (1996, 1998), Aboody, Barth and Kasznik (1999) and Cotter and Zimmer (2000). There exist similar strands of research relating to asset impairment tests and fair values for various classes of assets.

5 For example, there is some evidence that revalued tangible and intangible non-current assets are less strongly associated with firm market values than tangibles and intangibles carried at cost for industrial firms. However, this result does not extend to financial non-current assets, nor does it extend to other industry groups such as mining companies (Barth and Clinch 1998).

6 An example of this relating to asset measurement might be the availability of information regarding property markets that potentially could make redundant asset revaluations recorded in firms' balance sheets.

7 This result relates to the idea that the availability of information can have wealth distributive effects that do not make all economic agents better off even if they use the information in their decisions. See, for example, Verrecchia (1982) for a review of early related research in accounting.

8 For example, voluntary revaluations of non-current assets might reveal to investors something about the incentives managers are responding to (eg, the need to strengthen the balance sheet prior to raising capital) rather than the value *per se* being recognised.

9 Recent research (Barth and Clinch 1998, Aboody, Barth and Kasznik 1999) has begun to respond to this challenge by also investigating the association between accounting measures and indicators of future company performance such as earnings or cashflows. This provides a better indication of what information the relevant accounting number might be conveying to market participants.

10 There has been a temptation in the existing research literature to employ the strength or magnitude of the association between firm market values and competing accounting measures as an indication of measurement reliability. However, as discussed in this paper, I believe such attempts to be premature. That is, capital markets research can indicate sufficient reliability in a particular measure for there to be a detectable association between firm value and the accounting measure, but it cannot confidently be used to gauge the level of reliability beyond this.

11 There are some examples of research where explicit "pricing theories" are employed to assist in generating inferences regarding measurement properties of accounting numbers. For example, Barth (1991) assumes a simple link between share prices and investor perceptions of pension assets and liabilities together with an explicit specification of the measurement structure of accounting disclosures relating to pensions by US firms. Similarly, Barth and Clinch (1996) provide a simple model in their appendix linking explicitly prices, unobservable valuation relevant characteristics and accounting disclosures about those characteristics. They use the model to assist their interpretation of the measurement properties of various international accounting measurement differences. However, the models used in these papers have been very simple and their descriptive validity may be questioned.

12 For example, Barth, Clinch and Shibano (2000) investigate the impact of recognition versus disclosure of accounting amounts across differing levels of relevance and reliability of the accounting measures.

13 For example, the Ohlson (1995) model assumes a simple pricing approach based on homogenous investors assessing expected future dividends, but incorporates accounting features such as clean surplus and the evolution of accounting numbers over time. In contrast, the rational expectations models incorporate less of the specific accounting characteristics but allow a more complex pricing approach with potentially heterogeneous investors.

14 To illustrate, in the case of asset valuation, the Ohlson (1995) model might be extended to decompose book value and earnings into asset-valuation-related and other components. Suitable information dynamics related to each component could be developed/conjectured for alternative measurement bases that reflect the expected characteristics of each basis. These could then be used to derive "predictions" about the link between firm values and the asset-valuation-related components under alternative measurement bases that could guide the design and interpretation of subsequent empirical research.

A review of the empirical disclosure literature: discussion☆

John E. Core*

The Wharton School, University of Pennsylvania, 2400 Steinberg-Dietrich Hall, Philadelphia, PA 19104-6365, USA

Received 18 September 2000; received in revised form 9 March 2001

Abstract

Healy and Palepu, J. Account. Econ. (2001), this issue, provide a broad review of the empirical disclosure literature. This discussion focuses on the empirical voluntary disclosure literature, and assumes firms' disclosure policies are endogenously determined by the same forces that shape firms' governance structures and management incentives. This provides not only a more focused view of the literature, but also alternative explanations for some of the results discussed in *Review* and specific suggestions for future research. © 2001 Elsevier Science B.V. accounting information; the firms that produce it and use it to evaluate their employees; the persons who use this information in allocating capital to firms; and the persons who produce, verify, regulate and interpret this information. These questions are important, and much research remains to be done before we can confidently answer them.

In this discussion, I focus on *Review*'s analysis of the empirical voluntary disclosure literature for two reasons. First, other literature covered by *Review* is also covered by other conference surveys and discussions. More important, the voluntary disclosure literature appears to offer the greatest opportunity for large increases in our understanding of the role of accounting information in firm valuation and corporate finance.

Because of its broad perspective, *Review* does not specify an economic theory of voluntary disclosure, does not analyze the empirical literature in detail, and offers few specific suggestions for future research. This discussion attempts to complement *Review* by using a specific framework based on the economic theory of the firm. Briefly, this framework assumes that the relation between disclosure, managers, individual and institutional investors, and analysts is endogenously determined by the same forces that shape firms' governance structures and management incentives. This framework provides the basis for: (1) a more focused view of the literature; (2) alternative explanations for some of the results discussed in *Review*; and (3) specific suggestions for future research.

I present this framework in Section 2.1, and in Section 2.2 use it to analyze one of *Review's* hypothesized determinants of voluntary disclosure and to suggest an alternative interpretation of the evidence. Section 2.3 discusses literature on the association between institutional investors and disclosure, which is not examined in *Review*. I conclude Section 2 by briefly reviewing research on the economic consequences of voluntary disclosure with a focus on identifying needs for future research. Section 3 suggests that research efforts be concentrated on: (1) better understanding the link between information asymmetry and the cost of capital; (2) creating better measures of the information asymmetry component of the cost of capital; (3) and creating better measures of disclosure quality. Section 4 provides a summary and conclusion.

2. Discussion

2.1. Disclosure quality, disclosure credibility, and corporate finance theory

Corporate finance theory predicts that shareholders endogenously optimize disclosure policy, corporate governance, and management incentives in order to maximize firm value. This choice involves trading off the reduction in the information asymmetry component of the cost of capital that results from increased disclosure quality against the costs of reduced incentives (e.g., Evans and Sridhar, 1996), litigation costs (Skinner, 1994), and proprietary costs (Verrecchia, 1983). As a simple example of how this trade-off works in cross-section, assume that growth opportunities and the quality of mandated disclosure are exogenous, and consider whether firms provide voluntary disclosure to reduce information asymmetry.[1] For a firm without growth opportunities, mandated disclosure might be of sufficiently high quality to produce low information asymmetry. Because this firm has no need for external finance and has low litigation, incentive, and proprietary costs, it has little need for voluntary disclosure. For firms with high growth opportunities, mandated disclosure is low quality and information asymmetry is high. For these firms, some reduction in information asymmetry through voluntary disclosure is optimal, and the optimum is determined as a function of the quality of mandated disclosure and a trade-off of lower capital and litigation costs against higher proprietary and incentive costs. After this optimal choice, high-growth firms use more voluntary disclosure, but they likely still have greater information asymmetry than low-growth firms.

Perfectly credible (or, equivalently, completely unbiased) disclosure is not optimal because it is too costly:

> … Not all managerial accounting manipulation will be eliminated. It may be too costly … to eliminate all such manipulation … In labor and capital markets characterized by rational expectations, managers will not, on average, gain from such manipulation (Watts and Zimmerman, 1986, p. 205).

The statement that it is too costly to eliminate all manipulation means that managers can add some bias to disclosure at a low personal cost. If it is known that all managers wish to bias disclosure in the same direction and if disclosure is costly, the theory discussed in *Review* suggests that a "lemons" equilibrium can occur in which no firm discloses. However, if shareholders are uncertain about the direction of managers' incentives to bias disclosure, a pooling equilibrium occurs in which there is disclosure, and some disclosure contains bias (e.g., Dye, 1988; Fischer and Verrecchia, 2000).[2] Accordingly, theory predicts that even though disclosure contains some bias, in equilibrium it is still

[1] I follow previous research and define any disclosure above the mandated minimum as "voluntary" disclosure. For simplicity, I assume that the mandated minimum level of disclosure quality is exogenous. *Review* discusses how this minimum may evolve endogenously.

[2] Lang and Lundholm's (2001) study provides an example: Because shareholders do not know which firms intend to make stock offerings, and because not all firms that make offerings bias their disclosure, some firms can temporarily increase their stock prices through increased, "hyped" disclosure. However, once the offering is announced, the stock price falls dramatically for the firms with increased disclosure, but very little for firms without unusual disclosure increases.

credible. Therefore, all empirical studies of disclosure credibility will find disclosure to be credible; interesting studies explore cross-sectional variation in the bias in disclosure (e.g., Lang and Lundholm, 2001).

While the optimal disclosure policy allows some managerial manipulation of disclosure, it is the governance structure that constrains the manager to follow the optimal policy (e.g., Shleifer and Vishny, 1997; Zingales, 1998). Accordingly, cross-sectional differences in firms' disclosure policies result from cross-sectional differences in: (1) the optimal disclosure policy; and (2) the ability of firms' governance to enforce the optimal policy.[3] In summary, theory predicts an endogenous relation between information asymmetry, disclosure quality, managerial incentives, and corporate governance.

In contrast, *Review* uses a broad framework based on the intuition provided by Akerlof's (1970) illustration of adverse selection costs. This framework provides macro-economic intuition for why lack of disclosure is costly for firms, for the existence of financial and information intermediaries, and for why there may be a demand for disclosure regulation. While this framework confirms our intuition that we live in a world of partial disclosure, it is not specific enough to give satisfying explanations for cross-sectional differences in firms' disclosure policies. All of the managerial motives for voluntary disclosure described in *Review* assume that disclosure policy, corporate governance, and management incentives are exogenous at the time a manager makes a disclosure choice. Each of the following three sub-sections examines different contexts in which this simplifying assumption causes interpretation problems. Section 2.2 uses the more specific theory described above to reinterpret *Review's* hypothesized association between stock compensation and disclosure. Section 2.3 discusses the inter-relation between analysts, institutional investors, and information asymmetry, and Section 2.4 provides a brief alternative view of the evidence on the economic consequences of voluntary disclosure.

2.2. The endogenous relation between disclosure policy and management incentives

Because it does not explicitly recognize endogenous relations, *Review* does not always give a thorough and critical evaluation of the research it discusses. I choose to discuss in detail the following example, because I think that the

[3] That there is variation in disclosure policies around the optimum means that well-designed cross-sectional tests can avoid the problem of spurious correlation between disclosure quality and information asymmetry illustrated above and in Sections 2.2 and 2.4 below. For example, if industry membership is the primary endogenous determinant of an optimal disclosure policy, within-industry variation in disclosure policy can be considered exogenous in a test of the predicted negative effect of disclosure quality on the cost of capital (e.g., Botosan, 1997).

reader could be misled by the short discussion in *Review* of the evidence for the "stock compensation hypothesis:"

> Consistent with this hypothesis, Noe (1999) provides evidence that the incidence of management forecasts is positively associated with trading by insiders in the firm's stock. Aboody and Kasznik (2000) find that firms delay disclosure of good news and accelerate the release of bad news prior to stock option award periods, consistent with managers making disclosure decisions to increase stock-based compensation. Miller and Piotroski (2000) find that managers of firms in turnaround situations are more likely to provide earnings forecasts if they have higher stock option compensation at risk (Section 3.3.2).

At a superficial level, Noe's (1999) evidence supports the unsurprising result that managers follow the law and either disclose or abstain from trading. An alternative, more interesting, interpretation of the evidence in both Noe (1999) and Aboody and Kasznik (2000) is that managers selectively time trading and disclosures at the expense of other stockholders. This interpretation contradicts *Review's* hypothesis that managers use disclosure to reduce contracting costs, although it is consistent with the theory discussed above that it is too costly to eliminate all managerial manipulation. In addition, both Noe (p. 325) and Aboody and Kasznik (p. 98) are careful to point out that their evidence is consistent with managers acting in shareholders' interests. For example, because the incentives to increase stock-price volatility created by an in-the-money option are lower than those created by an at-the-money option (Lambert et al., 1991), firms may wish to issue in-the-money options but prefer to avoid the accounting cost of such options. To accomplish this objective, they allow managers to time disclosures.

Miller and Piotroski (2000) find that sample firms with more shares *reserved* for options (as a percentage of shares outstanding) make more forecasts.[4] Because their tests do not recognize that options use, disclosure quality, and information asymmetry are simultaneously determined, Miller and Piotroski provide no support for the hypothesis that option compensation motivates managers to provide more voluntary disclosure. Firms with greater information asymmetry use more stock and option incentives (Demsetz and Lehn,

[4] The percentage of shares *reserved* for options outstanding and future grants is an extremely weak proxy for managers' "stock option compensation at risk." Managers care about their dollar wealth, not their percentage ownership. It is well known that managers of larger firms have fewer options as a fraction of shares outstanding, but the dollar value of these options holdings is much higher than those of small firms (Baker and Hall, 1998). Further, options owned by the executives who are likely to make disclosure decisions constitute a small fraction of shares reserved for options (Core and Guay, 2001).

1985; Smith and Watts, 1992; Core and Guay, 1999; Bryan et al., 2000), and greater information asymmetry is associated with more voluntary disclosure (Lang and Lundholm, 1993). Therefore, as suggested above, we would expect an association between managers' equity incentives and voluntary disclosure, as they are both associated with information asymmetry, but this does not mean that options use causes disclosure.

2.3. The relation between voluntary disclosure, institutional investors, and financial analysts

Given the focus of *Review* on the role of intermediaries, it is odd that there is no analysis of empirical research on the relation between disclosure and institutional investors.[5] Healy et al. (1999) find that increases in disclosure are associated with increases in institutional ownership. Bushee and Noe (2001) confirm this association, but find that increases in "transient" institutional investors (institutions that trade aggressively) are associated with increases in stock price volatility. Assuming that increases in stock price volatility are costly, this finding is consistent with the intuition that partial disclosure is optimal, and that too much disclosure can be as costly as too little disclosure.

Tasker (1998) finds that firms with greater analyst following and greater institutional ownership are less likely to have conference calls, and Bushee et al. (2001) find that firms with greater analyst following and greater institutional ownership are less likely to have conference calls that provide open access to all investors. This evidence is consistent with the intuition that informed investors prefer less disclosure, but is also consistent with the notion that analysts and institutions produce information, and reduce information asymmetry and the need for conference calls.

Review discusses the endogenous relation between disclosure quality, information asymmetry, and financial analysts explored in Lang and Lundholm (1996). Brennan and Subrahmanyam's (1995) simultaneous-equations model provides evidence of this endogenous relation. One equation shows that the number of analysts reduces information asymmetry (proxied by the information asymmetry component "IAC" of the bid-asked spread). A second equation shows that the causality also runs in the opposite direction, that is, reductions in information asymmetry increase the number of analysts. Brennan and Subrahmanyam's (1995) predictions are based on a theory

[5] *Review* does mention the theoretical prediction of Diamond and Verrecchia (1991) and Kim and Verrecchia (1994) that disclosure attracts institutional investors: "In addition, these studies argue that expanded disclosure and stock liquidity will be associated with increased institutional ownership" (Section 3.4.2).

relating information asymmetry to informed trading, and they test the theory using analysts as a proxy for informed traders. The same theory predicts a simultaneous relation between information asymmetry and institutional investors, who are also informed.[6]

The interpretation of any evidence involving buy-side institutions or sell-side analysts is clouded because of the known, but not well understood, endogenous relation between these two intermediaries (e.g., O'Brien and Bhushan, 1990). The imbalance between the small amount of research on *buy-side* analysts and the vast amount of research on *sell-side* analysts suggests much opportunity for useful future research. While it is unclear how one would address such a broad question as "how effective are financial analysts as information intermediaries?" (Table 1, *Review*), there is no satisfying answer to this question that does not involve a theory of how the buy-side is related to the sell-side. For example, knowing how institutional investors interpret analysts' forecasts is likely to help us understand whether analyst optimism is a statistical artifact or whether it is an economically important phenomenon.[7] Clearly we want to understand how well the number of sell-side analysts and the number of institutional investors proxies for the degree of information asymmetry and the cost of capital, but can we know this without a better understanding of the joint relation between sell-side analysts and institutional investors?

One way of shedding light on these questions is to examine the extent to which buy-side analysts agree with (or disagree with) the sell-side's recommendations and earnings forecasts. For example, Krische and Lee (2000) provide indirect evidence that quantitative, "anomalies-based" trading firms use an information set that is mostly orthogonal to the recommendations of sell-side analysts. An extension of Ali et al. (2000) could provide more direct evidence on whether return variation associated with changes in institutional holdings is correlated with analysts' recommendations. Another way of addressing this question would be to compare the performance of industry-sector mutual funds to the weighted post-commission performance of the recommendations of the sell-side analysts who cover these industries (by extending the method of Barber et al., 2001). Evidence that the returns to these sector funds are correlated (uncorrelated) with the returns to the sell-side analysts' recommendations would be consistent with the hypothesis that buy-side analysts agree with (disagree with) the sell-side's recommendations.

[6] Brennan and Subrahmanyam ignore this theory, as they use institutional investors as a determinant for the number of analysts, but not as a determinant of the IAC of the bid-asked spread.

[7] While *Review* notes intertemporal differences in levels of analyst optimism, it does not discuss research that questions whether optimism tells us anything about analysts' abilities or incentives. For example, Abarbanell and Lehavy (2000) suggest that apparent differences in optimism are artifacts of data problems, and Gu and Wu (2000) suggest that optimism can be an outcome of a rational and unbiased forecasting process.

Understanding these correlations would in turn shed additional light on the interrelation between buy-side institutions, sell-side analysts, disclosure quality, and information asymmetry.

2.4. Empirical evidence on the consequences of voluntary disclosure

As *Review* alludes to in Section 3.3.2, disclosure quality is an *ex ante* commitment or policy to provide voluntary disclosure over time, and this endogenously determined policy affects the level of information asymmetry. When a manager receives information at a point in time, the manager may *ex post* choose to withhold or provide this information in order to correct mis-valuation (e.g., Healy and Palepu, 1995). If the manager chooses to disclose this information, this disclosure will change the stock price. However, firms with higher disclosure quality withhold less information. Therefore, there are two effects: (1) disclosure quality, which is the firm's ongoing *ex ante* commitment to provide disclosure; and (2) "discretionary" disclosure, which is an *ex post* realization of this *ex ante* commitment.

2.4.1. Discretionary disclosure

Because discretionary disclosure is a particular realization of a firm's disclosure policy, cross-sectional studies of discretionary disclosure are essentially equivalent to cross-sectional studies of disclosure quality. Accordingly, if the research design is not careful to control for the endogenous determinants of disclosure policy, there is the potential for spurious inference about the discretionary disclosure under study.

As an example, consider the Kasznik and Lev (1995) finding that firms that warn investors of bad earnings news experience significantly more negative returns per unit of unexpected earnings than firms that do not warn. This finding suggests that firms are penalized for disclosing bad news early. Shu (2000) argues that this apparently puzzling difference in returns occurs because of a failure to model firms' disclosure policies. Suppose that firms with high disclosure quality have policies to "disclose bad earnings news early." *Ceteris paribus*, firms with high disclosure quality have high earnings quality, which means that their earnings surprises contain more information about future cash flows. Therefore, the market reaction to the disclosure of earnings information will be higher for firms with higher disclosure quality. If firms that warn have higher disclosure quality, the market reaction per unit of unexpected earnings is greater, and the Kasznik and Lev finding is not puzzling, but what one would expect.

As a second example, consider Francis, Philbrick and Schipper (FPS, 1994), whom *Review* cites as mixed evidence on the litigation cost hypothesis. Firms in the FPS litigation sample were more likely to pre-announce bad news than firms in the no litigation sample. This greater incidence of litigation is interpreted by *Review* as evidence that pre-disclosure is ineffective. However, FPS are careful to point out that their litigation sample is about ten times larger than the no litigation sample, and subsequent research shows that firm size is a significant determinant of litigation risk. Therefore, an alternative interpretation is that the FPS evidence is completely consistent with firms' optimally using disclosure to minimize litigation costs. Larger firms expect to be sued more frequently, and their choice to pre-disclose more frequently lowers the conditional costs of these suits (Skinner, 1997).

2.4.2. Disclosure quality

Because a firm's optimal disclosure policy will trade-off its need for a low cost of capital against other costs, *ceteris paribus* one expects to find a negative relation between disclosure and the cost of capital. As discussed in *Review*, researchers examine how disclosure affects two separate components of the cost of capital: (1) liquidity costs such as the IAC of the bid-asked spread, which increase trading costs and reduce the net proceeds of a stock offering, and (2) the equity discount rate. In addition to the endogeneity problems discussed in *Review* and discussed above (e.g., the simultaneous relation between financial analysts and information quality), two additional factors complicate this research. First, there are measurement problems both with the proxies for disclosure quality (discussed by *Review*) and with the proxies for the cost of capital. These measurement problems both weaken the tests and also exacerbate the potential for endogeneity problems to cause spurious inference. Second, tests of a link between disclosure quality and the cost of capital are *joint* tests of a theory linking disclosure quality to information asymmetry *and* a theory linking information asymmetry to a cost of capital.

For example, the tests in Botosan and Plumlee (2000) are joint tests of the hypothesis that disclosure quality affects information asymmetry and the hypothesis that information asymmetry affects the equity discount rate (proxied by the cost of capital implied by inverting various dividend discount models). Assuming that information asymmetry affects discount rates, such a test can fail to find an association because of unsystematic error in the proxies for disclosure quality and the cost of capital. On the other hand, systematic error, such as biases in the analysts' disclosure ratings and in the analysts' forecasts on which the cost of capital are based, can show evidence of a non-existent relation.

3. Future research

It seems important to create better measures for the information asymmetry component of the cost of capital and for disclosure quality, and these are discussed below in Sections 3.2 and 3.3. First, however, we must establish whether information asymmetry only affects stock liquidity or if it also affects equity discount rates. This assessment will point to where disclosure quality can have an economically important effect on the cost of capital, where research efforts should be focused, and how to interpret prior research.

3.1. How does information asymmetry affect the cost of capital?

There seems to be consensus both in the theoretical and empirical market micro-structure literature that greater information asymmetry reduces stock liquidity (e.g., Brennan and Subrahmanyam, 1995; Verrecchia, 2001). However, conference participants noted that changes in the structure of US stock markets have resulted in bid-asked spreads that are economically negligible as a fraction of most firms' stock prices. Therefore, if the IAC of the bid-asked spread is the only means by which the cost of information asymmetry manifests itself, one would conclude, as do Leuz and Verrecchia (2001), that the US disclosure environment is already so rich that it would be difficult to find strong disclosure-related effects in broad cross-sections of US firms.[8] In this case, the effect of disclosure is likely to be a subtle, second-order, effect for most US firms, and this effect would only be detected in samples where there are large changes in disclosure policy such as in Healy et al. (1999), Lang and Lundholm (2001), and Leuz and Verrecchia (2001).

On the other hand, if information asymmetry affects expected returns, disclosure choices can have a first-order economic effect by reducing information asymmetry and lowering firms' equity discount rates, and this effect would be detected in broad samples. In this case, strong disclosure-related effects could be found in US return data, and it would be worthwhile to use more sophisticated measures for the cost of capital and to validate carefully prior results on US data before proceeding abroad where institutions and market-making are known to be quite different.

Recent finance literature shows that three proxies for information asymmetry appear to explain cross-sectional returns in excess of the three Fama and French (1992) factors. Brennan and Subrahmanyam (1996) find that firms with a lower IAC of the bid-asked spread have lower expected returns. In addition, lower information asymmetry is associated with higher volume, and recent empirical evidence suggests that higher-volume stocks have lower

[8] In this case, an additional interpretation suggested by *Review* is that there is too much disclosure regulation in the US, and that market participants would be willing to accept larger IAC (and larger spreads) in exchange for firms spending less cash on information production.

expected returns (Brennan et al., 1998; Chordia et al., 2001).[9] Finally, Easley, Hvidkjaer, and O'Hara, 2000 (EHO, 2000) proxy for information asymmetry using the Easley et al. (1996) probability of informed trade (PIN) metric. EHO find that firms with higher PINs have higher excess returns, and interpret this result as evidence that information risk increases expected returns.

Each of these three proxies for information asymmetry has been shown to be related to disclosure policy. For example, Leuz and Verrecchia (2001) show that a commitment to increased disclosure lowers bid-asked spreads and increases volume, and note that Easley et al. (1996) show a negative correlation between the PIN metric and volume. Finally, in research-in-progress, Brown et al. (2000) examine the association between the PIN metric and disclosure quality as measured by the AIMR scores for a cross-section of 200 firms in 1995. Preliminary results indicate that there is a significant negative correlation between the two variables.

Even if strong links from various proxies for information asymmetry to expected returns could be established, there remains the challenge of establishing strong links from disclosure quality to the information asymmetry proxies. If this can be accomplished, research could then seek to establish a direct link from disclosure quality to expected returns. This work would have the potential "added benefit of explaining why it is that some accounting data appear to be informative for asset pricing" (EHO, 2000, Section 6). However, to answer these questions requires better understanding of the various proxies for information asymmetry and for disclosure quality.

3.2. Measuring the information asymmetry component of the cost of capital

There is little research guidance as to which of the noisy proxies for the information asymmetry component of the cost of capital are likely to be more accurate. Researchers indirectly address measurement problems with the cost of capital by repeating their tests on different proxies for the cost of capital (e.g., Healy et al., 1999; Leuz and Verrecchia, 2001). However, because these tests are not independent, it is difficult to assess significance.

Moreover, when one has several noisy proxies, one can construct a more powerful test by using a weighted combination of the proxies in a single regression, where the weights are derived in order to diversify away the measurement error (see Ittner and Larcker, 2001). For example, consider the hypothesis that information asymmetry affects expected returns. One would expect that the three measures discussed above (the IAC of the bid-asked

[9] Findings in Brennan, Chordia, and Subrahmanyam suggest that the negative relation between firm size and expected returns (Fama and French, 1992) can be interpreted as size proxying for liquidity effects. When a more direct proxy for liquidity, dollar volume, is included in a regression of excess returns, it is significantly negative, and size becomes insignificant.

spread, volume, and the PIN metric) are noisy proxies for information asymmetry, and that power could be gained by aggregating the proxies into a single measure.

A large sample study could assess the measurement properties of various proxies for the cost of capital. Correlation analysis and factor analysis would shed light on the relative amounts of error in the proxies, and would suggest combinations of proxies that could be weighted together to create more powerful tests. Because they require the analysis of intra-day trading data, it is very expensive to compute some proxies such as the PIN metric and the IAC of the bid-asked spread. Another useful contribution would be to create a "good enough" measure for the information asymmetry component of the cost of capital. Such a measure would consist of easily-computed proxies and would be highly correlated with the most precise, but more expensive, measure.

3.3. Measures of disclosure quality

Improved measures of disclosure quality also need to be developed. The AIMR discontinued its disclosure rankings in 1997 (after ranking fiscal year 1995). There may be some small problems of judgment error in the metrics constructed by Botosan (1997), Lang and Lundholm (2001), and Miller (1999), but the real problem with these measures is that they are so labor-intensive that they are feasible only for small samples.

Here, I conjecture that researchers can substantially lower the cost of computing these metrics by importing techniques in natural language processing from fields like computer science, linguistics, and artificial intelligence. An example of a widespread natural language processing technology is the grammar-checking device provided with many word-processing programs. This device provides information on the frequency of use of the passive tense. Little (1998, pp. 96-98) identifies the passive tense as one of a number of linguistic devices for hiding meaning that are examined in the law and linguistics literature.

These programs also provide other readability statistics, and one would expect to see a correlation between these readability statistics and the AIMR ratings, which are analysts' ratings of written disclosure. It seems worthwhile to investigate whether more sophisticated natural language processing technology could be used to replicate ratings by the AIMR and ratings by researchers. If this can be accomplished, it would significantly reduce the cost of creating disclosure quality indices from firm reports and press releases. Assuming good voice-recognition technology, it would be possible to machine-code conference call disclosure as well.

Natural language processing programs could be also used to create proxies for the "tone" of disclosure (Lang and Lundholm, 2001) and proxies for the precision and bias of the information that is conveyed. Healy and Palepu (1993, 1995, 2001) emphasize the important idea that managers communicate with investors. Managers use natural language for this communication, and we can advance work in accounting by using research from other fields to find ways to machine-code the precision of this language and any bias contained in it.

4. Conclusion

This paper discusses *Review* and uses corporate finance theory to expand on and to provide an alternative analysis of the voluntary disclosure literature. The endogeneity problems and the measurement error problems that make this literature difficult are also what make this literature an especially promising area for future research. As discussed above and in Bushman and Smith (2001), the voluntary disclosure literature is interlinked with the literature on corporate governance and the literature on management incentives. Each of these literatures has endogeneity problems, and there is uncertainty and active debate on how to measure governance quality (e.g., Bushman et al., 2000) and how to measure incentives (e.g., Core and Guay, 1999).

A major contribution can be made to the voluntary disclosure literature by establishing how information asymmetry affects the cost of capital, and in particular determining whether information asymmetry affects expected returns. A second contribution can be made by creating more precise measures of the information asymmetry component of the cost of capital. A final contribution can be made by using computer technology to lower the cost of computing disclosure quality indices. These measures would add power to most disclosure-related research designs, as well as help address more general issues of fundamental interest to accounting researchers. Specifically, researchers could employ these measures to shed light on many of the broader questions proposed in *Review*.

Potentially the most interesting question for future research is to examine the firm's simultaneous choice of disclosure quality, management incentives, and corporate governance structure. Bushman et al. (2000) make an important start in this area by documenting that lower accounting quality (measured by a returns-earnings correlation) is associated with more costly corporate governance mechanisms. Future research can build on these results by examining whether firms with low accounting quality improve their disclosure quality through voluntary disclosures. In this case, one would expect an association between the level of voluntary disclosure and the firm's level of managerial equity incentives. This association would simply reflect firms' optimal choices, and would not provide evidence of a stock compensation hypothesis.

Information asymmetry, corporate disclosure, and the capital markets: A review of the empirical disclosure literature ☆

Paul M. Healy*, Krishna G. Palepu

Graduate School of Business, Harvard University, Boston, MA 02446, USA

Received 14 January 2000; received in revised form 16 March 2001

Abstract

Financial reporting and disclosure are potentially important means for management to communicate firm performance and governance to outside investors. We provide a framework for analyzing managers' reporting and disclosure decisions in a capital markets setting, and identify key research questions. We then review current empirical research on disclosure regulation, information intermediaries, and the determinants and economic consequences of corporate disclosure. Our survey concludes that current research has generated a number of useful insights. We identify many fundamental questions that remain unanswered, and changes in the economic environment that raise new questions for research. © 2001 Published by Elsevier Science B.V.

1. Introduction

Corporate disclosure is critical for the functioning of an efficient capital market.[1] Firms provide disclosure through regulated financial reports, including the financial statements, footnotes, management discussion and analysis, and other regulatory filings. In addition, some firms engage in voluntary communication, such as management forecasts, analysts' presentations and conference calls, press releases, internet sites, and other corporate reports. Finally, there are disclosures about firms by information intermediaries, such as financial analysts, industry experts, and the financial press.

In this paper we review research on financial reporting and voluntary disclosure of information by management, summarize key research findings, and identify areas for future work. Section 2 examines the forces that give rise to demand for disclosure in a modern capital-market economy, and the institutions that increase the credibility of disclosures. We argue that demand for financial reporting and disclosure arises from information asymmetry and agency conflicts between managers and outside investors. The credibility of management disclosures is enhanced by regulators, standard setters, auditors and other capital market intermediaries. We use the disclosure framework to identify important questions for research, and review available empirical evidence.

Section 3 reviews the findings on the regulation of financial reporting and disclosure. Much of this research documents that earnings, book values, and other required financial statement information is "value relevant". However, fundamental questions about the demand for, and effectiveness of, financial reporting and disclosure regulation in the economy remain unanswered.

Research on effectiveness of auditors and information intermediaries is discussed in Section 4. There is evidence that financial analysts generate valuable new information through their earnings forecasts and stock recommendations. However, there are systematic biases in financial analysts' outputs, potentially arising from the conflicting incentives that they face. While theory suggests that auditors enhance the credibility of financial reports, empirical research has provided surprisingly little evidence to substantiate it.

Section 5 reviews the economic determinants of managers' financial reporting and disclosure decisions. Research using the contracting perspective finds that accounting decisions are influenced by compensation and lending contracts, as well as political cost considerations. Research using the capital market perspective documents that voluntary disclosure decisions are related to capital market transactions, corporate control contests, stock-based compensation, shareholder litigation, and proprietary costs. There is also

[1] Corporate disclosure can also be directed to stakeholders other than investors. However, there has been relatively little research on these types of voluntary disclosures. Consequently, we focus in this paper on investor communication.

evidence that investors view voluntary disclosures, such as management forecasts, as credible information. In Section 6, we discuss the capital market consequences of managers' financial reporting and disclosure decisions. Studies document that voluntary disclosures are associated with stock performance, bid-ask spreads, cost of capital, analyst coverage and institutional ownership. However, many of the studies discussed in Sections 5 and 6 suffer from significant endogeneity and measurement error problems, making it difficult to interpret their findings.

We believe that financial reporting and disclosure will continue to be a rich field of empirical enquiry. Throughout the paper, we identify a number of unanswered questions. Further, as we discuss in Section 7, there are significant changes in the economic environment—rapid technological innovation, the emergence of network organizations, changes in the business economics of audit firms and financial analysts, and the globalization of capital markets. These changes have the potential to alter the nature of financial reporting and disclosure, creating rich new opportunities for research.

2. The role of disclosure in capital markets

In this section, we examine the role of disclosure in modern capital markets. Information and incentive problems impede the efficient allocation of resources in a capital market economy. Disclosure and the institutions created to facilitate credible disclosure between managers and investors play an important role in mitigating these problems. The framework for disclosure that we discuss in this section is then used to develop implications for research.

A critical challenge for any economy is the optimal allocation of savings to investment opportunities. There are usually many new entrepreneurs and existing companies that would like to attract household savings, which are typically widely distributed, to fund their business ideas. While both savers and entrepreneurs would like to do business with each other, matching savings to business investment opportunities is complicated for at least two reasons. First, entrepreneurs typically have better information than savers about the value of business investment opportunities and incentives to overstate their value. Savers, therefore, face an "information problem" when they make investments in business ventures. Second, once savers have invested in their business ventures, entrepreneurs have an incentive to expropriate their savings, creating an "agency problem".

2.1. Information problem

The information or "lemons" problem arises from information differences and conflicting incentives between entrepreneurs and savers. It can potentially lead to a breakdown in the functioning of the capital market (see Akerlof, 1970). For example, consider a situation where half the business ideas are "good" and the other half are "bad". Both investors and entrepreneurs are rational and value investments conditional on their own information. If investors cannot distinguish between the two types of business ideas, entrepreneurs with "bad" ideas will try to claim that their ideas are as valuable as the "good" ideas. Realizing this possibility, investors will value both good and bad ideas at an average level. Therefore, if the lemons problem is not fully resolved, the capital market will rationally undervalue some good ideas and overvalue some bad ideas relative to the information available to entrepreneurs.

There are several well-known solutions to the lemons problem. Optimal contracts between entrepreneurs and investors will provide incentives for full disclosure of private information, thus mitigating the misvaluation problem (see Kreps, 1990, Chapters 17 and 18). Another potential solution to the information asymmetry problem is regulation that requires managers to fully disclose their private information. Finally, because of the lemons problem, there is a demand for information intermediaries, such as financial analysts and rating agencies, who engage in private information production to uncover managers' superior information.

Fig. 1 provides a schematic of the role of disclosure, and information and financial intermediaries in the working of capital markets. The left side of Fig. 1 presents the flow of capital from savers to firms. Capital can flow to business ideas in two ways. First, it can flow directly from savers to businesses.

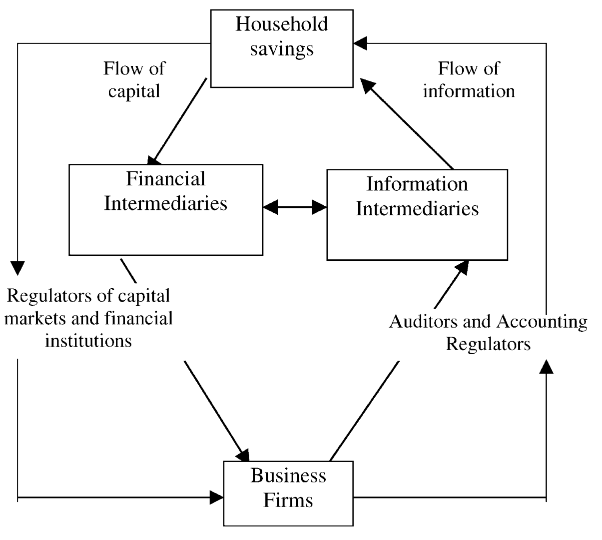

Fig. 1. Financial and information flows in a capital market economy.

Examples include private equity and angel financing. A second and more typical way for capital to flow from savers to businesses is through financial intermediaries, such as banks, venture capital funds, and insurance companies. The right side of the figure presents the flow of information from businesses to savers and intermediaries. Firms can communicate directly with investors through such media as financial reports and press releases. They also communicate with financial intermediaries or through information intermediaries, such as financial analysts.

A variety of economic and institutional factors determine whether contracting, regulation and information intermediaries eliminate information asymmetry, or leave some residual information problem. These factors include the ability to write, monitor, and enforce optimal contracts, proprietary costs that might make full disclosure costly for investors, regulatory imperfections, and potential incentive problems for intermediaries themselves. Research on corporate disclosure, therefore, focuses on cross-sectional variation in these factors and their economic consequences.[2]

2.2. Agency problem

The agency problem arises because savers that invest in a business venture typically do not intend to play an active role in its management—that responsibility is delegated to the entrepreneur. Consequently, once savers have invested their funds in a business venture, the self-interested entrepreneur has an incentive to make decisions that expropriate savers' funds. For example, if savers acquire an equity stake in a firm, the entrepreneur can use those funds to acquire perquisites, pay excessive compensation, or make investment or operating decisions that are harmful to the interests of outside investors (see Jensen and Meckling, 1976).

Alternatively, if savers acquire a debt stake in a firm, the entrepreneur can expropriate the value of the investment by issuing additional more senior claims, by paying out the cash received from savers as a dividend, or by taking on high risk capital projects (see Smith and Warner, 1979). The issuance of new senior debt and payment of dividends reduces the likelihood that there will be sufficient resources available to fully repay existing or lower priority debt in the event of financial distress, benefiting the entrepreneur. High risk capital projects increase the likelihood of both good outcomes that disproportionately benefit the entrepreneur, and bad outcomes that are disproportionately borne by debtholders.

There are several solutions to the agency problem. Optimal contracts between entrepreneurs and investors, such as compensation agreements and

[2] A similar approach is used by finance scholars to study corporate finance issues such as capital structure, dividends/stock repurchases and private equity financing (see, for example, Myers and Majluf, 1984).

debt contracts, seek to align the interests of the entrepreneur with those of external equity and debt claimants. These contracts frequently require entrepreneurs to disclose relevant information that enables investors to monitor compliance with contractual agreements and to evaluate whether entrepreneurs have managed the firm's resources in the interests of external owners. A second mechanism for reducing agency problems is the board of directors, whose role is to monitor and discipline management on behalf of external owners. Finally, information intermediaries, such as financial analysts and rating agencies, engage in private information production to uncover any manager misuse of firm resources. The market for corporate control, which includes the threat of hostile takeovers and proxy contests, also mitigates agency problems between corporate insiders and outside shareholders.

Whether contracting, disclosure, corporate governance, information intermediaries, and corporate control contests eliminate agency problems is an empirical question. A variety of economic and institutional factors determine their effectiveness, including the ability to write and enforce optimal contracts, potential incentive problems for corporate boards and intermediaries, and the nature of the corporate control market. As discussed below, empirical research on financial reporting and disclosure has focused primarily on cross-sectional variation in contracting variables to explain management's financial reporting decisions.

2.3. Research implications

The information and agency frameworks raise a number of important questions for financial reporting and disclosure researchers. These include questions on (i) the role of disclosure and financial reporting regulation in mitigating information and agency problems, (ii) the effectiveness of auditors and information intermediaries as a means of increasing the credibility of management disclosures and uncovering new information, (iii) factors affecting decisions by managers on financial reporting and disclosure, and (iv) the economic consequences of disclosure. Table 1 summarizes these questions. The remainder of this paper discusses the findings and limitations of research on these questions, as well as opportunities for future research. We focus on empirical research; analytical research is covered by other papers in this issue (see Verrecchia, 2001; Dye, 2001; Lambert, 2001).

3. Regulation of disclosure and financial reporting

3.1. Regulation of disclosure

There are significant regulations governing corporate reporting and disclosure in all countries around the world. For example, in the US,

Table 1
Research questions implied by disclosure framework

Topic	Questions
Regulation of disclosure	Why is there a need for regulation of disclosure in capital markets? What types of disclosures should be regulated and which should not? How effective are accounting standards in facilitating credible communication between managers and outside investors? What factors determine their effectiveness? Which mandated disclosures should be recognized directly in the financial statements and which should be included as supplemental disclosures?
Auditing/intermediaries and disclosure	How effective are auditors in enhancing the credibility of financial statements? What factors influence auditors' effectiveness? How effective are financial analysts as information intermediaries? What factors influence their effectiveness? How does corporate disclosure affect analyst coverage of firms?
Managers disclosure decisions	What factors affect management's disclosure choices? What is the relation between disclosure, corporate governance, and management incentives? What role do boards and audit committees play in the disclosure process?
Capital market consequences of disclosure	How do investors respond to corporate disclosures? Are firm disclosures made outside the financial statements credible? Do investors evaluate disclosures that are included directly in the financial statements differently from those that are included as supplemental disclosures? What factors influence investors' perception of the quality of capital market disclosures across economies? How does disclosure affect resource allocation in the economy?

companies accessing capital markets are required to follow disclosure rules set by the Securities and Exchange Commission (SEC). A long-standing research question is what economic rationale justifies regulating corporate disclosure. An equally important question is the effectiveness of disclosure regulation in solving the information and agency problems in capital markets.

Absent market imperfections or externalities, firms have incentives to optimally trade off the costs and benefits of voluntary disclosure, and to produce the efficient level of information for investors in the economy. Researchers, therefore, attempted to identify potential market imperfections that might justify the prevalence of disclosure regulations around the world. Leftwich (1980), Watts and Zimmerman (1986), and Beaver (1998) note that accounting information can be viewed as a public good since existing stockholders implicitly pay for its production but cannot charge potential investors for their use of the information. Prospective investors, therefore, free ride on information paid for by existing shareholders, leading to the potential underproduction of information in the economy.

A second explanation for regulation, also discussed by Leftwich (1980), Watts and Zimmerman (1986), and Beaver (1998), proposes that disclosure regulation is motivated by concerns other than market failures. For example, regulators may be concerned about the welfare of financially unsophisticated investors. By creating minimum disclosure requirements, regulators reduce the information gap between informed and uninformed. This explanation for disclosure implies that the objective of disclosure regulation is to redistribute wealth, rather than to improve economic efficiency. After all, unsophisticated investors could choose to reduce the information gap by investing in financial knowledge or hiring the services of sophisticated intermediaries.

Both the above arguments for regulation leave many unanswered questions. For example, are potential market failures in disclosure significant? Does regulation of disclosure materially improve the situation? Are there potential negative consequences of regulation? For example, Posner (1974) argues that regulators tend to become captured by those they regulate (see also Watts and Zimmerman, 1986). Is this an important problem for disclosure? How critical is disclosure regulation for the development of capital markets? Is disclosure regulation necessary for the functioning of capital markets even when there are sophisticated capital market intermediaries? Finally, if regulation is effective in increasing economic efficiency, what types of disclosure should be required by regulation and what should be left to the discretion of management?

Whether there is a market failure for disclosure and whether it is corrected through regulation are empirical questions. However, empirical research on the regulation of disclosure is virtually non-existent. This is surprising given the central role regulation plays in disclosure, and the limitations of the economic arguments supporting regulation.

3.2. Regulation of financial reporting choices

Accounting standards regulate the reporting choices available to managers in presenting the firm's financial statements. This type of regulation potentially reduces processing costs for financial statement users by providing a commonly accepted language that managers can use to communicate with investors.

Several questions arise about the regulation of financial reporting methods. First, what are standard setters' objectives? How do they decide to examine certain reporting issues and not others? Second, what are optimal forms of organization and due process for standard setting bodies? These issues have become highly relevant in the recent debate on the organizational structure of the IASC. Third, do accounting standards add value for investors or other stakeholders?

Accounting research has largely focused on the third question. This research has taken two forms. In the "capital markets" research, studies examine the relation between accounting information and security prices. This research is extensively reviewed by Kothari (2001). The most significant conclusion is that regulated financial reports provide new and relevant information to investors. Further, this research documents that the informativeness of required accounting varies systematically with firm and country characteristics (see Collins and Kothari, 1989; Easton and Zmijewski, 1989; Alford et al., 1993; Ball et al., 2000a). Several recent studies document a decline in the level of relevance of earnings and other financial statement items over the last 20 years. Using a variety of different research designs, Chang (1998), Lev and Zarowin (1999), and Brown et al. (1999) find that, in the US, the relations between stock returns and earnings, and between stock prices, earnings and book values have deteriorated over time.[3]

The above evidence suggests that regulated financial information provides valuable information to investors. However, because this research does not compare the relative informativeness of regulated and unregulated financial information, it does not necessarily imply that regulation is superior to a free market approach to disclosure. The finding that the value of regulated accounting data varies systematically based on firm characteristics, time-dependent variables, and country-specific institutions is also subject to alternative interpretations. Do the differences reflect the influence of systematic economic factors that make regulation more or less effective? Or, is the variation driven by correlated omitted variables such as firm- and country-growth, or risk?

Another branch of accounting research examines the value relevance of information presented under proposed new financial reporting standards. This research uses the association between earnings and stock prices or returns as a measure of value relevance. The evidence from this literature indicates that most recent standards generate accounting information that is value relevant. One notable exception is inflation accounting, where no relation to stock prices or returns is observed (see Beaver et al., 1980; Gheyara and Boatsman, 1980; Ro, 1980). A more comprehensive discussion of this literature is provided by Holthausen and Watts (2001), who criticize the use of value relevance as a metric for evaluating accounting standards, and Barth et al. (2001) who offer an alternative viewpoint on the subject.

[3] Collins et al. (1997), Francis and Schipper (1999), and Ely and Waymire (1999) examine the relation between returns, earnings and book values. They conclude that the relation between returns and earnings has deteriorated, but that this has been offset by an increase in the value-relevance of book values. However, Chang (1998) argues that these findings are sensitive to the authors' research design choices.

We identify four areas where we believe additional research on the role of standard setting is warranted. First, do current accounting standards provide timely information to investors or simply confirm information that is already available to them through other sources? Event study tests of the information content of particular accounting methods attempt to evaluate the timeliness of alternative methods.

Second, studies that evaluate the benefits of alternative reporting methods under consideration by standard setters are more likely to provide useful evidence if they examine costs and benefits of all of the alternatives considered. This has usually been difficult to accomplish since researchers do not have access to the inside information required to estimate performance under different reporting alternatives. Several studies attempt to mitigate this problem. Barth (1991) evaluates alternative metrics for pension liabilities using public disclosures available prior to the release of the new accounting standard. Healy et al. (1999b) develop a simulation model for a pharmaceutical firm, allowing them to compare the value relevance of alternative measures of R&D performance.

A third area for future research in the standard setting arena is to assess which types of standards are likely to be most useful for investors and other stakeholders. For example, on average do bright-line rules produce information that is more useful than rules that require managers to exercise judgment in selecting reporting methods? Under what conditions do bright-line rules dominate those that require management judgment and vice versa?

Finally, future research on standard setting can examine optimal standards across countries. There is currently heated debate about the merits of global standards. Global standards, however, are only likely to be optimal if the institutions that monitor and enforce adherence to standards work equally well across countries. In the US, auditors provide assurance that the financial statements comply with accounting regulations, and the SEC has enforcement authority. Dechow et al. (1996) and Beneish (1999) find that US companies face a significant stock price penalty if the SEC decides to pursue them for violating accounting standards. However, the magnitude of type one and type two errors in SEC enforcement actions is unclear. The effectiveness of monitoring and the penalties from enforcement of standards in other countries, particularly those that are only beginning to develop capital markets, is even more open to question.[4] For example, these countries typically lack established financial reporting and auditing standards, and well-trained business professionals required for effective auditing and investment banking.

In summary, surprisingly little is known about why financial reporting and disclosure is regulated in the capital market. Is there a significant market

[4] See DeFond et al. (1999), Ball et al. (2000a, b), and Eccher and Healy (2000) for studies that begin to examine this issue.

imperfection or externality that regulation attempts to resolve? If so, how effective is disclosure regulation in resolving this problem?

4. Role of auditors and intermediaries in the disclosure process

4.1. Auditors

Auditors provide investors with independent assurance that the firm's financial statements conform to GAAP. The fact that stock prices react to earnings announcements (see Kothari, 2001) suggests that overall investors regard accounting information as credible. However, does credibility arise from assurance provided by auditors or from other sources, such as managers' potential legal liability for providing misleading disclosures?

Studies of audit effectiveness examine whether audit qualifications add value for investors and whether auditors' actions are independent of the interests of their clients. Research shows that capital providers require firms to hire an independent auditor as a condition of financing, even when it is not required by regulation. For example, Leftwich (1983) finds that banks require firms to present audited financial information, even for private companies. This implies that capital providers regard auditors as enhancing credibility.

To our knowledge, there is no research that examines directly whether or not auditors significantly enhance the credibility of reported financial statements. Available evidence suggests that auditor qualifications do not provide timely signals to the capital market. For example, studies of the stock market reaction to audit qualifications show that qualified opinions do not provide new information to investors, in part because they can be anticipated (see Dodd et al., 1984, 1986; Dopuch et al., 1986, 1987). This evidence suggests that audit qualifications at best confirm information already available to investors. Choi and Jeter (1992) report that subsequent to qualifications, firms show lower stock price responses to earnings. However, since the study does not control for the unusual performance of firms with qualifications, it is difficult to attribute the decline in earnings response coefficients to reduced credibility.

There are several potential explanations for the paucity of evidence on the value of auditor opinions to investors. Watts and Zimmerman (1981a, b) posit that auditors act in the interest of the managers that hire them, rather than in the interest of the firms' investors. They report evidence that is weakly consistent with this hypothesis using data on auditors' responses to proposed new accounting standards. An alternative explanation is that auditors provide formal assurance only on the annual report, making it difficult for them to provide timely signals to the capital markets. A third explanation is that auditors are concerned about minimizing their legal liability, rather than enhancing the credibility of financial reports. Accordingly, they lobby for standards that reduce their own risk, even though such standards reduce the value of financial reports to investors. Future research may be able to distinguish between these explanations.

Several additional questions arise about the value of audit opinions. First, how do consulting services provided to audit clients affect auditors' perceived and actual independence, and the value of their audit report? Several large audit firms have recently spun-off their consulting operations, providing an opportunity to examine whether their clients have more credible financial statements than those for clients of competitors that continue to provide both audit and consulting services.

Second, there have been a number of important changes in the audit environment in the late 1990s. Legal and organizational changes have limited auditors' liability for audit failures. Also, several of the large audit firms have recently made significant changes in their audit methodology, focusing on a business audit rather than a transactions audit. What impact do these changes have on audit failures and the credibility of financial statements?

Third, what factors influence the credibility of audit reports and financial statements across countries? Factors that are likely to affect credibility could include differences in audit standards, the legal framework governing the audit profession, enforcement of standards and rules, and differences in professional training requirements. DeFond et al. (1999) examine the effect of new auditing standards that improved auditor independence in China. They find that the new standards increased the frequency of qualified opinions, but that this was accompanied by a "flight from audit quality". However, in general the role of auditors and auditing standards in emerging markets has been unexplored in the literature.

4.2. Intermediaries

Studies of the value of intermediaries largely focus on financial analysts. Financial analysts collect information from public and private sources, evaluate the current performance of firms that they follow, make forecasts about their future prospects, and recommend that investors buy, hold or sell the stock. Academic studies focus on information provided to investors from two summary measures produced by analysts, earnings forecasts and buy/hold/sell recommendations. Overall, this evidence indicates that financial analysts add value in the capital market. Their earnings forecasts are more accurate than time-series models of earnings, presumably in part because they are able to incorporate more timely firm and economy news into their forecasts than time-series models (see Brown and Rozeff, 1978; Brown et al., 1987; Givoly, 1982). Also, analysts' earnings forecasts and recommendations affect stock prices (see Givoly and Lakonishok, 1979; Lys and Sohn, 1990; Francis and Soffer, 1997).

There is also evidence of analyst bias in forecasting and making recommendations. Early evidence on bias indicated that analyst earnings forecasts tended to be optimistic, and that their recommendations were almost exclusively for buys (see Brown et al., 1985). However, recent evidence indicates a change in the pattern of analysts' earnings forecasts in the late 1990s. In this period there has been a marked decline in analyst optimism (see Brown, 1997; Matsumoto, 2000).

Research on the role of financial analysts in capital markets indicates that they play a valuable role in improving market efficiency. For example, Barth and Hutton (2000) find that stock prices for firms with higher analyst following more rapidly incorporate information on accruals and cash flows than prices of less followed firms.

Recent research on analysts attempts to improve our understanding of their cross-sectional performance. Two factors are examined, cross-sectional variation in analysts' incentives and expertise. Studies on incentives note that analysts are rewarded for providing information that generates trading volume and investment banking fees for their brokerage houses. Thus, analysts have incentives to make optimistic forecasts and recommendations when their brokerage house has been hired to underwrite or is being considered to underwrite a new securities issue (see Lin and McNichols, 1998; Dechow et al., 2000).

Studies of the role of analysts' expertise examine factors likely to influence their aptitude, such as experience, brokerage affiliation, and company or industry assignments. Jacob et al. (1999) find that analyst forecast accuracy is affected by innate ability, company assignments, brokerage affiliation, and industry specialization. There appears to be little benefit from experience. Gilson et al. (2000) find that, for focused companies, analysts that specialize by industry issue more precise forecasts than non-specialist analysts.

Academic research on financial analysts also examines whether there is any relation between management's disclosure decisions, and analyst decisions to cover firms. Bhushan (1989a, b) and Lang and Lundholm (1993) argue that voluntary disclosure lowers the cost of information acquisition for analysts and hence increases their supply. However, the effect of voluntary disclosure on demand for analysts' services is ambiguous. Expanded disclosure potentially enables financial analysts to create valuable new information, such as superior forecasts and buy/sell recommendations, thereby increasing demand for their services. However, public voluntary disclosure also pre-empts analysts' ability to distribute managers' private information to investors, leading to a decline in demand for their services.

Lang and Lundholm (1993) find that firms with more informative disclosures have larger analyst following, less dispersion in analyst forecasts, and less volatility in forecast revisions. Healy et al. (1999a) show that firms with increased analyst ratings of disclosure have lower analyst coverage than their industry peers in the pre-event period. After the increase in disclosure, however, analyst coverage for the sample firms reverts to the same level as other firms in the industry. Finally, Francis et al. (1998) find that there is an increase in analyst coverage for firms making conference calls.

Studies of intermediaries other than financial analysts include tests of the value provided by business journalists that analyze and evaluate companies' financial reporting decisions, and bond-rating agencies. Foster (1979, 1987) examined stock price reactions to the publication by Barrons of articles by Abraham Briloff, an academic accountant who periodically questioned firms' accounting decisions. Foster found that firms whose accounting was challenged by Briloff on average suffered an 8% decline in stock price when the article was released. He concluded that this reaction probably reflected Briloff's superior insights and analysis.

Studies of the value provided by bond-rating agencies (see Holthausen and Leftwich, 1986; Hand et al., 1992) conclude that rating downgrades provide new information to investors, but that upgrades are already reflected in stock and bond prices when they are announced.

In summary, there has been considerable academic research on the value provided by auditors and financial intermediaries in reviewing firm's disclosures and in making their own disclosures on the firm. This evidence shows that at least some of the disclosures made by financial analysts, the business press, and bond-rating agencies affect stock prices. However, there remain important gaps in our knowledge about the incentives of auditors and intermediaries, and the impact on their credibility.

Among all the areas of research reviewed in this paper, we view the research on financial analysts as the most advanced. Nonetheless, there are several opportunities for research in this area. First, how does Regulation Full Disclosure recently issued by the SEC affect financial analysts' forecasting performance? Second, what was the role of financial analysts and other information intermediaries in the recent dramatic run-up and decline in stock prices of US technology stocks?

5. Managers' reporting decisions

Research on managers' reporting decisions has focused on two areas. The first area, often called positive accounting theory, focuses on management's financial reporting choices. We provide a brief review of this literature; Fields et al. (2001) provide a more comprehensive survey of recent research in this area. The second area, the voluntary disclosure literature, focuses on management disclosure decisions.

5.1. Positive accounting theory literature

The positive accounting theory literature focuses on management's motives for making accounting choices when markets are semi-strong form efficient, there are significant costs in writing and enforcing contracts, and there are political costs arising out of the regulatory process (see Watts and Zimmerman, 1978, 1986). The central focus of this literature is to examine the role of contracting and political considerations in explaining management accounting choices when there are agency costs and information asymmetry. Two types of contracts are examined, contracts between the firm and its creditors (debt contracts), and contracts between management and shareholders (compensation contracts). Political considerations include management's concern about attracting explicit or implicit taxes, or regulatory actions.

Contracts are not the only mechanisms for dealing with information asymmetry discussed in the positive accounting literature. For example, Watts and Zimmerman (1983, 1986) discuss the role of reputation as a mechanism for resolving information problems in the context of auditing.

Empirical studies of positive accounting theory test whether managers make accounting method changes or accrual estimates to reduce the costs of violating bond covenants written in terms of accounting numbers, to increase the value of earnings-based bonuses under compensation contracts, or to reduce the likelihood of implicit or explicit taxes. Findings indicate that firms that use accounting methods to accelerate earnings are small and have relatively high leverage. Also, firms' accrual decisions appear to be affected by compensation contracts.

While a majority of positive accounting studies focus on analyzing post-contracting opportunistic accounting choices, some studies view the choice of accounting and disclosure as part of the contracting process itself. Holthausen and Leftwich (1983), Watts and Zimmerman (1990), Smith and Watts (1992), and Skinner (1993) argue that the use of accounting information in lending and compensation contracts should be viewed as endogenous. Consequently, the nature of a firm's assets and its investment opportunity set simultaneously determine its optimal contracting relations and its accounting method choices. Watts and Zimmerman (1983) examine the role of voluntary interim reporting as an ex ante contracting part of corporate governance. The ex ante role of accounting in the contracting process is also examined by Zimmer (1986), Christie and Zimmerman (1994), and Skinner (1993).

Although positive accounting theory studies generated several interesting empirical regularities regarding firms' accounting decisions, there is ambiguity about how to interpret this evidence (see reviews by Holthausen and Leftwich, 1983; Watts and Zimmerman, 1990). For example, size is typically viewed as a proxy for political sensitivity, but is likely to proxy for many other factors. Also, as Palepu (1987), Healy and Palepu (1990), and DeAngelo et al. (1996)

suggest, accounting decisions by managers of highly leveraged firms in financial distress may in part reflect an attempt to conserve cash, or changes in investment opportunities.

5.2. *Voluntary disclosure literature*

Research on voluntary disclosure focuses on the information role of financial reporting for capital markets (see Healy and Palepu, 1993, 1995). This research supplements the positive accounting literature by focusing on stock market motives for accounting and disclosure decisions.

Disclosure studies assume that, even in an efficient capital market, managers have superior information to outside investors on their firms' expected future performance. If auditing and accounting regulations work perfectly, managers' accounting decisions and disclosures communicate changes in their firm's business economics to outside investors. Alternatively, if accounting regulation and auditing are imperfect, a more likely possibility, managers trade off between making accounting decisions and disclosures to communicate their superior knowledge of firm's performance to investors, and to manage reported performance for contracting, political or corporate governance reasons. Management motives for making voluntary disclosure and their credibility are, therefore, interesting empirical questions. Below, we discuss empirical evidence on these questions. We also separately analyze potential limitations of the research, many of which are shared across studies.

5.2.1. *Motives for voluntary disclosure*

Researchers discuss six forces that affect managers' disclosure decisions for capital market reasons: capital market transactions, corporate control contests, stock compensation, litigation, proprietary costs, and management talent signaling.

(a) *Capital markets transactions hypothesis*

Theory. Healy and Palepu (1993, 1995) hypothesize that investors' perceptions of a firm are important to corporate managers expecting to issue public debt or equity or to acquire another company in a stock transaction. Consider a firm whose managers have superior information to outside investors regarding the firm's future prospects. Myers and Majluf (1984) point out that if this information asymmetry cannot be resolved, such firms will view making public equity or debt offers to be costly for existing shareholders. Consequently, managers who anticipate making capital market transactions have incentives to provide voluntary disclosure to reduce the information asymmetry problem, thereby reducing the firm's cost of external financing.

Barry and Brown (1985, 1986) and Merton (1987) reach a similar conclusion by modeling the premium that investors demand for bearing information risk when there is an information asymmetry between managers and outside investors. Managers can reduce their cost of capital by reducing information risk through increased voluntary disclosure. A corner solution is not possible because of costs associated with credible voluntary disclosure.

Evidence. Several studies provide evidence on voluntary disclosure policies of firms issuing new capital. In a comprehensive study of corporate disclosure, Lang and Lundholm (1993) document that analysts' ratings of disclosures are higher for firms issuing securities in the current or future periods. In a subsequent paper, Lang and Lundholm (1997) analyze disclosures specifically for firms that make equity offerings and find that there is a significant increase in disclosure beginning six months before the offering, particularly for the categories of disclosure over which firms have the most discretion. Finally, Healy et al. (1999a) find that firms with increased analyst ratings of disclosures have an abnormally high frequency of subsequent public debt offers.[5] However, as discussed below, debt and equity offers are not isolated events, making it difficult to assess whether managers' disclosure strategies are caused by public capital market transactions or by omitted related factors.

(b) *Corporate control contest hypothesis*

Theory. This hypothesis is motivated by evidence that boards of directors and investors hold managers accountable for current stock performance. Warner et al. (1988), and Weisbach (1988) show that CEO turnover is associated with poor stock performance. Poor stock price performance is also associated with the probability of hostile takeovers, which results in high CEO turnover (see Palepu, 1986; Morck et al., 1990). DeAngelo (1988) finds that dissident shareholders who wage a proxy fight for board representation frequently cite poor earnings performance as justification for proposed management changes. Voluntary disclosure theory hypothesizes that, given the risk of job loss accompanying poor stock and earnings performance, managers use corporate disclosures to reduce the likelihood of undervaluation and to explain away poor earnings performance.

One limitation is that this analysis does not take account of multi-period considerations. For example, if managers expect that a commitment to provide extensive disclosure today could be used to hold them more accountable for any subsequent poor performance, managers of firms subject to corporate control actions may not wish to expand disclosure in a period of poor performance.

Evidence. There has been relatively little research on voluntary disclosures accompanying hostile takeovers or for target firms engaged in proxy contests.

[5] Frankel et al. (1995) find that firms that raise new capital are not more likely to provide management forecasts in the period immediately prior to the offering than at other times. However, this finding is not surprising given that securities laws restrict managers from making forward-looking statements prior to equity offerings.

One recent exception is Brennan (1999), who finds that targets are more likely to make management earnings forecasts during contested takeover bids.

(c) *Stock compensation hypothesis*

Theory. Managers are also directly rewarded using a variety of stock-based compensation plans, such as stock option grants, and stock appreciation rights. These types of compensation schemes provide incentives for managers to engage in voluntary disclosures for several reasons.

First, managers interested in trading their stock holdings have incentives to disclose private information to meet restrictions imposed by insider trading rules and to increase liquidity of the firm's stock. Restrictions on insider trading also provide managers with incentives to make voluntary disclosures to correct any perceived undervaluation (relative to their own information set) prior to the expiration of stock option awards.[6]

Second, managers acting in the interests of existing shareholders have incentives to provide voluntary disclosures to reduce contracting costs associated with stock compensation for new employees. Stock compensation is more likely to be an efficient form of remuneration for managers and owners if stock prices are a precise estimate of firm values. Otherwise, managers will demand additional compensation to reward them for bearing any risk associated with misvaluation. Firms that use stock compensation extensively are therefore likely to provide additional disclosure to reduce the risk of misvaluation.[7]

Evidence. Consistent with this hypothesis, Noe (1999) finds that the incidence of management forecasts is positively associated with trading by insiders in the firm's stock. Aboody and Kasznik (2000) show that firms delay disclosure of good news and accelerate the release of bad news prior to stock option award periods, consistent with managers making disclosure decisions to increase stock-based compensation. Miller and Piotroski (2000) find that managers of firms in turnaround situations are more likely to provide earnings forecasts if they have higher stock option compensation at risk.

(d) *Litigation cost hypothesis*

Theory. The threat of shareholder litigation can have two effects on managers' disclosure decisions. First, legal actions against managers for inadequate or untimely disclosures can encourage firms to increase voluntary

[6] In the absence of insider trading restrictions, managers may benefit from the undervaluation by buying shares rather than making disclosures to enhance the value of their stock options.

[7] As discussed in Section 2, we use the term misvaluation to refer to the gap between the value of the firm conditional on managers' information set and on investors' information set. This gap arises when there is information asymmetry between managers and investors that is not fully resolved. Throughout our analysis, we assume that both managers and investors are rational, and that stock prices fully incorporate all public information.

disclosure. Second, litigation can potentially reduce managers' incentives to provide disclosure, particularly of forward-looking information.

Skinner (1994) examines the first of these effects and hypothesizes that managers of firms with bad earnings news have an incentive to pre-disclose that information to reduce the cost of litigation. This hypothesis presumes that in the absence of litigation managers have an incentive to time the disclosure of good and bad news symmetrically. Litigants and courts, therefore, rationally focus on whether there were delays in bad news announcements.

One question that arises about the litigation hypothesis is why pre-disclosure of poor performance reduces the risk of litigation. Is it because delaying bad news until a *required* earnings announcement is prima facie evidence that management did not *voluntarily* disclose information to investors in a timely manner? Alternatively, some suggest that pre-disclosure of bad news is beneficial because it spreads the stock price decline over multiple dates, thereby reducing the likelihood of being detected in screens used to identify claims. Of course, this presumes that investors do not make an unbiased assessment of the bad news conveyed by a pre-announcement of earnings. The price drop would then occur at the pre-release date rather than the subsequent earnings announcement, and would continue to hit the screen used to identify potential claims.

Litigation potentially reduces incentives to provide disclosure, particularly of forward-looking information, if managers believe that the legal system penalizes forecasts made in good faith because it cannot effectively distinguish between unexpected forecast errors due to chance and those due to deliberate management bias.

Evidence. The empirical evidence on the litigation hypothesis is mixed. Skinner (1994, 1997) finds that firms with bad earnings news are more than twice as likely to pre-disclose the poor earnings performance than are firms with good news. In addition, firms with negative earnings news are more likely to be subject to litigation. Finally, he finds weak evidence that litigation costs are lower for firms that pre-disclose earnings than for those that do not.

In contrast, Francis et al. (1994) find that 62% of the firms in their litigation sample were sued over earnings forecasts or pre-emptive earnings disclosures. In contrast, 87% of their sample of no-litigation firms with comparable stock price declines pre-announced an earnings decline. They concluded that pre-disclosure does not appear to be a deterrent to litigation.

Empirical evidence also suggests that litigation risk is not just relevant for firms with bad news, but also those with good news. For example, Miller and Piotroski (2000) report that managers of turnaround firms in industries subject to high litigation risk are more likely to make management forecasts of positive future earnings information than firms in low risk industries. However, this conclusion should be interpreted with caution because the study only examines the forecasting behavior of firms that ex post experienced a turnaround. It is unclear whether the findings can be extended to firms that were ex ante expected by managers to show a turn around, but failed to do so ex post.

(e) *Management talent signaling hypothesis*

Theory. Trueman (1986) argues that talented managers have an incentive to make voluntary earnings forecasts to reveal their type. A firm's market value is a function of investors' perceptions of its managers' ability to anticipate and respond to future changes in the firm's economic environment. The earlier that investors infer that the manager has received information, the more favorable will be their assessment of the manager's ability to anticipate future changes and the higher will be the firm's market value. To the best of our knowledge, there is no evidence to either support or refute this hypothesis.

(f) *Proprietary cost hypothesis*

Theory. Several researchers hypothesize that firms' decisions to disclose information to investors is influenced by concern that such disclosures can damage their competitive position in product markets. (see Verrecchia, 1983; Darrough and Stoughton, 1990; Wagenhofer, 1990; Feltham and Xie, 1992; Newman and Sansing, 1993; Darrough, 1993; Gigler, 1994). These studies conclude that firms have an incentive not to disclose information that will reduce their competitive position, even if it makes it more costly to raise additional equity. However, this incentive appears to be sensitive to the nature of the competition, in particular whether firms face existing competitors or merely the threat of entry, and on whether firms compete primarily on the basis of price or long-run capacity decisions.

This literature is extensively reviewed in Verrecchia (2001) and Dye (2001). Unlike the previous five hypotheses on voluntary disclosure, the proprietary cost hypothesis assumes there are no conflicts of interest between managers and shareholders. As a result, this literature predicts that voluntary disclosure will always be credible. The focus of this literature, therefore, is on examining the economic forces that constrain full disclosure.

Hayes and Lundholm (1996) argue that proprietary costs induce firms to provide disaggregated data only when they have similarly performing business segments. Firms with widely varying performance across business segments have incentives to conceal these performance differences from competitors by only reporting aggregate performance.

Evidence. There has been relatively little direct evidence on the proprietary cost hypothesis. Piotroski (1999a) examines firms' decisions to provide additional segment disclosures. He concludes that firms with declining profitability and with less variability in profitability across industry segments are more likely to increase segment disclosures, consistent with the proprietary cost hypothesis.

The proprietary cost hypothesis can be potentially extended to include other externalities from information disclosure. For example, Watts and Zimmerman (1986) argue that firms are concerned about potential political and contracting costs from financial disclosures, which may in turn affect their voluntary disclosure.

5.2.2. Credibility of voluntary disclosure

The extent to which voluntary disclosure mitigates resource misallocation in the capital market depends on the degree of credibility of information on the firm's economics that is not available from other sources, including required disclosures. Because managers have incentives to make self-serving voluntary disclosures, it is unclear whether management disclosures are credible.

There are potentially two mechanisms for increasing the credibility of voluntary disclosures. First, third-party intermediaries can provide assurance about the quality of management's disclosures. Second, there can be validation of prior voluntary disclosures through required financial reporting itself.[8] For example, managers' forecasts of revenues and earnings can be verified using actual realizations. This mechanism will be effective in making disclosures credible if there are adequate penalties for managers that knowingly make disclosures that are subsequently proven false. The legal system and board monitoring play an important role in imposing such penalties.

Much of the evidence on the credibility of voluntary disclosures focuses on the accuracy and stock price effects of management forecasts. Waymire (1984) and Ajinkya and Gift (1984) show that there are positive stock price reactions to management forecasts of earnings increases, and negative reactions to forecasts of earnings decreases.[9] Pownall and Waymire (1989) find that the market reaction to unexpected management earnings forecasts is similar in magnitude to the reaction to unexpected earnings announcements themselves. This suggests that management forecasts have comparable credibility to audited financial information.

There is also evidence that investors are justified in viewing management forecasts as providing credible new information. Tests of the accuracy of these forecasts indicate that they are more accurate than contemporaneous analysts' forecasts (see Hassell and Jennings, 1986; Waymire, 1986), and are unbiased (see McNichols, 1989). In addition, financial analysts appear to revise their forecasts in response to information reflected in management's forecasts (see Hassell et al., 1988). Piotroski (1999a) provides evidence that voluntary disclosures other than management forecasts are also credible. He examines a sample of firms that increase segment reporting disclosures, and finds that the

[8] Lundholm (1999) points out that this role of accounting can be exploited to increase disclosures on intangible assets. However, if the legal system cannot distinguish between random forecast errors from deliberate management bias, such disclosures can potentially impose significant litigation costs.

[9] Hutton et al. (2000) find that good news forecasts, however, are only informative if they are accompanied by verifiable forward-looking statements.

expanded disclosure is associated with an increase in analysts' forecast accuracy and a decline in dispersion.

Other evidence on the credibility of voluntary disclosure is provided by Amir and Lev (1996). They report that voluntary disclosures such as market population size (POPS) and market penetration have a more significant relation to stock prices than required financial statement information, indicating that investors view such voluntary disclosures as credible. Finally, Frost (1997) finds evidence that disclosure credibility declines for financially distressed firms.

5.2.3. Limitations of studies on voluntary disclosure

One of the major limitations of the above studies is the difficulty in measuring the extent of voluntary disclosure. Researchers use several proxies for this variable, including management forecasts (see Miller and Piotroski, 2000), and metrics based on the AIMR database (see Lang and Lundholm, 1993, 1997; Healy et al., 1999a), and self-constructed measures (see Botosan, 1997; Miller, 1999). However, each approach has its limitations.

There are some significant advantages to using management forecasts as a voluntary disclosure proxy. First, they can be precisely measured. Managers' estimates are typically either point or range estimates for earnings or revenues. Second, the timing of the disclosure is typically known. As a result it is possible to assess whether the forecast preceded or lagged particular changes in variables of interest using daily or weekly data. This enables researchers to conduct more powerful tests of motivations for and consequences of voluntary disclosure.

However, one limitation of management forecasts as a proxy is that their accuracy can be easily verified by outside investors through actual earnings realizations. In contrast, it is more difficult to ex post verify the accuracy of many other types of voluntary disclosures, such as customer satisfaction and human capital. As a result, research using management forecasts as the metric for voluntary disclosure is likely to increase the power of the tests, but these findings may not generalize to other forms of voluntary disclosure.

The AIMR data provides a more general measure of voluntary disclosure than management forecasts. The annual survey produces firm rankings of aggregate voluntary disclosure for each industry covered in the survey, as well as disaggregate rankings for voluntary disclosure published in annual financial statements and 10-Ks, voluntary disclosures published in quarterly financial reports, and voluntary disclosure provided through firms' investor relations. The panels that provide the rankings comprise the leading analysts in each industry, and are therefore likely to be particularly well qualified to judge firms' disclosures. In addition, the metric covers all disclosure, including that through analyst meetings and conference calls. However, it is unclear whether the analysts on the AIMR panels take the ratings seriously, how they select firms to be included in the ratings, and what biases they bring to the ratings.

Studies with self-constructed measures of disclosure face a different set of problems. Because the authors have developed their own metric of voluntary disclosure, there is increased confidence that the measure truly captures what is intended. However, to the extent that construction of the metrics involves judgment on the part of the researcher, the findings may be difficult to replicate. In addition, these metrics typically rely on disclosures provided in the annual report or other such public documents. As a result any disclosures that firms provide in analysts meetings, conference calls, and other such venues are omitted from the analysis.

Endogeneity is a potentially serious problem for some of the above studies. For example, firms that have public capital market transactions are also likely to be facing changes in their investment opportunity sets. It is then difficult to assess whether the relation between high levels of disclosure and increases in disclosure for these firms is attributable to the public issue per se, or to other changes that the firm is experiencing.

Thus, the analyst ratings and self-constructed proxies are likely to be a noisy measure of disclosure. This is likely to reduce the power of the tests used in examining the motives for voluntary disclosure.[10]

6. Capital market consequences of reporting and disclosure

Both the positive accounting theory and the voluntary disclosure literatures have examined the capital market consequences of changes in corporate reporting. Positive accounting theory research has focused on effects of changes in accounting methods and regulatory decisions to change standards. Voluntary disclosure research has examined the capital market effects of changes in corporate disclosure.

6.1. Positive accounting theory literature

As noted above, the major focus of the positive accounting literature has been to document contracting and political factors that explain management financial reporting decisions. However, several studies have examined the economic consequences and shareholder wealth effects of changes in accounting choices. For example, studies of the effects of changes in oil and gas accounting standards find that firms required to change from the full cost

[10] In contrast, the measurement problems that we discussed for the positive accounting literature are for the independent variables, leading to a concern about bias in the findings due to correlated omitted variables.

method to successful efforts experienced a decline in stock prices (see Dyckman and Smith, 1979; Collins et al., 1981). There is some evidence that the decline is correlated with contracting variables (see Lys, 1984). However, studies of the stock price effects of other accounting standards report largely insignificant incremental contracting or political cost effects (Leftwich, 1981). Similarly, studies of firms' accounting method changes indicate that there is generally no significant relation between stock returns at announcement of the accounting change and contracting or political cost considerations (see Holthausen, 1981).

There are at least three potential explanations for this finding. First, accounting decisions have no significant shareholder wealth effects. However, there is some evidence that contradicts this explanation. The oil and gas studies themselves find that there is a significant stock price effect associated with the unanticipated change in accounting standard. Also, Foster (1979) documents significant stock price changes for critiques of firms' accounting decisions by analysts such as Abraham Briloff.[11]

A second explanation is that it is difficult to measure stock price effects for many of the events studied (see Holthausen and Leftwich, 1983; Watts and Zimmerman, 1983). For example, accounting standards are set through a lengthy process, making it difficult to capture shareholder wealth effects of the announcement of the standard itself. Similarly, it is often difficult to identify the date when outside investors first learned of an accounting change. Finally, since accounting changes are often accompanied by other economic changes, it is difficult to isolate the stock price effect of the accounting change itself.

A third explanation for the findings is that contracting and political cost considerations are economically unimportant in explaining wealth effects of reporting changes. Consistent with this explanation, Healy et al. (1987) find that the average annual CEO compensation effects from a change in depreciation accounting method amount to 1.5 percent of their base salary. Since CEO base salary is usually only a small fraction of a firm's market value, this evidence suggests that the CEO compensation effect of depreciation changes on shareholder wealth is likely to be insignificant.[12]

[11] One potential explanation for the market reaction is that Briloff's analysis provides new information about the validity of managers' forecasts underlying their accounting judgments. Some researchers argue that the ''Briloff effect'' reflects changes in the firms' economics subsequent to the publication of his articles, such as tax, litigation and regulatory effects. Foster examines this explanation, and concludes that the non-information related economic factors cannot fully explain the observed market reaction to the accounting critiques.

[12] One explanation for the small economic magnitude of compensation and other contracting effects is that investors anticipate such potential costs in writing the contracts. Surviving contracts, therefore, are likely to be efficient, making the observed contracting costs small. However, this does not suggest that the concept of contracting costs is unimportant for managers' accounting decisions.

6.2. Voluntary disclosure literature

A number of studies examine the economic consequences of voluntary disclosure. These studies argue that there are potentially three types of capital market affects for firms that make extensive voluntary disclosures: improved liquidity for their stock in the capital market, reductions in their cost of capital, and increased following by financial analysts. Each of these effects and the relevant empirical evidence is discussed below. Since many of the studies discussed have common limitations, we discussed these limitations together, subsequent to the presentation of their main findings; the findings summarized below, therefore, should be interpreted with these limitations in mind.

(a) *Improved stock liquidity*

Theory. Diamond and Verrecchia (1991), and Kim and Verrecchia (1994) argue that voluntary disclosure reduces information asymmetries among informed and uninformed investors. As a result, for firms with high levels of disclosure, investors can be relatively confident that any stock transactions occur at a "fair price", increasing liquidity in the firm's stock. In addition, these studies argue that expanded disclosure and stock liquidity will be associated with increased institutional ownership.

Evidence. Several papers provide evidence that is consistent with this hypothesis. Healy et al. (1999a) find that firms that expand disclosure experience significant contemporaneous increases in stock prices that are unrelated to current earnings performance. Gelb and Zarowin (2000) find that firms with high disclosure ratings have high stock price associations with contemporaneous and future earnings relative to firms with low disclosure ratings. These findings suggest that firms' disclosure strategies affect the speed with which information gets into prices.

In addition, several studies attempt to measure stock liquidity and to examine its relation to firm disclosure proxies. Welker (1995) documents a significant negative relation between analysts' ratings of firms' disclosures and bid-ask spreads. Healy et al. (1999a) find firms with increased analyst ratings of disclosure had significantly higher bid-ask spreads than their industries prior to the disclosure change. After the disclosure increase, bid-ask spreads for the sample firms reverted to the same levels as their industry peers. Finally, Leuz and Verrecchia (2000) examine bid-ask spreads for firms listed on the Neuer Market, which has higher disclosure requirements. They find that these firms have lower bid-ask spreads than firms listed on the Frankfurt Exchange.

(b) *Reduced cost of capital*

Theory. As discussed in Section 2, the lemons problem in capital markets creates an incentive for managers to provide voluntary disclosure to reduce the cost of capital. A similar argument is made by Barry and Brown (1984–1986), who note that when disclosure is imperfect, investors bear risks in forecasting the future payoffs from their investment. If this risk is non-diversifiable, investors will demand an incremental return for bearing the information risk. As a result, firms with high levels of disclosure, and hence low information risk, are likely to have a lower cost of capital than firms with low disclosure levels and high information risk.

Evidence. Botosan (1997) provides some evidence consistent with the cost of capital hypothesis. She finds that for firms with low analyst following, there is a negative relation between cost of equity capital and the extent of their voluntary disclosures. Piotroski (1999b) finds that firms providing additional segment disclosures have a contemporaneous increase in the market's capitalization of their earnings, consistent with the firm having a lower cost of capital.[13] Finally, Botosan and Plumlee (2000) find a negative cross-sectional relation between cost of capital and analyst rankings of annual report disclosures. However, they also find that firms' cost of capital is positively related to rankings of quarterly disclosures, and unassociated with investor relations' activities.

(c) *Increased information intermediation*

Theory. Bhushan (1989a, b) and Lang and Lundholm (1996) argue that if management's private information is not fully revealed through required disclosures, voluntary disclosure lowers the cost of information acquisition for analysts and hence increases their supply. However, the effect of voluntary disclosure on the demand for analysts' services is ambiguous. Expanded disclosure enables financial analysts to create valuable new information, such as superior forecasts and buy/sell recommendations, thereby increasing demand for their services. However, public voluntary disclosure also preempts analysts' ability to distribute managers' private information to investors, leading to a decline in demand for their services.

Evidence. Lang and Lundholm (1993) find that firms with more informative disclosures have larger analyst following, less dispersion in analyst forecasts, and less volatility in forecast revisions. Healy et al. (1999a) show that firms with increased analyst ratings of disclosure have lower analyst coverage than their industry peers in the pre-event period. After the increase in disclosure, however, analyst coverage for the sample firms reverts to the same level as other firms in the industry. Finally, Francis et al. (1998) find that there is an increase in analyst coverage for firms making conference calls.

6.3. Limitations of studies of voluntary disclosure capital market consequences

Potential endogeneity is the most important limitation of the above findings. For example, firms with the highest disclosure ratings tend to also show the

[13] The increased segment disclosure is potentially endogenous to the changes in the economics of the sample firms, potentially confounding this conclusion. The endogeneity issue is a common concern for many other studies discussed in this section. We discuss this issue further later.

highest contemporaneous earnings performance (see Lang and Lundholm, 1993). This may be caused by a self-selection bias—firms may increase disclosure when they are performing well. As a result the association between capital market variables and disclosure may be driven by firm performance rather than disclosure per se. More generally, disclosure changes are unlikely to be random events: they are likely to coincide with changes in firm economics and governance.

Several studies attempt to control for performance changes to isolate the impact of disclosure. For example, Healy et al. (1999a) control for contemporaneous earnings levels and earnings changes in examining the cross-sectional relation between disclosure increases and variables such as stock performance, analyst following, institutional ownership, and analyst forecast dispersion. However, such controls are likely to be imperfect in the absence of a reliable model of the relation between performance and disclosure. In addition, as noted above, there are likely to be other correlated omitted variables in these analyses.

A related problem with both AIMR and self-constructed measures of voluntary disclosure is that it is difficult to precisely define the timing of any change in disclosure. Typically disclosure is measured for a given year, making it difficult to infer whether disclosure changes followed or preceded changes in variables of interest. Consequently, it is difficult to draw strong conclusions about the direction of causality underlying the documented associations.

7. Where do we go from here?

Empirical research discussed in this paper supports the following broad conclusions: (1) Regulated financial reports are informative to investors, and the degree of informativeness varies systematically with firm and economy characteristics. (2) Financial analysts add value in the capital market through their analysis of firms' financial reporting decisions, forecasts of future earnings, and buy/sell recommendations. (3) There is a market-driven demand for auditing services. (4) Both financial analysts and auditors are imperfect intermediaries, in part because of incentive conflicts. (5) Managers' financial reporting and disclosure choices are associated with contracting, political cost, and capital market considerations. (6) Disclosure is associated with stock price performance, bid-ask spreads, analysts' following, and institutional ownership.

Despite the progress in the last 30 years, many of the questions identified in Table 1 have yet to be fully addressed, or are not yet answered. Some fundamental unanswered questions we identify throughout the paper include: (1) What is the objective of disclosure regulation, and what is its effect on capital market development? (2) What types of accounting standards produce high quality financial reports? (3) Do auditors enhance the credibility of financial statements? (4) Why are sell-side analysts' forecasts and recommendations credible given their well-documented biases and conflicts of interests? (5) What is the role of analysts in rapid swings in stock prices? (6) Why do firms engage in voluntary disclosure? (7) Does disclosure affect firms' cost of capital?

In addition to these unanswered questions, we believe that recent macro-economic forces create several new opportunities for research. We discuss four forces: rapid technological innovations, the advent of network organizations, changes in business economics of audit firms and financial analysts, and globalization.

(a) *Rapid technological innovation*

There have been phenomenal technological innovations in the last 20 years in areas such as computers, communications, biotechnology, and the internet. The economic consequences of these innovations are typically not reflected in financial statements in a timely manner. Except for software R&D occurring after technological feasibility, US firms expense R&D outlays immediately, regardless of their economic values. As a result, investors that are interested in assessing the potential economic performance of innovative firms in the current period, as well as potential future benefits from innovations-in-progress are forced to look beyond the financial statements.

Chang (1998) and Lev and Zarowin (1999) find that the decline in value relevance of financial statement items is partially explained by an increase in innovation. Further, Amir and Lev (1996) show that for firms in the wireless communications industry non-financial indicators of performance, such as market population size (POPS) and market penetration, have a more significant relation to stock prices than financial statement information.

Technological innovation has also created new channels for investor communication. For example, conference calls and the internet make it easier for firms to communicate rapidly with key investors and financial intermediaries. Conference calls are large-scale telephone conversations between managers and key financial analysts, where managers provide voluntary disclosure by answering analysts' questions about the firm's current and future performance. Tasker (1998) documented that 35% of mid-sized firms hosted a conference call in the period 1995–1996 and that many firms used this channel to mitigate limitations in required financial reporting.

The internet provides management with the opportunity to access all investors and to provide daily updates of important information. Many corporate internet sites provide an overview of the company's performance, a review of performance, press releases, stock quotes, frequently asked investor relations questions, earnings forecasts (by financial analysts), as well as annual reports, SEC reports. The increasing use of the internet by investors is likely to continue, reducing the costs of providing voluntary disclosures and presumably increasing their supply.

(b) *Network organizations*

Innovations in organizational forms, such as closely-coordinated supply chains and strategic alliances, also significantly affect the nature of financial reporting and disclosure. These organizational forms facilitate efficient risk sharing and market-based coordination of activities that were traditionally performed internally. However, by blurring the boundaries of firms, they pose difficult challenges to the entity measurement concept. For example, it is difficult for financial statements to fully reflect the complex relations and implicit commitments that underlie network relations between Coca Cola Company and its bottlers. As a result of its exclusive contracts with bottlers, Coke has been able to outsource the capital-intensive, low margin activities for its business. Consequently, bottlers have reported marginal financial performance while Coke has shown strong earnings performance. However, the reported financial performance of Coke does not fully reflect the complex relationship and implicit commitments between the companies. Reflecting these types of interdependencies in financial statements is challenging for standard setters. Current standards ignore them, potentially reducing the timeliness of accounting information.

(c) *Changes in business economics of audit firms and financial analysts*

A third current phenomenon is changing business economics of audit firms and financial analysts. Audit firms are increasingly reliant on management consulting, rather than assurance services. Regulators and commentators have argued that there is a potential conflict between the two. For example, they question whether an audit firm will challenge management of corporate clients if the same management is responsible for hiring the audit firm for a consulting engagement. To our knowledge there is no large sample empirical evidence of a decline in the credibility of audit reports. However, the issue has prompted the SEC to propose that audit firms divest their consulting practices and disclose consulting fees for each of their clients.

There have also been changes in the business model of financial analysts. The decline in trading costs has reduced soft dollars available for funding research. Therefore, these activities are increasingly linked to investment banking and underwriting activities. In addition, leading financial analysts are beginning to be viewed as strategy advisors to the companies that they are analyzing. For example, the financial press is replete with stories on the increasingly important roles of telecommunication analyst Jack Grubman and internet analyst Mary Meeker in the strategic decisions of their respective industries (see Business Week, 2000). These trends are likely to exacerbate potential conflicts of interest that analysts face, raising questions about the effectiveness as information intermediaries.

(d) *Globalization*

Capital markets are becoming increasingly global as a result of a variety of developments. Institutional investors are looking to diversify by investing around the globe; corporations are seeking capital wherever the terms are most attractive; and internet-based trading is making it easier for individual investors to invest in international capital markets. Financial deregulation is encouraging these activities.

The globalization of capital markets has been accompanied by calls for globalization of financial reporting. This raises several interesting questions. First, is it optimal to have a global accounting standard setter given wide disparities in the development of financial reporting infrastructure across counties? Second, what economic forces will determine the speed with which convergence of financial reporting institutions will take place? Third, what are the political and economic consequences of such a convergence? Fourth, in the absence of convergence, will financial reporting informativeness be enhanced by global accounting standards?

In summary, the increased pace of entrepreneurship and economic change has probably increased the value of reliable information in capital markets. However, the traditional financial reporting model appears to do a poor job of capturing the economic implications of many of these changes in a timely way. There is, therefore, an opportunity for future disclosure research to examine how financial reporting and disclosures adapt to changes in business and capital market environments. In addition, as we note earlier, there are many areas where our understanding of existing disclosure institutions and phenomena are limited. We believe that both opportunities make the disclosure area an exciting area of study for accounting scholars.

Capital markets research in accounting ☆

S.P. Kothari*

Sloan School of Management, Massachusetts Institute of Technology, Cambridge, MA 02142, USA

Received 22 November 1999; received in revised form 8 March 2001

Abstract

I review empirical research on the relation between capital markets and financial statements. The principal sources of demand for capital markets research in accounting are fundamental analysis and valuation, tests of market efficiency, and the role of accounting numbers in contracts and the political process. The capital markets research topics of current interest to researchers include tests of market efficiency with respect to accounting information, fundamental analysis, and value relevance of financial reporting. Evidence from research on these topics is likely to be helpful in capital market investment decisions, accounting standard setting, and corporate financial disclosure decisions. © 2001 Elsevier Science B.V. 1. Introduction

1.1. Objective of the review article

My assignment is to review research on the relation between capital markets and financial statements. This is a broad area of research that originated with the seminal publication of Ball and Brown (1968). The literature has grown rapidly with over 1000 published papers in leading academic accounting and finance journals in the past three decades. The approach I adopt for the review involves a survey of the literature using an economics-based framework. I begin with a discussion of the demand for and supply of research on the relation between financial information and capital markets. This is the organizing framework of my discussion of various areas within capital markets research.

An important objective of the review is to produce a pedagogically valuable document. Toward this end, the review extends at least two previous comprehensive surveys of the capital markets research in accounting by Lev and Ohlson (1982) and Bernard (1989). Because they provide in-depth summaries of research in the 1970s and 1980s, the bulk of the research examined in my study is from the late 1980s and 1990s. In addition to offering a fairly detailed summary of research in the past 10–15 years, I discuss the genesis of important ideas in the literature and the concurrent developments that stimulated many of the ideas. I also critically evaluate the research findings and research designs employed in past research. The main objective is to offer competing hypotheses and explanations for the observed findings. This naturally leads to unresolved issues and directions for future research noted throughout the review. I hope doctoral students (and their instructors) find the study useful in preparing themselves for successful careers in research.

I review almost exclusively empirical capital markets research. However, empirical research is (or should be) informed by theory, since interpretation of empirical analysis is impossible without theoretical guidance. Therefore, I refer to the underlying theory and alternative hypotheses that bear on the analysis, some of which Verrecchia (2001) reviews.

While I attempt to be thorough, my own tastes and interests as well as my differential expertise in various areas within capital markets research influence the review's contents. In addition, within the empirical capital markets area, there are at least three topics that are examined extensively elsewhere. Holthausen and Watts (2001) present a critical assessment of the research on value relevance in the context of standard setting. Healy and Palepu (2001) evaluate empirical research on corporate disclosure and Shackelford and Shevlin (2001) examine tax-related capital markets research. Accordingly, I do not discuss the capital markets research in the above three areas, although I make references to them.

1.2. Summary

Capital markets research in accounting includes several topics, including research on earnings response coefficients and properties of analysts' forecasts, fundamental analysis and valuation research, and market efficiency tests. Instead of summarizing each topic, I comment on areas of current interest in capital markets research and offer thoughts on how academics can prepare themselves for producing high impact research.

The capital market research topics of primary interest to researchers currently appear to be tests of market efficiency with respect to accounting information (e.g., accounting methods and accruals), fundamental analysis and accounting-based valuation, and value relevance of financial reporting (see Holthausen and Watts, 2001). The mounting evidence of apparent market inefficiency documented in the financial economics and accounting literature has fueled accounting researchers' interest in fundamental analysis, valuation, and tests of market efficiency. Evidence of market inefficiency has created an entirely new area of research examining long-horizon stock-price performance following accounting events. This is in sharp contrast to the boom in short-window event studies and studies of economic consequences of standard setting of the 1970s and 1980s. Future work on tests of market efficiency with respect to accounting information will be fruitful if it recognizes that (i) deficient research design choices can create the false appearance of market inefficiency; and (ii) advocates of market inefficiency should propose robust hypotheses and tests to differentiate their behavioral-finance theories from the efficient market hypothesis that does not rely on irrational behavior.

I expect capital markets research on issues surrounding market efficiency, fundamental analysis, and valuation to continue. It is worthwhile thinking about how best to prepare for such research. A historical perspective provides helpful guidance. Capital markets research in accounting began in the late 1960s soon after the development of the efficient markets hypothesis and event study methodology (see Section 3) at the University of Chicago. Many of the early capital markets investigators in accounting also came from Chicago and were typically trained in finance and economics. I believe future successful capital markets researchers will also be similarly well trained with a solid grounding in economics-based and behavioral theories of market inefficiency, which have begun to mushroom in finance and economics. This will prepare accounting academics to make a meaningful contribution, not simply within the field of accounting, but in finance and economics as well.

1.3. Outline of the review

Section 2 presents a discussion of the sources of demand for capital markets research in accounting. I review early capital markets research in Section 3, primarily with a pedagogical motivation. It contains an overview of the state of accounting research in the era prior to the Ball and Brown (1968) and Beaver (1968) and the developments in finance and economics in the mid-1960s that facilitated capital markets research in accounting. I discuss much of the capital markets research in the past two decades in Section 4. Section 4 is split into four subsections. Section 4.1 examines methodological research. Section 4.2 focuses on research evaluating alternative performance measures. Fundamental analysis research in accounting is the topic of Section 4.3 and tests of market efficiency in accounting are critically evaluated in Section 4.4. Capital markets research on standard setting is also a capital markets research topic, but I refer the reader to the Holthausen and Watts (2001) review. Section 5 presents a summary and conclusions.

2. Demand for capital markets research in accounting

A large fraction of published research in leading academic accounting journals examines the relation between financial statement information and capital markets, referred to as capital markets research. This voluminous published research is an indication of the demand for capital markets research.[1] There are at least four sources of the demand for capital markets research in accounting that explain its popularity: (i) fundamental analysis and valuation; (ii) tests of capital market efficiency; (iii) role of accounting in contracts and in the political process; and (iv) disclosure regulation. I discuss the four sources of demand for capital markets research below, and list the types of research studies I subsequently summarize in the review. While I believe the four sources account for a large fraction of the demand for capital markets research in accounting, these sources are neither mutually exclusive nor collectively exhaustive.

2.1. Fundamental analysis and valuation

Shareholders, investors, and lenders have an obvious interest in the value of a firm. In an efficient market, firm value is defined as the present value of expected future net cash flows, discounted at the appropriate risk-adjusted rate

[1] I do not examine the decline in the cost of doing capital market research as an explanation for the explosive growth in the supply of capital market research over the past three decades. The cost has declined with the low-cost availability of computing power, statistical packages, and machine-readable databases such as security price data from the Center for Research in Security Prices (CRSP), financial statement data from Standard & Poor's Compustat, and analysts' forecast data from Institutional Brokers Estimate System (IBES).

of return. A firm's current performance as summarized in its financial statements is an important, but not the only input to the market's assessment of the firm's future net cash flows and thus into the firm's market valuation. This is consistent with the Financial Accounting Standard Board's (FASB's) conceptual framework that financial statements should help investors and creditors in "assessing the amounts, timing, and uncertainty" of future cash flows (FASB, 1978). Therefore, a temporal association between current financial performance and future cash flows, as well as a contemporaneous association between financial performance and security prices or price changes is expected. An important goal of capital markets research is to provide evidence on these relations.

The principal focus of fundamental analysis is on valuation aimed at identifying mispriced securities. This has been popular at least since Graham and Dodd published their book *Security Analysis* in 1934.[2] A large fraction of the nearly $5 trillion currently invested in US mutual funds is actively managed, with fundamental analysis as the guiding principle of most mutual fund managers. Fundamental analysis entails the use of information in current and past financial statements, in conjunction with industry and macroeconomic data to arrive at a firm's intrinsic value. A difference between the current price and the intrinsic value is an indication of the expected rewards for investing in the security. Capital markets research on fundamental analysis has become extremely popular in recent years in part because of mounting evidence in the financial economics literature against the efficient markets hypothesis. The belief that "price convergence to value is a much slower process than prior evidence suggests" (Frankel and Lee, 1998, p. 315) has acquired currency among leading academics, spurring research on fundamental analysis. Capital markets research on fundamental analysis examines whether it successfully identifies mispriced securities. Fundamental analysis research thus cannot be disentangled from capital markets research on testing market efficiency.

The research on valuation and fundamental analysis that I review includes valuation models, such as those presented in Fama and Miller (1972, Chapter 2), Beaver et al. (1980), Christie (1987), Kormendi and Lipe (1987), Kothari and Zimmerman (1995), Ohlson (1995), and Feltham and Ohlson (1995). I then examine recent empirical applications of the valuation models like Dechow et al. (1999) and Frankel and Lee (1998). Finally, I discuss studies that employ fundamental analysis to forecast earnings and future stock returns (i.e., a test of market efficiency). Examples include Ou and Penman (1989a, b), Stober (1992), Lev and Thiagarajan (1993), Abarbanell and Bushee (1997, 1998), and Piotroski (2000).

[2] Recent editions of the book are titled "Graham and Dodd's Security Analysis" by Cottle et al. (1988).

2.2. Tests of market efficiency

Fama (1970, 1991) defines an efficient market as one in which "security prices fully reflect all available information". Whether security markets are informationally efficient is of great interest to investors, managers, standard setters, and other market participants. The interest stems from the fact that security prices determine the allocation of wealth among firms and individuals. The security prices themselves are influenced by financial information, which explains academic and practicing accountants and standard setters' interest in market efficiency research.

Market efficiency has important implications for the accounting profession. For example, rewards from fundamental analysis would diminish in an efficient market. A switch from one accounting method to another without a direct cash flow effect, a signaling effect, or incentive consequences does not affect security prices in an efficient market. Choice between disclosure in footnotes and recognition in financial statements (e.g., accounting for employee stock options) is less contentious from the perspective of its effect on security prices in an efficient market. Naturally, the opposite would be true in all of the above examples if markets were not efficient. Therefore, there is a demand for empirical research on market efficiency.

There is a huge literature testing market efficiency in finance, economics, and accounting. I concentrate on the literature in accounting. The accounting literature draws inferences about market efficiency from two types of tests: short- and long-horizon event studies and cross-sectional tests of return predictability or the anomalies literature. Event studies, which constitute the bulk of the literature, include the post-earnings-announcement drift literature (e.g., Ball and Brown, 1968; Foster et al., 1984; Bernard and Thomas, 1989, 1990; Ball and Bartov, 1996; Kraft, 1999); market efficiency with respect to accounting methods and method changes and research on functional fixation (e.g., Ball, 1972; Kaplan and Roll, 1972; Dharan and Lev, 1993; Hand, 1990; Ball and Kothari, 1991); and accrual management and analyst forecast optimism and long-term returns to initial public offerings and seasoned equities (e.g., Teoh et al., 1998a, b; Dechow et al., 1999; Kothari et al., 1999b).

Cross-sectional tests of return predictability, or the anomalies literature, examine whether the cross section of returns on portfolios formed periodically using a specific trading rule is consistent with a model of expected returns like the CAPM. The trading rules used have been either univariate indicators like earnings yield, or multivariate indicators employing a fundamental analysis of accounting ratios. Examples of research using univariate indicators are tests of the market's (mis)pricing of earnings and cash flow yield (e.g., Basu, 1977, 1983; Lakonishok et al., 1994), accounting accruals (e.g., Sloan, 1996; Xie, 1997; Collins and Hribar, 2000a, b), and analysts' forecasts (e.g., LaPorta, 1996; Dechow and Sloan, 1997). Examples of tests using multivariate indicators to earn long-horizon abnormal returns include ratio-based fundamental analysis (e.g., Ou and Penman, 1989a, b; Greig, 1992; Holthausen and Larcker, 1992; Abarbanell and Bushee, 1997, 1998), and fundamental value strategies (e.g., Frankel and Lee, 1998).

2.3. Role of accounting in contracts and in the political process

Positive accounting theory (see Watts and Zimmerman, 1986) predicts that the use of accounting numbers in compensation and debt contracts and in the political process affects a firm's accounting choices. A large body of literature in accounting tests predictions of positive accounting theory. Many of these tests entail the use of capital market data. For example, tests of the economic consequences of accounting examine stock price reactions to new accounting standards, and study whether cross-sectional variations in these stock price reactions are related to financial variables that proxy for contracting and/or political costs. To perform powerful tests of positive accounting theory and to ameliorate the effects of correlated omitted variables on the tests, researchers attempt to control for the effect of financial information on security prices that is unrelated to the positive accounting theory.[3] This creates a demand for capital markets research that aids researchers in designing more powerful stock-price-based tests of the positive accounting theory.

I review a large body of methodological capital markets research that facilitates research on positive accounting theory. The methodological research includes the earnings response coefficient literature (e.g., Kormendi and Lipe, 1987; Easton and Zmijewski, 1989; Collins and Kothari, 1989); research on the properties of time series, management, and analysts' forecasts of earnings (e.g., Ball and Watts, 1972; Foster, 1977; Brown and Rozeff, 1978; Patell, 1976; Penman, 1980; Waymire, 1984); research about problems in drawing statistical inferences (e.g., Collins and Dent, 1984; Bernard, 1987); and discretionary accrual models (e.g., Healy, 1985; Jones, 1991; Dechow et al., 1995; Guay et al., 1996).

2.4. Disclosure regulation

In the US, the FASB, with authority delegated by the Securities and Exchange Commission (SEC), is charged with issuing standards that govern

[3] Watts (1992) makes a symmetric argument in the context of tests of the relation between financial statement numbers and stock prices. He contends that in order to perform powerful tests of competing theories about the relation between accounting numbers and stock prices, it behooves researchers to include positive accounting theory-based variables in the tests to control for their effects that are correlated with the capital market relations being tested.

the disclosure of financial information by publicly traded firms. Capital markets research can help ascertain whether FASB's stated objectives are served by the standards it has issued, either singly or collectively. For example, do financial statement numbers prepared according to a new standard convey new information to the capital markets? Are financial statement numbers prepared according to a new standard more highly associated with contemporaneous stock returns and prices? What are the economic consequences of the issuance of a new disclosure standard? The nature and extent of standard setting is also likely influenced by standard setters' perception of whether security markets are informationally efficient. Thus, standard setters have an interest in the capital markets research on tests of market efficiency.

Internationally, standard setters presumably seek evidence from capital markets research. The rapid globalization of capital, product, and labor markets has created a strong demand for international accounting standards in recent years. Perhaps the most important issue facing practitioners, and standard setters is whether there should be a uniform set of accounting standards or whether there should be diversity. If standards were to be uniform, should US generally accepted accounting principles (GAAP) be the standard? Or should standards be developed internationally? Or should standards differ across nations, depending on differences in legal, political, and economic environments? Are capital markets in other countries as (in)efficient as they are in the US, which could affect the nature of international accounting standards? Interest in these and related issues has precipitated a demand for capital markets research using international accounting and capital markets data.

Holthausen and Watts (2001) review and analyze the capital markets research on issues surrounding disclosure regulation, so I refrain from reviewing this area of capital markets research in detail.

3. Early capital markets research

Ball and Brown (1968) and Beaver (1968) heralded empirical capital markets research as it is now known. This section describes the state of accounting theory and thought that preceded the positive-economics-based empirical capital markets research of the late 1960s. Concurrent developments in economics and finance constituted the theoretical and methodological impetus to the early capital markets research in accounting. In my opinion, this historical detour exploring the forces that shaped early capital markets research has positive pedagogical externalities, particularly for guiding new researchers. Seasoned researchers can skip over portions of this section without a loss of continuity.

More importantly, another reason for a historical review is that capital markets research in accounting today appears to be in a similar state as accounting theory was prior to 1968. The efficient markets hypothesis and positive economics, as well as other related developments, facilitated the birth of capital markets research in the 1960s. In contrast, theoretical models of inefficient capital markets, research methodology, and evidence of apparent market inefficiency are the catalysts for a large portion of the capital markets research in accounting today.

3.1. The state of accounting theory in the early 1960s

Until the mid-1960s, accounting theory was generally normative. Accounting theorists advanced their accounting policy recommendations on the basis of an assumed set of accounting objectives. Hendriksen (1965, p. 2) defines "a most appropriate theory" as one that "supports the development of procedures and techniques that best fulfill the objectives of accounting".[4] He adds, "One of the first steps in the development of accounting theory, therefore, is a clear statement of the objectives of accounting." Thus, theory development depended on the objectives assumed by a researcher, and theory evaluation was based on logic and deductive reasoning. There was little emphasis on the empirical validity of the theory's predictions.

Since the theories were logically consistent, the basis for selecting one accounting policy over another was reduced to choosing among alternative objectives of accounting. However, since individuals disagreed on the objectives of accounting, there was no consensus on the optimal set of accounting policies. This led to skepticism about the usefulness of accounting income reported in the financial statements. Hendriksen (1965, p. 97) observes that "already there are rumblings that the income statement will see its demise in the near future unless drastic changes are made to improve the story it tells". For a variety of reasons, many doubted whether historical cost accounting numbers conveyed useful information about, or an accurate assessment of, a firm's financial health.

3.2. Concurrent developments that facilitated capital markets research in accounting

While accounting theorists and practitioners held a dim view of whether historical cost accounting numbers accurately reflected a firm's financial health, scientific evidence on the issue did not exist. Providing empirical evidence to

[4] I use the discussion of accounting theory in Hendrikson's book as a reasonable description of the state of accounting theory at the time. That description is similar to the one in Ball and Brown (1968) and Watts and Zimmerman (1986, Chapter 1).

ascertain whether accounting numbers contained or conveyed information about a firm's financial performance was the major motivation that led to the research of Ball and Brown (1968) and Beaver (1968). There were three major concurrent developments in finance and economics that forged the way for the seminal research by both Ball and Brown (1968) and Beaver (1968): (i) positive economics theory, (ii) the efficient markets hypothesis and the capital asset pricing model (CAPM) and (iii) the event study of Fama et al. (1969).

3.2.1. Positive economics

Friedman (1953) was perhaps the most prominent among those who were instrumental in making positive, as opposed to normative, science the mainstream research methodology in economics, finance, and accounting. Following Keynes' (1891) definition of positive science as "a body of systematized knowledge concerning what is", Friedman (1953, p. 7) describes positive science as "the development of a 'theory' or 'hypothesis' that yields valid and meaningful (i.e., not truistic) predictions about phenomena yet to be observed". Most accounting research since Ball and Brown (1968) and Beaver (1968) is positive and the role of accounting theory is no longer normative. Watts and Zimmerman (1986, p. 2) state: "The objective of accounting theory is to *explain* and *predict* accounting practice." This is noteworthy departure from the widespread practice of normative accounting theory.

3.2.2. Efficient markets hypothesis and the capital asset pricing model (CAPM)

Building on past theoretical and empirical work, Fama (1965) introduced, and subsequently made major contributions to the conceptual refinement and empirical testing of the efficient markets hypothesis. Fama (1965, p. 4) notes "In an efficient market, *on the average*, competition" among rational, profit-maximizing participants "will cause the full effects of new information on intrinsic values to be reflected 'instantaneously' in actual prices".

The maintained hypothesis of market efficiency opened the doors for positive capital markets research in accounting. Ball and Brown (1968, p. 160) assert that capital market efficiency provides "justification for selecting the behavior of security prices as an operational test of usefulness" of information in financial statements. Beaver (1968) offers a similar argument. Unlike previous normative research on accounting theories and optimal accounting policies, positive capital markets research began using changes in security prices as an objective, external outcome to infer whether information in accounting reports is useful to market participants.

Sharpe (1964) and Lintner (1965) developed the capital asset pricing model, CAPM. The CAPM predicts that a security's expected rate of return is increasing in the *covariance* risk of its cash flows, which is the covariance of a security's expected return with the expected return on the market portfolio. Therefore, a portion of the cross-sectional variation in security returns is due to differences in the covariance risks of the securities. This risk-related variation in returns is generally not of interest to researchers who focus on firm-specific accounting information and its relation to the firm-specific component of the stock return. Therefore, the CAPM, along with the efficient market hypothesis, greatly facilitated the estimation of the firm-specific return component. The use of the firm-specific component alone enhances the power of the tests of information content of accounting reports (Brown and Warner, 1980, 1985).

3.2.3. Event study of Fama et al. (1969)

Fama et al. (1969) conducted the first event study in financial economics. Event studies are joint tests of market efficiency and the model of expected rates of return used in estimating abnormal returns. Fama et al.'s research design innovation permits researchers to align sample firms in event time and to then examine their security price performance before, during, and after economic events such as stock splits (Fama et al., 1969) and earnings announcements (Ball and Brown, 1968; Beaver, 1968).

3.2.4. Positive accounting theory development: a short detour

Circumstances similar to those that facilitated the Ball and Brown (1968) study also contributed to Watts and Zimmerman's positive accounting theory that revolutionized the accounting literature in the late 1970s (see Watts and Zimmerman, 1978, 1979, 1983, 1986). Watts and Zimmerman capitalized on the concurrent developments in finance and economics to explain some of the puzzles facing accounting researchers and practitioners. The impetus to Watts and Zimmerman's work was the seminal work of Jensen and Meckling (1976) and Ross (1977) that altered the course of the corporate finance literature. Jensen and Meckling (1976) articulate the implications of the agency problem between a firm's shareholders (principal) and the management (agent) and between shareholders and bondholders in an informationally efficient capital market. The agency problem arises in part because of the imperfect observability of managerial effort and costly contracting. This nexus of contracts view of a corporation enabled Watts and Zimmerman to develop hypotheses as to why there should be predictable variation in how firms account for their economic activities as well as why accounting standards would matter, even if capital markets were informationally efficient.

Watts and Zimmerman's political cost hypothesis extends the economics literature on regulation in a political process, as distinct from a market process (see Olson, 1971; Stigler, 1971; Posner, 1974; McCraw, 1975; Peltzman, 1976; Watts and Zimmerman, 1986, Chapter 10). Thus, the insight that led to the development of Watts and Zimmerman's positive accounting theory involves the accounting implications of the concurrent theoretical developments in finance and economics. Watts and Zimmerman then tailored those theories to explain accounting phenomena.

3.3. Association and event studies

Ball and Brown (1968) and Beaver (1968) are the pioneering studies in capital markets research in accounting. Both perform an event study and Ball and Brown also conduct an association study. Both types of studies are now common in the literature.

In an event study, one infers whether an event, such as an earnings announcement, conveys new information to market participants as reflected in changes in the level or variability of security prices or trading volume over a short time period around the event (see Collins and Kothari, 1989, p. 144; Watts and Zimmerman, 1986, Chapter 3). If the level or variability of prices changes around the event date, then the conclusion is that the accounting event conveys new information about the amount, timing, and/or uncertainty of future cash flows that revised the market's previous expectations. The degree of confidence in this conclusion critically hinges on whether the events are dispersed in calendar time and whether there are any confounding events (e.g., a simultaneous dividend and earnings announcement) co-occurring with the event of interest to the researcher. As noted earlier, the maintained hypothesis in an event study is that capital markets are informationally efficient in the sense that security prices are quick to reflect the newly arrived information. Because event studies test for the arrival of information through an accounting event, they are also referred to as tests of information content in the capital markets literature in accounting. Besides Ball and Brown (1968) and Beaver (1968), other examples of event studies include Foster (1977), Wilson (1986), Ball and Kothari (1991), Amir and Lev (1996), and Vincent (1999).

An association study tests for a positive correlation between an accounting performance measure (e.g., earnings or cash flow from operations) and stock returns, both measured over relatively long, contemporaneous time periods, e.g., one year. Since market participants have access to many more timely sources of information about a firm's cash flow generating ability, association studies do not presume that accounting reports are the only source of information to market participants. Therefore, no causal connection between accounting information and security price movements is inferred in an association study. The objective is to test whether and how quickly accounting measures capture changes in the information set that is reflected in security returns over a given period. In addition to Ball and Brown (1968), other pertinent studies include Beaver et al. (1980), Rayburn (1986), Collins and Kothari (1989), Livnat and Zarowin (1990), Easton and Harris (1991), Easton et al. (1992), Dechow (1994), and Dhaliwal et al. (1999).

3.4. Early evidence from event studies and association studies

3.4.1. Event study evidence

Ball and Brown (1968) and Beaver (1968) provide compelling evidence that there is information content in accounting earnings announcements. Ball and Brown correlate the sign of the abnormal stock return in the month of an earnings announcement with the sign of the earnings change over that firm's previous year's earnings. They find a significantly positive correlation.

The maintained hypothesis underlying the Ball and Brown test is that the earnings expectation model is well specified in providing a clean measure of earnings surprise. That is, at least a portion of the earnings increase experienced by the firms classified as "good news" firms was a favorable surprise to the market, which led to increased security prices. Thus, the strength of the association between earnings announcement period abnormal return and the earnings surprise is a function of both the information content of earnings and the quality of the earnings expectation model employed. Ball and Brown provide evidence using two earnings expectation models: a simple random walk model and a market model in earnings.

Beaver (1968) circumvents the problem of specifying an earnings expectation model by examining the variability of stock returns and trading volume around earnings announcements. Beaver hypothesizes that the earnings announcement period is characterized by an increased flow of information compared to a non-earnings announcement period. He uses return volatility to infer the flow of information. The evidence supports Beaver's hypothesis.

Beaver also tests for the flow of information by comparing trading volume in the earnings announcement periods to that in the non-announcement periods. The notion here is that market participants have heterogeneous expectations about a forthcoming earnings announcement. Earnings announcements resolve some of the uncertainty and thus narrow the heterogeneity of beliefs, but in the process contribute to increased trading among the market participants who might have taken positions based on their pre-earnings announcement period heterogeneous expectations.[5]

3.4.2. Association study evidence

The Ball and Brown evidence clearly demonstrates that accounting earnings contemporaneously capture a portion of the information set that is reflected in security returns. The evidence also suggests that competing sources of information (including quarterly earnings) preempt the information in annual

[5] Recent models of investors' belief revision show that increased heterogeneity is also possible as a consequence of news events such as an earnings announcement (see Harris and Raviv, 1993; Kandel and Pearson, 1995; Bamber et al., 1999).

earnings by about 85%. In this sense, annual accounting numbers are not a particularly timely source of information to the capital markets.

The use of annual earnings to infer earnings' timeliness weakens the case in favor of earnings' timeliness because one of the sources of other information to the capital markets is quarterly earnings (see Foster, 1977). Even so, earnings are unlikely to be a particularly timely source of information. Because accounting earnings measurement rules emphasize transaction-based revenue recognition, compared to the stock market's focus on current and expected future net revenues, earnings' lack of timeliness is not surprising (e.g., Beaver et al., 1980; Collins et al., 1994). In other words, stock prices lead accounting earnings in terms of reflecting new information.

In addition to studying the association and information content of accounting earnings with respect to security returns, Ball and Brown also test for market efficiency by examining whether the market's reaction to good and bad news earnings announcement is quick and unbiased. They find preliminary evidence of a post-earnings announcement drift in that the market's adjustment to bad news in particular takes several months. This suggests market underreaction and subsequent gradual adjustment to the information in earnings. While Ball and Brown provide preliminary evidence of a post-earnings announcement drift, the anomaly literature on the drift took a solid root with the works of Jones and Litzenberger (1970), Litzenberger et al. (1971), Foster et al. (1984), and Bernard and Thomas (1989, 1990).[6] This research is reviewed in Section 4 under tests of market efficiency.

Ball and Brown also compare the informativeness of earnings and cash flows to test whether the accrual process makes earnings more informative than cash flows. Their evidence suggests the annual abnormal return adjustment is greater for earnings changes than for cash flow changes, consistent with the accrual process making earnings more informative. Following Ball and Brown, a long stream of research examines the relative informativeness of earnings and cash flows.[7] This research is reviewed in Section 4.

3.5. Beyond the early evidence

Ball and Brown (1968) and Beaver (1968) spawned an industry of capital markets research, which is systematically reviewed in the next two sections. Some of the research following Ball and Brown and Beaver replicates their results in different settings, e.g., in different countries, using interim earnings compared to annual earnings, using shorter earnings announcement periods, and by examining both the sign and magnitude compared to only the sign in

[6] See Ball (1978) for an early survey of this literature.

[7] Examples include Rayburn (1986), Bowen et al. (1987), Wilson (1986, 1987), Bernard and Stober (1989), Livnat and Zarowin (1990), and Dechow (1994).

Ball and Brown. I review this and subsequent capital markets research in Sections 4 and 5.

3.5.1. Market efficiency and evaluation of accounting standards

The early evidence of earnings' association with security returns and evidence of capital market efficiency in finance and economics led some accounting researchers to draw standard-setting implications.[8] For example, Beaver (1972) in the *Report of the American Accounting Association Committee on Research Methodology in Accounting*, suggests that the association of accounting numbers with security returns can be used to rank order alternative accounting methods as a means of determining the accounting method that should become a standard. The report states that the "method which is more highly associated with security prices… ought to be the method reported in the financial statements" (p. 428), subject to considerations of competing sources of information and costs.[9]

The initial high expectations of the usefulness of capital markets research in guiding accounting standard setters to the socially most desirable accounting methods proved ephemeral. Gonedes and Dopuch (1974) and others quickly pointed out weaknesses (e.g., the free rider problem of non-purchasers' access to accounting information) in using the strength of the association with security returns as a determining criterion for the social desirability of an accounting standard. The debate, however, continues.

Many advocate changes in financial accounting standards because of the perception that current GAAP earnings have low correlation with security prices (e.g., Lev, 1989). They propose alternative accounting methods that arguably would improve the correlation with stock returns (e.g., Lev and Zarowin, 1999). Others contend that the correlation between accounting numbers and security returns would be a function of the objectives of financial statements. There is a demand for objective, verifiable information that is useful for contracting and performance evaluation purposes (Watts and Zimmerman, 1986). Such demand skews the accounting process in the direction of presenting historical information summarizing the effects of actual, rather than expected, transactions, i.e., the application of the revenue recognition principle. In contrast, security price changes primarily reflect revisions in expectations of future profitability. Consequently, the contemporaneous return–earnings association is expected to be small (Kothari, 1992). Commenting on standard setting and the research on the association between security returns and financial information, Lee (1999, p. 13) concludes: "Until accounting regulators decide that reported earnings should include anticipated profits from future exchanges (that is, until we abandon the "revenue

[8] Holthausen and Watts (2001) discuss this topic in detail.

[9] Also see Beaver and Dukes (1972) and Gonedes (1972).

recognition" principle), it is difficult to see how higher correlation with contemporaneous returns should have *any* standard setting implications."[10]

Notwithstanding the conceptual debate over the appropriateness of the correlation with security returns as a criterion for evaluating financial accounting standards, the criterion continues to be used frequently, albeit with some cautionary language. For example, Dechow (1994) uses correlation with stock returns to compare earnings and cash flows as measures of a firm's periodic performance and Ayers (1998) examines whether deferred tax accounting under SFAS No. 109 provides incremental value relevance over the previous standard for income taxes. One of the objectives of financial reporting, as stated in FASB (1978, paragraph 47), is "Financial reporting should provide information to help present and potential investors and creditors and other users in assessing the amounts, timing, and uncertainty" of prospective cash flows. This serves as a major motivation for researchers to use correlation with stock returns as a criterion for evaluating alternative accounting methods and performance measures.

3.5.2. Role of maintained hypothesis

A maintained hypothesis in research that uses correlation with stock returns as a criterion for evaluating accounting methods is that capital markets are efficient. However, in recent years, market efficiency has been subjected to significant empirical assault. There is mounting evidence of capital market anomalies, which suggests that capital markets might be inefficient. Section 4 examines some of this evidence in the context of the accounting capital markets literature. My limited objective here is to comment on the implications for capital markets research that assumes capital market inefficiency.

The appealing feature of market efficiency as a maintained hypothesis is that it often facilitates the specification of a relation between accounting information and security prices under the null hypothesis. For example, neither systematic positive nor negative abnormal returns are predicted in periods following the announcement of an accounting method change. Systematic evidence of non-zero abnormal returns would refute market efficiency.

If market inefficiency is the maintained hypothesis, then the relation between security prices and financial information under the null hypothesis is difficult to specify a priori. The challenge facing researchers is to place more structure on the form of the relations under market inefficiency (Fama, 1998). A wide range of relations is feasible under market inefficiency. It is important to develop refutable hypotheses on the basis of behavioral theories of inefficient financial

[10] Barclay et al. (1999) make a similar point using managerial performance measurement as the motivation.

markets and to perform tests that discriminate between efficient and inefficient market hypotheses.[11] This is the essence of the positive theory of economics that has guided much capital markets research for the past three decades. Accountants armed with the knowledge of institutional details about accounting and the use of accounting information by financial analysts have a comparative advantage in developing theories and in designing more powerful tests of market efficiency and/or specific forms of market inefficiency.

3.6. Summary

The early event studies and association studies were seminal in several respects. First, they refuted the then prevailing concern that the historical cost earnings measurement process produces meaningless numbers. Second, these studies introduced positive empirical methodology and event study research design to the accounting literature. The early capital markets research amply demonstrated the benefits of incorporating the developments from, and contributing to, the economics and finance literature. Finally, the studies helped dispel the notion that accounting is a monopoly source of information to the capital markets. The early evidence clearly establishes that accounting is not a particularly timely source of information affecting security prices, with many competing sources of information pre-empting earnings information. This has accounting standard-setting implications.

4. Capital markets research in the 1980s and 1990s

Early capital markets research demonstrates that accounting reports have information content and that financial statement numbers reflect information that influences security prices, although not on a timely basis. The decades following the early research witnessed an explosive growth in capital markets research. I categorize the demand of this research into five main areas: (i) methodological capital markets research, (ii) evaluation of alternative accounting performance measures, (iii) valuation and fundamental analysis research, (iv) tests of market efficiency, and (v) value relevance of disclosures according to various financial accounting standards and economic consequences of new accounting standards. (Since Holthausen and Watts (2001) and Healy and Palepu (2001) examine item (v) in great detail, I do not discuss this item.)

Considerable overlap exists among the first four areas of research, but they have sufficiently different motivations and they strike me as quite distinct from

[11] See Barberis et al. (1998), Daniel et al. (1998), and Hong and Stein (1999) for behavioral models that produce predictable security return patterns consistent with market inefficiency.

each other. The next four subsections consider the above four areas of research.

4.1. Methodological capital markets research

Capital markets research seeks to answer a wide range of questions. A sample of the questions examined in previous research includes:

- Do current cost earnings have incremental information content over historical cost earnings?
- Do differences in corporate governance structures affect the degree of information asymmetry in capital markets and, in turn, influence the timing and strength of the relation between security returns and earnings information?
- Does managerial ownership affect the informativeness of accounting numbers because of the separation of corporate ownership and control?
- Does the perceived quality of an auditor affect the relation between corporate earnings and security returns?
- How does the reporting of transitory gain as part of ordinary income and transitory loss as an extraordinary item affect prices?
- How do we test for the capital market effects of accounting method changes?
- Are disclosures about other post-retirement employee benefits (OPEB) value relevant?
- Does an economic value added (EVA®) performance measure correlate more highly with stock returns and prices than historical cost accounting earnings?
- What would be the consequence of the Securities and Exchange Commission discontinuing the requirement of reconciliation between the US GAAP and the foreign- or the International Accounting Standards-GAAP for the non-US firms seeking to list their shares on the US exchanges and raise capital in the US?
- Would financial statements be more informative about current economic income (i.e., change in the market value) if GAAP were changed to permit managers to capitalize R&D outlays?

To answer these questions, a researcher must control for the "normal" relation between financial statement information and security returns to isolate the treatment effect of interest. The normal relation obviously varies with the research setting, and could mean any relation other than the treatment effect. For example, in examining the effect of managerial ownership on the informativeness of accounting numbers, the investigator must control for the influence of growth opportunities on earnings' informativeness because managerial ownership percentage is likely to be correlated with growth opportunities, which affect earnings' informativeness. This effect of growth might be unrelated to the potential agency effect of ownership control on earnings' informativeness.

I review methodological research in four sub-sections.

(i) Earnings response coefficients research (Section 4.1.1),
(ii) Properties of time series, management, and analysts' forecasts of earnings and earnings growth rates (Section 4.1.2).
(iii) Methodological issues in drawing statistical inferences from capital markets research (Section 4.1.3).
(iv) Models of discretionary and non-discretionary accruals (Section 4.1.4). Additional details on this issue are deferred to Section 4.4 on tests of market efficiency because in the capital markets context, the models of discretionary and non-discretionary earnings are frequently used in tests of market efficiency.

4.1.1. Earnings response coefficients research

4.1.1.1. Motivation for research on earnings response coefficients. Earnings response coefficient research is motivated by its potential use in valuation and fundamental analysis. As seen below, a valuation model underlies earnings response coefficient estimation. Another important methodological motivation for research on earnings response coefficients is to facilitate the design of more powerful tests of the contracting and political cost hypotheses or voluntary disclosure or signaling hypotheses in accounting.

4.1.1.2. Intuition for earnings response coefficients. Kormendi and Lipe (1987) is an early paper on earnings response coefficients (also see Miller and Rock, 1985). They build on the accounting association studies literature[12] and the macroeconomics literature on the permanent income hypothesis, which relates the time-series properties of consumption and income.[13] Kormendi and Lipe estimate the magnitude of the relation between stock returns and earnings, the earnings response coefficient, and test whether firm-specific estimates of earnings response coefficients cross-sectionally exhibit a positive correlation with the time-series properties of the firms' earnings. Thus, earnings response coefficients are a mapping of earnings' time-series properties and discount rates into changes in equity market values. For example, if earnings' time-series properties are such that earnings innovations are permanent, then assuming a

[12] See, for example, Ball and Brown (1968), Foster (1977), Beaver et al. (1979, 1980, 1987), and Watts and Zimmerman (1986, Chapter 2).

[13] See, for example, Hall (1978), Flavin (1981), and Kormendi and LaHaye (1986). The permanent income hypothesis is developed in Modigliani and Brumberg (1954), Friedman (1957), and Ando and Modigliani (1963).

one-to-one relation between earnings innovations and net cash flow innovations, the earnings response coefficient is the present value of the perpetuity of the earnings innovation calculated by discounting the perpetuity at the risk-adjusted rate of return on equity. The present value of a \$1 permanent innovation in annual earnings is $(1 + 1/r)$, where r is the annual risk-adjusted discount rate for equity.

To predict earnings response coefficient magnitudes, a researcher thus requires a valuation model (e.g., dividend-discounting model), revisions in forecasts of future earnings based on current earnings information, and a discount rate. Time-series properties of earnings play a role in parsimoniously describing the revisions in earnings forecasts based on current earnings, but a rigorous theory for the time-series properties does not exist. The most promising area of research in the earnings response coefficient literature is to relate time-series properties of earnings to economic determinants like competition, technology, innovation, effectiveness of corporate governance, incentive compensation policies, etc. (see below). I believe further refinements in the valuation models and more accurate estimates of discount rates are likely to be only incrementally fruitful in furthering our understanding of the return–earnings relation or the earnings response coefficients.

4.1.1.3. Economic determinants of earnings response coefficients. Early research by Kormendi and Lipe (1987), Easton and Zmijewski (1989), and Collins and Kothari (1989) identifies four economic determinants of earnings response coefficients. These studies all begin with the discounted net cash flow valuation model that is standard in the finance and economics literature. To link earnings to security returns, a one-to-one link between revisions in the market's expectations of earnings and net cash flows is assumed. The price change in response to a \$1 earnings innovation is the \$1 innovation plus the discounted present value of the revision in expectations of all future periods' earnings. The four determinants of this price change or the earnings response coefficient are: persistence, risk, growth, and interest rate. I discuss each briefly.

Kormendi and Lipe (1987) and Easton and Zmijewski (1989) show that the greater the impact of an earnings innovation on market participants' expectations of future earnings, i.e., the more persistent the time-series property of earnings, the larger the price change or the earnings response coefficients. Collins and Kothari (1989, Table 1) relate the earnings response coefficient to a number of commonly assumed ARIMA time-series properties of earnings, including the random walk, moving average, and autoregressive properties.

Easton and Zmijewski (1989) explain why risk negatively affects earnings response coefficient. Risk here refers to the systematic (or non-diversifiable or the covariance) component of the equity cash flows' volatility. Single- or multi-beta versions of the CAPM imply that the equity discount rate increases in the equity cash flows' systematic risk.[14] Thus, greater risk implies a larger discount rate, which reduces the discounted present value of the revisions in expected future earnings, i.e., the earnings response coefficient.

Collins and Kothari (1989) predict a positive marginal effect of a firm's growth opportunities on the earnings response coefficient. Growth here refers either to existing projects or to opportunities to invest in new projects that are expected to yield rates of return that exceed the risk-adjusted rate of return, r, commensurate with the systematic risk of the project's cash flows (see Fama and Miller, 1972, Chapter 2). A firm's ability to earn above-normal rates of return on its current or future investments does not contradict capital market efficiency. It only means that the firm has monopoly power in the product markets and is able to earn (quasi) rents for a finite period. Stated differently, entry or exit in the product markets often does not instantaneously eliminate firms' ability to earn super-normal rates of return.[15] To the extent current earnings are informative about the firm's growth opportunities, the price change is expected to be large. Collins and Kothari (1989, pp. 149–150) argue that the price reaction would be greater than that implied by the time-series persistence of earnings in part because persistence estimates from historical data are likely to be "deficient in accurately reflecting *current* growth opportunities".

Finally, Collins and Kothari (1989) predict a negative temporal relation between earnings response coefficients and the risk-free rate of interest. The logic here is straightforward. The discount rate, r, at any point in time is the sum of the risk-free rate of return at the time and a risk premium. If the risk-free rate of interest rises, then ceteris paribus the discounted present value of the revisions in expectations of future earnings innovations falls, inducing a negative temporal association between interest rate levels and earnings response coefficients.[16]

[14] The Sharpe (1964) and Lintner (1965) CAPM is a single-beta CAPM whereas the Fama and French (1993) three-factor model that includes size and book-to-market factors beyond the market factor or the Carhart (1997) four-factor model that adds the momentum factor to the Fama–French three-factor model is an example of multi-beta CAPM. The state-of-the-art in the finance literature is to use either the three- or the four-factor CAPM models (see Fama and French, 1997).

[15] In contrast, in an efficient capital market, prices adjust immediately to reflect changing expectations about a firm's earnings generating ability such that at any point in time an investor can only expect a normal rate of return on an investment in any stock.

[16] The argument ignores the possibility that changes in interest are simply changes in expected inflation and that the firm passes on the changes in inflation to its customers in the form of higher prices. In this case earnings response coefficients would be unrelated to interest rate changes. The negative relation between interest rates and earnings response coefficient implicitly assumes either interest rate changes covary positively with changes in real interest rates or inflation negatively impacts stock prices because of unanticipated inflation's negative effects on economic activity (see Fama and Schwert, 1977; Fama, 1981). See further discussion in Section 4.1.1.4.

4.1.1.4. Assessment of the early evidence on earnings response coefficients. Evidence in Kormendi and Lipe (1987), Easton and Zmijewski (1989), and Collins and Kothari (1989) indicates a statistically significant effect of the cross-sectional and temporal determinants on estimated earnings response coefficients. Numerous studies replicate these results and it has become an industry standard now in the capital markets literature to control for the effects of persistence, risk, and growth and focus on the incremental effect of a treatment variable, like ownership control, on earnings response coefficients.

Notwithstanding the success and impact of the earnings response coefficients literature, there are at least three criticisms of this research. First, the research on persistence and its relation to earnings response coefficients tends to be statistical in nature. I will revisit this issue in the context of research on time-series properties of earnings. Research on earnings response coefficients can be enriched by focusing on the economic determinants of the time series properties of firms' earnings. There is some work in this area. Ahmed (1994) draws on the works of Lev (1974, 1983), Thomadakis (1976), Lindenberg and Ross (1981), and Mandelker and Rhee (1984) on the relation between the potential to earn economic rents on a firm's assets and the degree of competition in the firm's industry and the firm's cost structure. Ahmed (1994, p. 379) then proposes and reports consistent evidence that "if accounting earnings reflect information about future economic rents generated by firms' assets-in-place, earnings response coefficients will vary inversely with competition and directly with the ratio of fixed costs to variable costs".[17]

Anthony and Ramesh (1992) draw on research on the relation between a firm's life cycle and business strategy[18] to explain cross-sectional variation in earnings response coefficients. They argue that depending on a firm's stage in its life cycle, financial statement information is differentially informative about a firm's cash flow generating ability such that earnings response coefficients are predictably related to a firm's stage in its life cycle.[19]

[17] Also see Biddle and Seow (1991) for evidence on cross-industry variation in earnings response coefficients and Baginski et al. (1999) for the impact of economic characteristics on earnings persistence measures.

[18] See Porter (1980), and Spence (1977, 1979, 1981), Wernerfelt (1985), Richardson and Gordon (1980), and Rappaport (1981).

[19] There is another stream of literature that derives predictions about the behavior of earnings response coefficients as a function of a firm's life cycle that is rooted in the resolution of uncertainty about the parameter values of the time-series properties of earnings (see Rao, 1989; Lang, 1991).

More recently, Ohlson (1995) introduces a mean-reverting process for residual income, which is in the spirit of competition eroding a firm's sustained ability to earn supernormal earnings. By modeling residual income, instead of total income or changes in income, as an autoregressive process, Ohlson (1995) better captures the intuitive economic effect of product-market competition. Dechow et al. (1999) report evidence that supports the economic modeling of residual income as an autoregressive process. However, they are able to achieve "only modest improvements in explanatory power" over research using simpler earnings capitalization and dividend-discounting models (Dechow et al., 1999, p. 3).

The second weakness of the literature linking earnings response coefficients to persistence is that it tends to present in-sample evidence. For example, Kormendi and Lipe (1987) and Collins and Kothari (1989) estimate time-series parameters and perform cross-sectional tests of a relation between the persistence parameters and earnings response coefficients over the same sample period.[20] The absence of a predictive test weakens our confidence in the results, even though the arguments and hypothesis are intuitive.[21] Dechow et al. (1999) confirm that the autoregressive properties at the industry level have predictive power with respect to the persistence of earnings in future, but their objective was not to explicitly link persistence to earnings response coefficients.

The third criticism of the literature on earnings response coefficient determinants, made in Watts (1992, p. 238), is that it does "not control for differences in accounting earnings' ability to proxy for current and future cash flows and differences in accounting methods. This raises the distinct possibility of a correlated omitted variables problem". Salamon and Kopel (1991) independently make a similar point. The potential for a correlated omitted variables problem arises in part because of the following two possibilities. (i) There is an association between the earnings response coefficients' economic determinants like risk and accounting method choice. (ii) Accounting method

[20] Ali and Zarowin (1992) point out that tests that ignore the effect of transitory earnings components (see below) in relating earnings response coefficients to persistence overstate the importance of persistence. However, even after controlling for this overstatement, they report that persistence is a significant determinant of earnings response coefficients.

[21] One weakness of Lys et al. (1998) is precisely that their use of in-sample time-series properties does not permit them to convincingly discriminate between the following two hypotheses: The effect of time-series properties on earnings response coefficients and the Easton et al. (1992) argument that temporal aggregation of earnings is key to a strong relation between returns and earnings. I will revisit this issue below in the context of research on reasons why estimated earnings response coefficients are too small compared to their predicted values under certain modeling assumptions.

choice is correlated with earnings' predictive power with respect to future cash flows. In general, the literature on economic determinants of earnings response coefficients has not adequately explored economic variables based on the contracting or accounting-choice theory literature as earnings response coefficients' determinants.[22] This is worthy of future investigation.[23]

4.1.1.5. Competing hypotheses to explain why estimated earnings response coefficients are "too small". Empirical estimates of earnings response coefficient magnitudes range from 1 to 3 (see, for example, Kormendi and Lipe, 1987; Easton and Zmijewski, 1989). Assuming a random walk as a reasonable description of the time series of annual earnings (see Ball and Watts (1972), and further discussion below) and a discount rate of about 10%, the expected magnitude of the earnings response coefficient is about 11 ($= 1 + 1/r$). Using price–earnings multiple as a reasonable estimate of the earnings response coefficient, one expects a magnitude of 8–20 depending on the time period examined. The relatively small magnitude of the earnings response coefficient compared to its predicted value motivated researchers to advance several hypotheses and explanations that I survey below. Interestingly, however, the inquiry into a comparison of the estimated with the predicted magnitude of the earnings response coefficients predates the earnings response coefficient literature that began with Kormendi and Lipe (1987).

Beaver et al. (1980) attempt to explain the difference between predicted and estimated values of earnings response coefficients by introducing three interrelated ideas: prices lead earnings (see below), a true-earnings-plus-noise model of accounting earnings, and a reverse-regression econometric research design. Another notable attempt appears in Easton and Harris (1991). Assuming the book value of equity is a noisy proxy for the market value of equity and assuming clean surplus, they argue that earnings measures the change in the market value of equity. They therefore argue that earnings-deflated-by-price should be used in addition to earnings-change-deflated-by-price in explaining

[22] Exceptions include studies like Baber et al. (1996, 1998) that examine the interplay between earnings response coefficients, investment opportunities, and management compensation.

[23] There is another criticism that concerns the temporal relation between interest rates and earnings response coefficients. Is the interest rate a causal determinant of earnings response coefficients? A large component of nominal interest rates is inflation. Finance and macroeconomics literature documents that shocks to inflation are negatively related to both shocks to real economic activity and stock market returns (see Fama and Schwert, 1977; Fama, 1981). Furthermore, real economic activity and business outlook are negatively related to expected rates of returns on stocks and bonds (see Fama and French, 1988, 1989; Balvers et al., 1990; Chen, 1991). This means interest rates might be positively related to the risk premium, as suggested in the literature on time-varying expected rates of returns. Thus, the interest rate effect on earnings response coefficients (or on price–earnings multiples) might be via time-varying risk premium (i.e., expected return on the market minus the risk-free rate of interest). Interest rate itself might not be the causal factor contributing to its negative relation with earnings response coefficients.

earnings. If the balance sheet perspective in Easton and Harris (1991) is adopted, the predicted coefficient on earnings is one, which implies earnings are entirely transitory. Since earnings are highly persistent, I find the Easton and Harris (1991) explanation unsatisfactory even though their evidence clearly shows that earnings-deflated-by-price significantly explains stock returns beyond the earnings-change variable. Kothari (1992) and Ohlson and Shroff (1992) offer alternative, earnings-expectations-based motivation for using earnings-deflated-by-price to explain stock returns in a return–earnings regression. In recent years, researchers estimating a return–earnings regression frequently use earnings-deflated-by-price variable to explain stock returns. However, the estimated earnings response coefficient is far from its predicted value of approximately the price–earnings multiple.

At least four hypotheses explain the observed low magnitudes of earnings response coefficients: (a) prices lead earnings; (b) inefficient capital markets; (c) noise in earnings and deficient GAAP; and (d) transitory earnings.[24] I discuss these below along with a summary of the evidence.

(a) *Prices lead earnings*: An important paper, Beaver et al. (1980), develops the idea that the information set reflected in prices is richer than that in contemporaneous accounting earnings.[25] In an efficient market, price changes instantaneously incorporate the present value of the revisions in the market's expectations of future net cash flows. In contrast, because of the revenue realization and expense matching principles that are fundamental to the earnings determination process (Statement of Financial Accounting Concepts No. 6, paras 78–79), accounting earnings incorporate the information reflected in price changes systematically with a lag. This is parsimoniously referred to as "prices lead earnings".

One implication of prices leading earnings is that even though annual earnings' time-series properties are reasonably described as a random walk and thus successive earnings changes are unpredictable using the information in past time series of earnings, the information set reflected in prices contains

[24] An additional reason is whether the earnings response coefficient is estimated using time-series data for an individual firm or it is estimated for classes of securities in the cross section. Teets and Wasley (1996) offer compelling evidence that firm-specific, time-series estimates of earnings response coefficients are substantially larger than those estimated using cross-sectional regression. They show that the firm-specific estimates are on average larger because of a strong negative cross-sectional correlation between the variance of unexpected earnings and firm-specific earnings response coefficient. In pooled estimations, the high, unexpected earnings variance firms receive disproportionate weight, which causes the estimated coefficient to be smaller than the average of the firm-specific estimates.

[25] Following Beaver et al. (1980), there has been voluminous work on the implications of prices leading earnings. A selected list of papers includes Collins et al. (1987, 1994), Beaver et al. (1987, 1997), Freeman (1987), Collins and Kothari (1989), Kothari (1992), Kothari and Sloan (1992), Easton et al. (1992), Warfield and Wild (1992), Jacobson and Aaker (1993), Basu (1997), Ball et al. (2000), and Liu and Thomas (2000).

information about future earnings changes. That is, from the perspective of the market, successive annual earnings changes are not unpredictable. The econometric consequence of prices leading earnings is that when returns are correlated with contemporaneous earnings changes, only a portion of the earnings change is a surprise to the market. In an efficient market, the anticipated portion of the earnings change is irrelevant in explaining contemporaneous returns. This informationally irrelevant portion of earnings change contributes to a standard errors-in-variables problem (see Maddala, 1988, Chapter 11; or Greene, 1997, Chapter 9), which biases downward the earnings response coefficient and reduces the explanatory power of the return–earnings regression. Thus, simply correlating earnings change with returns or failure to use an accurate proxy for unexpected earnings in the presence of prices leading earnings is hypothesized as a reason for earnings response coefficients that are "too small".

(b) *Inefficient capital markets*: If the market fails to correctly appreciate the implications of a current earnings surprise in revising its expectations of future earnings, the price change associated with earnings change will be too small. There is a large body of evidence that suggests that the stock market underreacts to earnings information and recognizes the full impact of the earnings information only gradually over time (see references in Section 3 on the post-earnings-announcement-drift literature and further discussion in this section under "tests of market efficiency"). Smaller-than-predicted values of earnings response coefficients are consistent with capital market inefficiency. Such an interpretation, however, should be tempered unless there is a logically consistent inefficient markets theory that predicts underreaction to earnings information. The reason is that overreaction is just as easily possible as underreaction in an inefficient market without a theory that predicts a particular phenomenon.

(c) *Noise in earnings and deficient GAAP*: The "noise in earnings" argument gained currency among accounting academics with Beaver et al. (1980).[26] While Beaver et al. elegantly express the intuition for why prices lead earnings, their modeling (Beaver et al., 1980, Section 2) relies on defining accounting earnings as the sum of "true earnings" plus value-irrelevant noise or a garbling component that is uncorrelated with stock prices (i.e., value) or returns in all periods.[27] This assumption enables Beaver et al. to present one model of the prices-lead-earnings phenomenon.[28] However, the "true-earnings-plus-noise"

[26] Also see Choi and Salamon (1990), Collins and Salatka (1993), Ramesh and Thiagarajan (1993), and Ramakrishnan and Thomas (1998).

[27] However, there is no consensus in the literature on the definition of value-irrelevant noise (see, for example, Ramakrishnan and Thomas, 1998).

[28] For a different approach, see Fama (1990), Lipe (1990), Ohlson and Shroff (1992), Kothari (1992), Kothari and Sloan (1992), and Kothari and Zimmerman (1995). This alternative approach is described below.

view of earnings suggests that accountants garble an otherwise "true earnings" signal about firm value. This seems counterintuitive and contrary to evidence on at least two grounds. First, there is evidence that accounting accruals are informative (see Rayburn (1986) and Dechow (1994), and many other studies). Second, regardless of whether accruals are informative or not, it seems unlikely that earnings without the accruals would be "true income". There is no economic intuition to suggest that an earnings-measurement process that emphasizes a transaction-based approach would generate "true income", which means earnings that capture all of the information that is in economic income, i.e., the change in equity market capitalization. In fact, the thesis of Beaver et al. is that prices lead earnings, which means the information set in price changes is richer than that in accounting earnings.

The deficient-GAAP argument takes the major objective of financial reporting to be "the prediction of future investor cash flows or stock returns" (Lev, 1989, p. 157). Proponents of the deficient-GAAP argument therefore use the return–earnings correlation as a measure of GAAP's success in fulfilling its objective. The maintained hypothesis is that capital markets are informationally efficient and the major objectives of financial reporting are generally inferred from the FASB's Statements of Financial Accounting Concepts.[29] In a series of papers, Baruch Lev with numerous coauthors has been probably the single biggest advocate of the "deficient GAAP" argument. Deficient GAAP is claimed to produce "low quality" earnings that exhibit only weak correlation with security returns. Lev (1989, p. 155) states, "While misspecification of the return/earnings relation or the existence of investor irrationality ("noise trading") may contribute to the weak association between earnings and stock returns, the possibility that the fault lies with the low quality (information content) of reported earnings looms large."

Lev expresses similar views in the context of accounting for research and development in Amir and Lev (1996), Aboody and Lev (1998), Lev and Sougiannis (1996), Lev and Zarowin (1999), and other papers. In addition, there is a vast positive empirical literature that examines the "deficient-GAAP" argument without making regulatory prescriptions. See, for example, Abraham and Sidhu (1998), Healy et al. (1999), and Kothari et al. (1999a) in the context of the capitalization versus expensing of research and development costs and Bryant (1999) in the context of full cost versus successful efforts method of accounting for oil-and-gas drilling costs.

[29] For example, Lev (1989) quotes the following from FASB (1978, para. 43): "The primary focus of financial reporting is information about an enterprise's performance provided by measures of earnings and its components. Investors, creditors, and others who are concerned with assessing the prospects for enterprise net cash flows are especially interested in that information. Their interest in an enterprise's future cash flows and its ability to generate favorable cash flows leads primarily to an interest in information about its earnings…"

The noise-in-earnings and deficient-GAAP arguments have similar consequences for the return–earnings correlation. Both weaken the contemporaneous return–earnings correlation and bias downward the earnings response coefficient (see, for example, Beaver et al., 1980; Lev, 1989, the appendix; or Kothari, 1992). However, I believe the two arguments are different. Noise is defined as a variable that is uncorrelated with the information in security returns in all time periods, i.e., current, past, and future. Deficient GAAP, in contrast, is simply another form of the prices-lead-earnings argument, except that there is a normative undercurrent in the deficient-GAAP argument. The deficient-GAAP argument posits that financial statements are slow to incorporate the information that is reflected in contemporaneous market values. In addition, it assumes that the greater the contemporaneous correlation of earnings with returns, the more desirable the GAAP that produces that earnings number. Unfortunately, the reasons why maximizing the earnings' correlation with stock returns is desirable are not well articulated or proven logically. I have touched upon this issue earlier, but a detailed treatment appears in Holthausen and Watts (2001).

(d) *Transitory earnings*: Although annual earnings are frequently assumed to follow a random walk, the presence of transitory components in earnings has long been recognized in the literature (see, for example, Brooks and Buckmaster, 1976; Ou and Penman, 1989a, b). There are several reasons for transitory earnings. First, certain business activities, like asset sales, produce one-time gains and losses.[30]

Second, because of information asymmetry between managers and outsiders, and because of potential litigation, there is a demand for and supply of conservative accounting numbers. Following Basu (1997, p. 4), I define conservatism as asymmetry in the speed with which accounting numbers reflect economic gains and losses or earnings reflecting ‘‘bad news more quickly than good news'' (also see Ball et al., 2000). Both information asymmetry and threat of litigation motivate management to disclose bad news on a more timely basis than good news. That is, the accounting recognition criteria have evolved to be less stringent for losses than gains such that anticipated losses, but not gains, are recognized more often and more quickly. Recognition of anticipated losses approximates recognition of the market value effect (loss) as it becomes known, so losses, like market value *changes*, are transitory. Hayn (1995) points out another reason for losses being transitory. She argues that the firm has an abandonment put option to discontinue the loss-making (or below-market return generating) operation and recoup the book value of the firm's assets. So,

[30] Here I assume the business events that produce one-time gains or losses are exogenous. If managerial incentives were to influence the occurrence of these events, then they would be endogenous (e.g., Bartov, 1991). The endogenous nature of these events is more realistic and it is discussed below.

only firms expecting to improve will continue operations, which means observed losses would be temporary. The loss-making firms' ability to recoup the book value through abandonment and adaptation enhances the book value's association with prices in periods when a firm is performing poorly (also see Berger et al., 1996; Burgstahler and Dichev, 1997; Barth et al., 1998; Wysocki, 1999).[31] The role of book values in valuation and book values' association with prices are topics examined in some detail below and especially in Holthausen and Watts (2001).

Finally, managerial motivations rooted in agency theory might contribute to transitory gains and losses. For example, Healy (1985) hypothesizes and documents evidence that for compensation considerations in a costly contracting setting, managers might generate discretionary accruals that reduce high levels of non-discretionary earnings or might take a "big bath" to report an extreme loss.[32] The "big bath" discretionary accrual behavior is also observed with incoming CEOs (see Pourciau, 1993; Murphy and Zimmerman, 1993). The discretionary component of the accruals is likely to be transitory and in fact mean reverting because accruals (eventually) reverse.

4.1.1.5.1. Econometric consequence of transitory earnings. The econometric consequence of transitory earnings components is straightforward. A simple model based on the analysis in Kothari and Zimmerman (1995, Section 5.1) illustrates the effect. I follow it up with a richer analysis later. Suppose

$$X_t = x_t + u_t,$$

where X_t is the reported earnings consisting of a random walk component, $x_t = x_{t-1} + e_t$, $e_t \sim \mathrm{N}(0, s_e^2)$ and a transitory component, $u_t \sim \mathrm{N}(0, s_u^2)$. Also assume that the market has no information beyond the time-series property of earnings and that e_t and u_t are uncorrelated. The earnings response coefficient on the transitory component is one. However, the market's sensitivity to the random walk component, i.e., the permanent component of earnings is $\beta = (1 + 1/r)$ or the average price–earnings multiple. Using the beginning-of-period-price, P_{t-1}, as the deflator, a return–earnings regression

$$R_t = \gamma_0 + \gamma_1 X_t/P_{t-1} + error_t$$

[31] The abandonment option is a real option. See Robichek and Van Horne (1967) for an early treatment of the abandonment option in capital budgeting. The role of real options in valuation is an important emerging area in financial economics. See Pindyck (1988), Dixit and Pindyck (1994), Abel et al. (1996), and Trigeorgis (1996) for excellent treatments of real options and valuation. The idea of real options has recently been applied in accounting (see Wysocki, 1999), but I believe there is far more potential still to be realized.

[32] Following Healy (1985), there is a huge literature that examines compensation-motivated earnings management. This and other earnings management literature on the debt and political cost hypotheses that originated with the positive accounting theory (see Watts and Zimmerman, 1978, 1986) is beyond the scope of my review, unless it is related to the capital markets research.

will yield a slope coefficient that falls between 1 and β because X_t is the sum of two independent variables with two different slope coefficients relating them to the dependent variable. Disentangling the two components and including those separately in the regression will yield coefficients on the two components that are closer to their predicted values (see, for example, Collins et al., 1997) and the model's explanatory power will increase. The γ_1 coefficient's magnitude depends on the relative magnitudes of the variances of the random walk and transitory components of earnings. If k is defined as $s_e^2/(s_e^2 + s_u^2)$, then γ_1 is expected to equal $k(\beta - 1) + 1$. Thus, if there are no transitory earnings, then $k = 1$ and the slope coefficient will be β. Alternatively, at the other extreme, if there are no permanent earnings, then $k = 0$ and the slope coefficient will be 1 on entirely transitory earnings.

As the assumption of zero correlation between the random walk and transitory earnings components is relaxed, the predictions about γ_1's magnitudes naturally change. Economic hypotheses about managers' incentives would generally suggest a non-zero correlation between the two components, which complicates the analysis.

4.1.1.5.2. Evidence on transitory earnings' effect on earnings response coefficients. There is an extensive literature documenting a smaller earnings response coefficient on transitory earnings as proxied for by non-recurring items reported in the financial statements (see, for example, Collins et al., 1997; Hayn, 1995; Elliott and Hanna, 1996; Ramakrishnan and Thomas, 1998; Abarbanell and Lehavy, 2000a). In addition, there is a literature on non-linearities in the return–earnings relation that attempts to infer transitory earnings from the magnitude of earnings response coefficients. An S-shaped return–earnings relation is seen from the empirical results of Beaver et al. (1979). They find that abnormal returns associated with extreme earnings changes are not proportionately as large as those associated with the non-extreme earnings change portfolios, which gives rise to an S-shaped return–earnings relation. One interpretation is that the market does not expect extreme earnings changes to be permanent, so the price adjustment is smaller. Thus, there is a negative correlation between the absolute magnitude of the earnings change and the likelihood that it is permanent. An appealing economic intuition exists for this correlation. Either extreme earnings changes are a result of one-time, windfall gains and losses, or competition in the product market makes it unlikely that the extreme high level of profitability can be sustained. At the extreme low level of earnings, the abandonment option argument is relevant.

Freeman and Tse (1992) model the non-linear relation using an arc-tangent transformation. Cheng et al. (1992) propose a rank-regression approach to tackle non-linearity. Other research on the non-linear return–earnings relation includes Abdel-khalik (1990), Das and Lev (1994), Hayn (1995), Subramanyam (1996a), Basu (1997), and Beneish and Harvey (1998). While the research on non-linearity is successful in improving the return–earnings regression fit, a strong economic foundation for the modeling is not apparent. Therefore, researchers must exercise caution in employing ad hoc statistical refinements.

4.1.1.6. Discriminating between competing hypotheses. Researchers have used many different research designs to discriminate between the above four competing hypotheses to explain the weak return–earnings correlation and why estimated earnings response coefficients are too small compared to those predicted on the basis of a random walk time series property of annual earnings. Prices leading earnings and the presence of transitory earnings appear to be the dominant explanations for the modest contemporaneous return–earnings association and for the observed magnitudes of earnings response coefficients. A summary of this research will hopefully make this apparent.

There is another reason for summarizing the above research. In many applications, researchers choose a research design from among many alternatives available. To facilitate research design selection in the future, I summarize the central features of and pros and cons of the research designs using common notation. The modeling below extends Fama's (1990) analysis of the effect of expanding the measurement window for both returns and earnings (industrial production) on the return–earnings correlation and earnings response coefficient.

An important distinction between the analysis in Fama (1990) or similar studies in finance and the return–earnings literature in accounting centers around the maintained hypothesis and motivation for the studies. In the finance literature, the maintained hypothesis is that explanatory variables like industrial production are real, economic, fundamental variables that a researcher has measured with a reasonable degree of accuracy. The motivation for their tests is to examine whether time-series or cross-sectional variation in stock returns is rational (efficient) in the sense that it is largely explained by economic fundamentals. The alternative hypothesis is that pricing in the market is not an outcome of the market participants' rational economic behavior. The objective of the accounting literature like Ball and Brown (1968) or Easton et al. (1992) is to assess whether the accounting earnings determination process captures the factors that affect security prices, with the maintained hypothesis that capital markets are informationally efficient. So, market efficiency is a maintained hypothesis and whether accounting captures underlying economic reality that moves the market is tested in the research (see Patell (1979) for a mathematically elegant treatment of these issues).

4.1.1.6.1. Assumptions and variable definitions. I present a simple model of the relation between earnings *growth* rates and stock returns, which captures the prices-lead-earnings phenomenon. I use growth rates because it simplifies the analysis. However, the intuition from the analysis is equally applicable to return–earnings analysis that uses earnings or earnings change deflated by price as the earnings variable in the regressions. The particulars of the econometrics naturally change with different specifications of the variables, but the qualitative results continue to hold.

Suppose earnings growth in period t, X_t, is

$$X_t = x_t + y_{t-1}, \tag{1}$$

where x_t is the portion of earnings growth that is news to the market, whereas y_{t-1} is the portion of earnings growth that the market had anticipated at the beginning of period t. Stated differently, y_{t-1} is past earnings news that shows up in period t's earnings, i.e., prices lead earnings. Further assume that x_t and y_{t-1} are uncorrelated and i.i.d. with $\sigma^2(x) = \sigma^2(y) = \sigma^2\cdot$ These assumptions imply earnings follow a random walk and that each component of earnings growth contributes to a new permanent level of earnings. Using earnings growth rates empirically poses practical difficulties because earnings can be negative. I assume this issue away here in the interest of a simple analysis that communicates the intuition.

Stock prices respond only to information about earnings growth, i.e., discount rates are assumed constant inter-temporally and cross-sectionally. Given the assumptions about earnings growth rates, return in period t, R_t, is

$$R_t = x_t + y_t. \tag{2}$$

Current stock return reflects the news in current earnings and news about earnings growth that will be captured in the next period's earnings. In this model, the market is assumed to have information about one-period-ahead earnings growth rate. This is a conservative assumption in that previous research suggests prices reflect information about two-to-three-year-ahead earnings growth (e.g., Kothari and Sloan, 1992).

Since all the earnings information is expressed in terms of growth rates and because all earnings growth is assumed to be permanent, annual stock returns are simply the sum of the earnings growth rates that are news to the market. That is, there is a one-to-one correspondence between stock returns and news in earnings growth rates, and the price response to unexpected earnings growth, i.e., the earnings response coefficient, is one. If, instead of using earnings growth rates, unexpected earnings deflated by the beginning of the period price are used, then the earnings response coefficient is $(1 + 1/r)$.

4.1.1.6.2. Contemporaneous one-period return–earnings relation. This is the commonly estimated annual return–earnings relation:

$$R_t = a + bX_t + e_t, \tag{3}$$

where b is the earnings response coefficient. The regression estimate of b is

$$\begin{aligned} b &= \mathrm{Cov}(R_t, X_t)/\mathrm{Var}(X_t) \\ &= \mathrm{Cov}(x_t + y_t, x_t + y_{t-1})/\mathrm{Var}(x_t + y_{t-1}) \\ &= \mathrm{Cov}(x_t, x_t)/[\mathrm{Var}(x_t) + \mathrm{Var}(y_{t-1})] \\ &= \sigma^2/(\sigma^2 + \sigma^2) \\ &= 0.5. \end{aligned} \tag{4}$$

To determine the explanatory power, adjusted R^2, of the regression, consider the decomposition of the dependent variable's variance ($= 2\sigma^2$):

$$\mathrm{Var}(R_t) = b^2\,\mathrm{Var}(X_t) + \mathrm{Var}(e_t),$$

$$\begin{aligned} 2\sigma^2 &= 0.5^2[\mathrm{Var}(x_t) + \mathrm{Var}(y_{t-1})] + \mathrm{Var}(e_t) \\ &= 0.5^2[\sigma^2 + \sigma^2] + \mathrm{Var}(e_t) \\ &= 0.5\sigma^2 + 1.5\sigma^2. \end{aligned} \tag{5}$$

From (5), the adjusted R^2, denoted as R^2 for parsimony, is

$$R_2 = (2\sigma^2 - 1.5\sigma^2)/2\sigma^2 = 25\%. \tag{6}$$

Eqs. (4) and (6) provide results of a contemporaneous return–earnings regression with the market anticipating half the information in earnings growth rates [i.e, $\mathrm{Var}(x_t) = \mathrm{Var}(y_{t-1})$] one period ahead. The earnings response coefficient is 50% biased and the explanatory power of the regression is 25%. The estimated earnings response coefficient is biased because the anticipated portion of the earnings growth rate, y_{t-1}, is stale information that is irrelevant to explaining variation in current returns and it acts as measurement error in the independent variable. Bias in the slope coefficient reduces the model's explanatory power. This errors-in-variables problem is exacerbated if the market anticipated earnings growth rates more than one period in advance.

In addition to the errors-in-variables problem, note also that whereas variation in R_t is due to earnings growth rates x_t and y_t, which are reflected in current and next period's earnings, y_t is not included in the regression model. The absence of y_t means there is an omitted variable. This also contributes to reducing the model's explanatory power. Since y_t is (assumed to be) uncorrelated with the included independent variable, $X_t(= x_t + y_{t-1})$, the coefficients on the included earnings growth rates are not biased due to a correlated omitted variable.

Include future earnings in the return–earnings model: Previous research in accounting and finance employs several alternative approaches to mitigate the errors-in-variables and omitted-variable problems in the return–earnings or similar regressions. Jacobson and Aaker (1993) and Warfield and Wild (1992) in return–earnings regressions and Fama (1990) and Schwert (1990) in

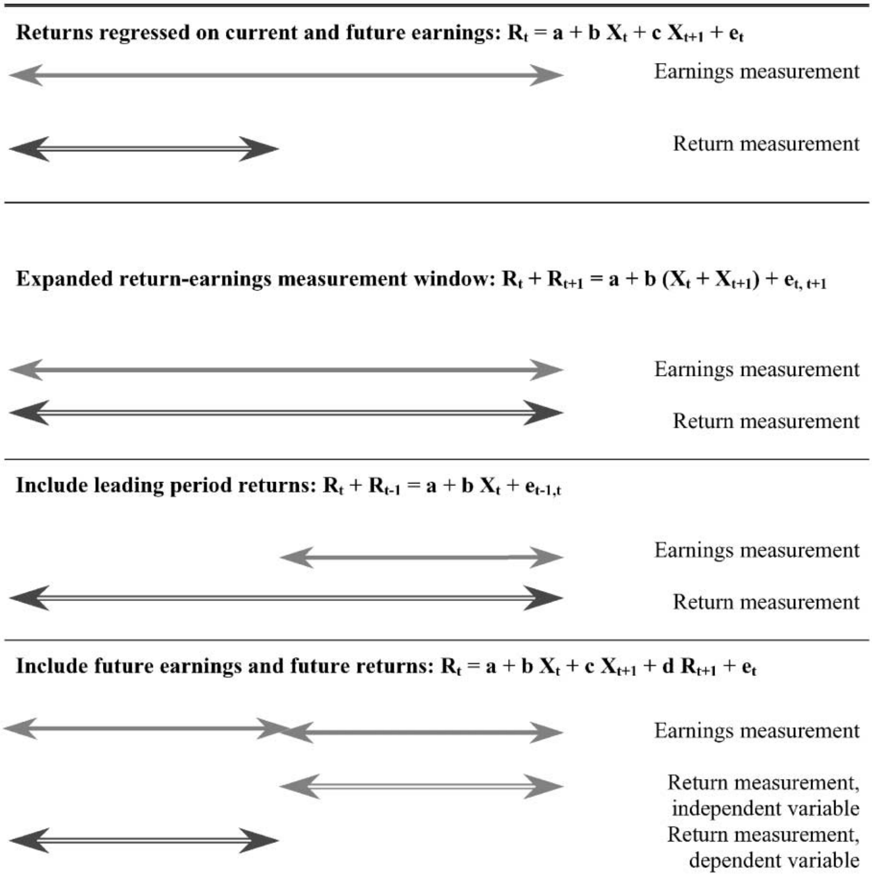

Fig. 1.

regressions of returns on industrial production include future years' earnings or production growth. In the context of the simple model, their approach estimates the following model (see Fig. 1):

$$R_t = a + bX_t + cX_{t+1} + e_t. \quad (7)$$

In this case, since X_t and X_{t+1} are uncorrelated (because the x and y components of earnings growth rates are assumed to be i.i.d.), b is the same as before in the univariate regression of returns on contemporaneous earnings growth, i.e., $b = 0.5$. The expected value of c is

$$c = \mathrm{Cov}(x_t + y_t, x_{t+1} + y_t)/\mathrm{Var}(x_{t+1} + y_t) = 0.5. \quad (8)$$

To derive the model's explanatory power, I decompose the variances

$$\mathrm{Var}(R_t) = b^2\,\mathrm{Var}(X_t) + c^2\,\mathrm{Var}(X_{t+1}) + \mathrm{Var}(e_t),$$

$$2\sigma^2 = 0.5^2[2\sigma^2] + 0.5^2[2\sigma^2] + \mathrm{Var}(e_t) = \sigma^2 + \sigma^2(e_t), \tag{9}$$

$$R^2 = \sigma^2/2\sigma^2 = 50\%. \tag{10}$$

The explanatory power increases from 25% for the contemporaneous regression model to 50% upon the inclusion of future earnings growth rate. Coefficients on both current and future earnings growth will be value relevant, but biased because both contain earnings growth rate components that are irrelevant to explaining R_t. This also dampens the explanatory power. The R^2 is greater than that of the contemporaneous model because there is no omitted variable in Eq. (7).

4.1.1.6.3. Expanding the return–earnings measurement window. Easton et al. (1992), Warfield and Wild (1992), Fama (1990), and Schwert (1990) report results of estimating contemporaneous return–earnings models in which both returns and earnings measurement windows are allowed to vary. Expanding the measurement window mitigates both errors-in-variable and omitted-variable problems that arise because of prices leading earnings. In addition, if the noise is mean-reverting, then the ratio of the variance of noise to the variance of value-relevant earnings will decrease as the measurement window is expanded.[33] Ignoring noise, the effect of expanding the return–earnings measurement window on the following contemporaneous regression is (see Fig. 1)

$$R_t + R_{t+1} = a + b(X_t + X_{t+1}) + e_{t,t+1}. \tag{11}$$

The slope coefficient is

$$\begin{aligned} b &= \frac{\mathrm{Cov}[(x_t + y_t + x_{t+1} + y_{t+1}), (xt + y_{t-1} + x_{t+1} + y_t)]}{\mathrm{Var}[(x_t + y_{t-1} + x_{t+1} + y_t)]} \\ &= 3\sigma^2/4\sigma^2 \\ &= 0.75. \end{aligned} \tag{12}$$

The explanatory power is

$$\mathrm{Var}(R_t + R_{t+1}) = b^2\,\mathrm{Var}(X_t + X_{t+1}) + \mathrm{Var}(e_{t,t+1}),$$

$$4\sigma^2 = 0.75^2 \times 4\sigma^2 + \mathrm{Var}(e_{t,t+1}). \tag{13}$$

[33] In case of mean-reverting noise, variance of the sum of noise over n periods is less than n times the variance of noise in a single period. In contrast, i.i.d. value-relevant growth implies the variance of the sum of earnings growth rates over n periods is n times the single-period variance of the earnings growth rate. This causes the ratio of the variance of noise to the variance of earnings growth to decline as the measurement window is expanded.

From Eq. (13), the R^2 of the regression model (11) is 56.25%. The above analysis demonstrates that expanding the return measurement window yields a less biased earnings response coefficient and a higher explanatory power than in the case of a single-period contemporaneous return–earnings regression. If the measurement window is expanded further, then an even stronger regression fit will be obtained and the estimated slope becomes less biased.[34] However, there will always be an end-point problem. Some forward-looking information about earnings growth exists in returns, y_{t+1} in Eq. (12), but it is missing from the earnings variable (i.e., the omitted-variable problem). Similarly, earnings growth at the beginning part of the measurement window contains some stale information, y_{t-1} in Eq. (12), which serves as measurement error in the independent variable.

4.1.1.6.4. Including leading period return. Kothari and Sloan (1992), Warfield and Wild (1992), and Jacobson and Aaker (1993) regress current and past returns on current period earnings to overcome the errors-in-variables problem that arises in a return–earnings regression as a result of prices leading earnings. The regression in the context of the simple model here is (see Fig. 1)

$$(R_t + R_{t-1}) = a + bX_t + e_{t-1,t}. \tag{14}$$

The slope coefficient is

$$\begin{aligned} b &= \mathrm{Cov}[(x_t + y_t + x_{t-1} + y_{t-1}), (x_t + y_{t-1})]/\mathrm{Var}[(x_t + y_{t-1})] \\ &= 2\sigma^2/2\sigma^2 \\ &= 1. \end{aligned} \tag{15}$$

The explanatory power is

$$\mathrm{Var}(R_t + R_{t-1}) = b^2\,\mathrm{Var}(X_t) + \mathrm{Var}(e_{t-1,t}),$$

$$4\sigma^2 = 1^2 \times 2\sigma^2 + \mathrm{Var}(e_{t-1,t}). \tag{16}$$

From Eq. (16), the R^2 of the regression model (14) is 50%, even though the slope coefficient is unbiased. The return–earnings association is not perfect because there are omitted (explanatory) variables in the model to explain information about future earnings growth that is reflected in current returns. In

[34] Unfortunately there are disadvantages of expanding the window too much. First, as the window is expanded, a larger fraction of the variation in the dependent variable in the cross section is accounted for by differences in expected rates of returns in the cross section. Therefore, it becomes increasingly difficult to unambiguously attribute explained variation from the return–earnings regression to earnings (or cash flow) information (see Easton et al. (1992) for a discussion of this concern and Fama and French (1988), Fama (1990), and Sloan (1993) for a discussion of the sources of variability in returns). Second, as the measurement window is expanded, a researcher must impose increasingly stringent data availability requirements, which introduces survivor biases. Third, discriminating between noise and prices-lead-earnings explanations becomes tenuous.

addition, the dependent variable has some news about earnings in period $t-1$, x_{t-1}, that is also not included in the explanatory variable, X_t.

Leading period returns in regression model (14) are helpful in discriminating between the noise and prices-lead-earnings hypotheses. In the presence of noise the slope coefficient will not approach one, whereas by including higher-order lagged returns, the prices-lead-earnings phenomenon will be captured and the slope coefficient will increase towards one. Presence of transitory components in earnings will prevent the model from yielding a slope coefficient of one, however. Evidence in Kothari and Sloan (1992) suggests a dramatic rise in the earnings response coefficient as leading period returns are included, consistent with price leading earnings being an important characteristic of the information environment. Their estimated slope coefficients fall short of approaching the price–earnings multiples, consistent with both noise and transitory earnings components.

4.1.1.6.5. Including future earnings and future returns. We saw earlier that when returns are regressed on current and future earnings growth, an errors-in-variables problem arises in part because future earnings growth contains future information that cannot explain current returns. Drawing on Kothari and Shanken (1992), Collins et al. (1994) mitigate this errors-in-variables problem by including future return as an independent variable. The benefit of future return arises through its correlation with the new information in future earnings growth. Econometrically, future return removes the new information error from the future earnings growth variable.[35] Specifically, the regression model is (see Fig. 1)

$$R_t = a + bX_t + cX_{t+1} + dR_{t+1} + e_t. \tag{17}$$

The intuition for why including R_{t+1} mitigates the errors-in-variables problem in using future earnings growth is best seen from the following equivalent two-stage procedure (see the appendix of Kothari and Shanken, 1992). If X_{t+1} is regressed on R_{t+1} in a first stage regression, then the residual from that regression will be the portion of $t+1$ period earnings growth that is unrelated to new information in R_{t+1}. This residual is (a noisy estimate of) the anticipated portion of earnings growth or the y_t component of X_{t+1} in the context of the simple model in this section. The second-stage of the procedure is a regression of R_t on X_t and the residual from the first stage regression, i.e., an estimate of y_t.

If proxies for both the new information in future earnings growth and for the anticipated component of current growth are accurate, then the approach in

[35] For a related practice in the accounting literature of using prior returns as a proxy for expected earnings, see Brown et al. (1987b), Collins et al. (1987), and Lys and Sivaramakrishnan (1988). Instead of past returns, Collins et al. (1994) use earnings yield at time $t-1$ to control for the anticipated earnings growth for period t.

Kothari and Shanken (1992) and Collins et al. (1994) will be successful. That is, the estimated earnings response coefficients will be unbiased and the model's explanatory power will approach 100%. Note that the model in Eq. (17) will have to be expanded to also include proxies for the anticipated component of current growth, X_t. Of course, success of the model depends crucially on the quality of the proxies. Evidence in Collins et al. is largely consistent with the prices-lead-earnings argument and they find little support for the noise-in-earnings hypothesis.

4.1.1.6.6. Use of analysts' forecasts instead of future returns. Recently, Liu and Thomas (1999a, b), Dechow et al. (1999), and others have begun to directly incorporate information about revised expectations of future earnings growth in a return–earnings regression through the use of analysts' forecasts.[36] This is similar in spirit to the model in Eq. (17) in which expectations about earnings growth are econometrically backed out through the use of actual future earnings growth minus the impact of new information on future earnings growth. The Liu and Thomas (1999a, b) type of research begins with the Edwards and Bell (1961), Peasnell (1982), Ohlson (1995), and Feltham and Ohlson (1995) residual income valuation model. This model defines price as the sum of the book value of equity and the discounted present value of expected future residual earnings (i.e., earnings in excess of the cost of the expected book value of the equity capital employed in future years).[37] Residual income valuation models are a transformation of the dividend-discounting model (see Feltham and Ohlson, 1995; Dechow et al., 1999; or Lee, 1999), but express value directly in terms of current and future accounting numbers, book values and earnings. This potentially facilitates the use of analysts' forecasts.

Researchers typically use analysts' forecasts of earnings and book values of equity to proxy for expected future residual earnings.[38] Availability of forecasts in a machine-readable form has spurred the use of analysts' forecasts in capital markets research (see below). Recent research that uses analysts' forecasts documents a strong association between returns and contemporaneous earnings and revisions in analysts' forecasts in a residual income framework. However, more research is needed to determine whether the source of the

[36] Also see Abdel-khalik (1990) for a similar approach with the motivation of developing a return–earnings model that accounts for non-linearity.

[37] For a historical perspective on the concept of residual income valuation, see Biddle et al. (1997), who trace it all the way back to Hamilton (1777) and Marshall (1890).

[38] Use of analysts' forecasts generally violates the clean surplus assumption underlying the residual income model because analysts' forecasts often exclude items that affect book values of equity. However, the use of analysts' forecasts should be guided by their usefulness in explaining and predicting empirical phenomena rather than whether they are consistent with the clean surplus assumption.

improved association is the use of analysts' forecasts or the residual income model or a combination. A comparison with simpler models with and without analysts' forecasts would be a natural next step. Dechow et al. (1999) have made a very good beginning in this respect.[39]

4.1.1.6.7. Levels regression to obtain less biased estimates of earnings response coefficients. Kothari and Zimmerman (1995) argue that one advantage of the levels regression (i.e., price regressed on earnings) is that the errors-in-variables problem is avoided. The logic is straightforward. Current price contains all the information in current earnings plus some forward-looking information that is missing from current earnings because prices lead earnings. Therefore, when price is regressed on earnings, there is no errors-in-variables problem in the right-hand-side variable. Only forward-looking information, which is uncorrelated with the included independent variable, earnings, is omitted from the regression. The econometric consequence is that the estimated earnings response coefficient is unbiased, but that the explanatory power is sacrificed because of the omitted forward-looking information.

The bad news in using levels regressions is that there are potentially other econometric problems, like correlated omitted variables (e.g., growth), and heteroskedasticity. These and other related issues are discussed thoroughly in Brown et al. (1999) and Holthausen and Watts (2001).

4.1.1.7. Bottom line. The earnings response coefficient research has made significant progress in the last decade. However, notwithstanding these refinements, I believe the best a researcher can do currently is to test whether a coefficient is statistically significant or whether it is significantly greater than the coefficient on another variable (e.g., coefficient on earnings versus on cash flow from operations). The research also suggests that controlling for the effects of persistence, growth, and risk on earnings response coefficients is important. It is rare to see research examining whether the estimated coefficient equals some predicted value. Only occasionally have researchers attempted to test whether the estimated coefficient on transitory earnings equals one (e.g., Barth et al., 1992). The lack of tests of predicted coefficient magnitudes is in part because predicted values depend on unobservable forecasted earnings growth rates over all future periods and expected discount rates for future periods' earnings. Levels regressions yield earnings response coefficient estimates that are closer to economically plausible values. However, severe econometric problems make their use less attractive (see Holthausen and Watts, 2001).

[39] While there are advantages of using analysts' forecasts, there are also problems because of apparent optimism in analysts' forecasts, which varies cross-sectionally with earnings skewness (see Gu and Wu, 2000). I defer a detailed discussion of these issues to the next section.

4.1.2. Time series, management, and analysts' forecasts of earnings

This section explains the motivation for research on properties of time series, management, and analysts' forecasts of earnings (Section 4.1.2.1). I then describe research on the properties of time-series forecasts of earnings in Section 4.1.2.2, management's forecasts in Section 4.1.2.3, and finally the research on analysts' forecasts in Section 4.1.2.4.

4.1.2.1. Motivation for research on earnings forecasts. There are at least five reasons for research on the time-series properties of earnings and properties of management and analysts' forecasts (see Watts and Zimmerman (1986, Chapter 6), Schipper (1991), and Brown (1993) for discussions of some of these reasons). First, almost all models of valuation either directly or indirectly use earnings forecasts. The discounted cash flow valuation models (Fama and Miller, 1972, Chapter 2) often use forecasted earnings, with some adjustments, as proxies for future cash flows. The analytically equivalent residual-income valuation models (e.g., Edwards and Bell, 1961; Ohlson, 1995; Feltham and Ohlson, 1995) discount forecasted earnings net of "normal" earnings.

Second, capital markets research that correlates financial statement information with security returns frequently uses a model of expected earnings to isolate the surprise component of earnings from the anticipated component. In an efficient capital market, the anticipated component is uncorrelated with future returns, which are measured over the announcement period or the association study period. Any anticipated component that smears the estimated proxy for the surprise component of earnings, serves as noise or measurement error in the proxy and weakens the estimated return–earnings association. Thus, the degree of return–earnings association hinges critically on the accuracy of the unexpected earnings proxy used by a researcher, which naturally creates a demand for the time-series properties of earnings or analysts' forecasts.

Third, the efficient markets hypothesis is being increasingly questioned, both empirically and theoretically (with behavioral finance models of inefficient markets; see Daniel et al., 1998; Barberis et al., 1998; Hong and Stein, 1999). Accounting-based capital market research has produced evidence that is apparently inconsistent with market efficiency (see the detailed review below). A common feature of this research is to show that security returns are predictable and that their predictability is associated with the time-series properties of earnings and/or properties of analysts' forecasts, which creates a demand for research in the time-series properties of earnings and earnings forecasts.

Fourth, positive accounting theory research hypothesizes efficient or opportunistic earnings management and/or seeks to explain managers' accounting procedure choices. In this research there is often a need for "normal" earnings that are calculated using a time-series model of earnings.

For example, tests of the earnings smoothing hypothesis might examine properties of pre-smoothed and smoothed time series of earnings.

Finally, analyst and management forecasts are a source of information in the capital markets. The forecasts thus affect the information environment and influence the level and variability of security prices. There is a large literature (see Healy and Palepu, 2001) that examines the nature of the information environment, the demand and supply of forecasts, the incentives facing management and analysts and their effect on the properties of the forecasts, the effect of the properties of the forecasts on the variability of security returns and cost of capital, etc. In this research, properties of management and analysts' forecasts are an input.

4.1.2.2. Time-series properties of earnings. Brown (1993) examines the large body of literature on the time-series properties of earnings. I deliberately keep my remarks on the earnings' time-series properties short because I believe this literature is fast becoming extinct. The main reason is the easy availability of a better substitute: analysts' forecasts are available at a low cost in machine-readable form for a large fraction of publicly traded firms (see below).

4.1.2.2.1. Properties of annual earnings. Random walk: A large body of evidence suggests a random walk or random walk with drift is a reasonable description of the time-series properties of annual earnings. The early evidence appears in Little (1962), Little and Rayner (1966), Lintner and Glauber (1967), and additional references in Ball and Watts (1972). Ball and Watts (1972) conduct the first systematic study and fail to reject the random walk time-series property for annual earnings. Subsequent research confirms their conclusion (see Watts, 1970; Watts and Leftwich, 1977; Albrecht et al., 1977) by testing against the predictive ability of Box–Jenkins models of annual earnings vis-à-vis the random walk model. This is notwithstanding the indication of negative first-order autocorrelation in Ball and Watts (1972, Table 3) and other research.[40]

The random walk property of annual earnings is puzzling. Unlike the random walk property of security prices, which is a theoretical prediction of the efficient capital markets hypothesis, economic theory does not predict a random walk in earnings.[41] Accounting earnings do not represent the capitalization of expected future cash flows like prices. Therefore, there is no

[40] In-sample estimates of autocorrelation coefficients are biased downward because of the small sample bias that equals $-1/(T-1)$, where T is the number of time-series observations (see Kendall, 1954; Jacob and Lys, 1995). Bias-adjusted first-order serial correlation coefficients for annual earnings changes are close to zero (see Dechow et al., 1998a, Table 5).

[41] The random walk property of security prices in an efficient capital market requires the additional assumption of constant expected rates of return, which might not be descriptive (see Fama, 1976, Chapter 5; Fama and French, 1988; Kothari and Shanken, 1997). Therefore, the random walk property is only an approximate prediction.

economic reason to expect annual earnings to follow a random walk (see, for example, Fama and Miller, 1972, Chapter 2; Watts and Zimmerman, 1986, Chapter 6).

Mean reversion: Starting with Brooks and Buckmaster (1976), a number of studies document evidence of mild mean reversion in annual earnings (see, for recent studies, Ramakrishnan and Thomas, 1992; Lipe and Kormendi, 1994; Fama and French, 2000). However, interpreting evidence of mean reversion from in-sample estimates of the time-series parameter values requires caution. Notwithstanding the evidence of mean reversion, predictive ability might not be much better than a random walk model in holdout samples (see Watts, 1970; Watts and Leftwich, 1977; Brown, 1993).

Economic reasons for mean reversion: There are several economic and statistical reasons to expect mean reversion in earnings. First, competition in product markets implies that above-normal profitability is not sustainable (Beaver and Morse, 1978; Lev, 1983; Ohlson, 1995; Fama and French, 2000). Second, accounting conservatism (see Basu, 1997) and litigation risk (see Kothari et al., 1988; Ball et al., 2000) motivate managers to recognize economic bad news more quickly than good news. As a result, firms often recognize anticipated losses.[42] This recognition of losses makes losses less permanent and thus induces negative autocorrelation in earnings. Third, firms incurring losses have the option to liquidate the firm if the management does not anticipate recovery (Hayn, 1995; Berger et al., 1996; Burgstahler and Dichev, 1997; Collins et al., 1999). That means surviving firms are expected to reverse the poor performance. Thus, the abandonment option and survivor bias together imply the time series of earnings will exhibit reversals. Finally, the incidence of transitory special items and losses has increased dramatically over time (see, for example, Hayn, 1995; Elliott and Hanna, 1996; Collins et al., 1997), which means earnings changes are predictable. The increase in transitory items might be due in part to a shift in standard setting by the SEC and FASB toward mark-to-market accounting for some assets and liabilities.

Cross-sectional estimation: Fama and French (2000) introduce a cross-sectional estimation approach to the earnings forecasting literature to uncover the time-series properties of earnings. They argue that time-series estimation lacks power because there are only a few time-series observations of annual earnings available for most firms. In addition, use of a long time series introduces survivor bias. The survivor bias implies more observations of positive earnings changes following positive changes than expected by chance, for reasons discussed above. This offsets the underlying negative time-series correlation in earnings changes. The effect of survivor bias, together with low

[42] Agency theory-based reasons (e.g., the nature of compensation contracts and CEO turnover) also might motivate managers to take a "big bath" in earnings.

power (i.e., large standard errors) of time-series estimation, favors the conclusion of a random walk in annual earnings.

In a cross-sectional estimation, annual earnings (levels or changes, and with or without a deflator) are regressed on its lagged observation. The estimation is performed annually and inferences are drawn on the basis of the time series of annual parameter estimates from the cross-sectional regressions. This is the well-known Fama and MacBeth (1973) procedure.

One weakness of cross-sectional estimation is that firm-specific information on the time-series properties is sacrificed. However, this is mitigated through a conditional estimation of the cross-sectional regression. Conditional estimation is an attempt to capture cross-sectional variation in the parameters of the time-series process of earnings (e.g., the autocorrelation coefficient). This approach is grounded in economic analysis, rather than the previous statistical exercise of fitting the best time-series model of earnings (e.g., fitting the best Box–Jenkins model). The conditional approach models the cross-sectional variation in earnings' autocorrelation coefficient as a function of its economic determinants. That is, the coefficient is hypothesized to vary with the realized values of a set of conditioning variables like past performance, dividend yield, leverage, industry competition, etc.[43] Since the number of observations in a cross section is typically large, it is generally possible to accommodate many economic determinants in the estimation. Overall, cross-sectional estimation enhances power, overcomes survivor bias problems, and permits a researcher to incorporate the effect of economic determinants of the time-series properties of earnings.

Conditional cross-sectional estimation: Previous research employs at least three different approaches to expand the information set beyond the past time series of earnings in obtaining conditional earnings forecasts (or conditional estimates of the parameters of the time-series process of earnings).

First, a conditional forecast is obtained using information on one or more determinants of the autocorrelation coefficient of earnings. For example, Brooks and Buckmaster (1976) focus on extreme earnings changes, Basu (1997) examines negative earnings changes, and Lev (1983) identifies economic determinants like barriers-to-entry in an industry, firm size, product type, and capital intensity of a firm; also see Freeman et al. (1982) and Freeman and Tse (1989, 1992). Recent studies estimating conditional forecasts include Fama and French (2000) and Dechow et al. (1999).

Second, price-based forecasts are used to improve on the time-series forecasts of earnings on the premise that prices reflect a richer information set than the past time series of earnings (Beaver et al., 1980). Research

[43] The econometric approach to estimate a parameter conditional on a set of (state) variables is well developed in finance and economics. See, for example, Shanken (1990), Chan and Chen (1988), and Ferson and Schadt (1996) for time-varying conditional best estimation.

examining price-based earnings forecasts includes Beaver and Morse (1978), Freeman et al. (1982), Collins et al. (1987), Beaver et al. (1987), and Freeman (1987). Notwithstanding the fact that prices reflect a richer information set than the past time series of earnings, researchers have found it difficult to harness the information in prices at the firm level to make an economically important improvement. Therefore, this research has had only a modest impact on forecasting. The benefit of prices in improving forecasts or in backing out market expectations is primarily in long-horizon settings (e.g., Easton et al., 1992; Kothari and Sloan, 1992; Collins et al., 1994) precisely because prices anticipate earnings information for several future periods.

Finally, Ou and Penman (1989a, b), Lev and Thiagarajan (1993), and Abarbanell and Bushee (1997, 1998) use financial statement analysis of income statement and balance sheet ratios to forecast future earnings and stock returns. The primary motivation for this research is to employ fundamental analysis to identify mispriced securities. Superior earnings forecasts are only an intermediate product of this research.

4.1.2.2.2. Properties of quarterly earnings. Interest in the time-series properties of quarterly earnings arises for at least four reasons. First, quarterly earnings are seasonal in many industries because of the seasonal nature of their main business activity (e.g., apparel sales and toy sales). Second, quarterly earnings are more timely, so the use of a quarterly earnings forecast as a proxy for the market's expectation is likely more accurate than using a stale annual earnings forecast.

Third, GAAP requires that the quarterly reporting period is viewed as an integral part of the annual reporting period (see APB, 1973, Opinion No. 28; FASB, 1974, SFAS No. 3; FASB, 1977, FASB Interpretation No. 18). As a result, firms are required to estimate annual operating expenses and allocate these costs to quarterly periods. The fourth quarter thus offsets the intentional (i.e., opportunistic) and unintentional estimation errors in allocating expenses to the first three quarterly periods. This contributes to differences in the properties of fourth versus the first three quarterly earnings (see Bathke and Lorek, 1984; Collins et al., 1984; Mendenhall and Nichols, 1988; Salamon and Stober, 1994). More importantly, quarterly earnings are potentially a more powerful setting to test positive accounting theory based and capital markets research hypotheses (see, for example, Salamon and Stober, 1994; Hayn and Watts, 1997; Rangan and Sloan, 1998). The source of the power comes from the fact that the errors in estimating operating expenses in the first three quarters are offset in the fourth quarter, thus permitting tests that exploit this property of error reversals. One downside of using quarterly earnings is that they are not audited.

Finally, there are four times as many quarterly earnings observations as annual earnings observations. To the extent there is a loss of information in aggregation, a quarterly earnings time series has the potential to generate more precise annual earnings forecasts than annual earnings-based forecasts (see for evidence, Hopwood et al., 1982). That is, less stringent data availability requirements are necessary using quarterly than annual earnings to achieve the same degree of precision of the forecasts. This enables the researcher to reduce survivor biases and to use a larger sample of firms.

While a quarterly earnings forecast is likely a more timely and accurate proxy for the market's expectation of earnings at the time of an earnings announcement, this benefit should be tempered by the following potential downside. The market's reaction to any information event reflects the revision in expectation of cash flows for all future periods. The market might be responding to information about future quarters, which may or may not be highly correlated with the information over a quarter (a relatively short time period). Therefore, despite greater accuracy, the strength of the association between the quarterly earnings surprise and narrow-window stock price reaction to the surprise is not higher than a long-window association (e.g., one year or longer). Recent evidence in Kinney et al. (1999) shows that the odds of the same sign of stock returns and earnings surprise are no greater than 60–40% even when using composite earnings forecasts tabulated by First Call Corporation.[44] The lack of a strong association should not be interpreted mechanically as an indication of noise in the earnings expectation proxy. The modest association is likely an indication of prices responding to information about future income that are unrelated to the current earnings information. That is, the forward-looking nature of prices with respect to earnings becomes an important consideration (see Kinney et al., 1999; Lev, 1989; Easton et al., 1992; Kothari and Sloan, 1992; Collins et al., 1994). In addition, increased incidence of transitory items in earnings in recent years further weakens the relation between current earnings surprise and revisions in expectations about future periods' earnings as captured in the announcement period price change.

ARIMA properties of quarterly earnings: Well-developed Box–Jenkins autoregressive integrated moving average (ARIMA) models of quarterly earnings exist (Foster, 1977; Griffin, 1977; Watts, 1975; Brown and Rozeff, 1979). Research comparing the models shows that the Brown and Rozeff (1979) model is slightly superior in forecast accuracy at least over short horizons (see Brown et al., 1987a). However, this advantage does not necessarily show up as a stronger association with short-window returns around quarterly earnings announcements (see Brown et al., 1987b). Simpler models like Foster (1977) do just as well as the more complicated models. The

[44] Kinney et al. (1999) use annual, not quarterly earnings forecast error. However, since first three quarters' earnings are known at the time of the annual earnings announcement, examining the association of annual earnings forecast error with a narrow window return is almost equivalent to examining a relation between quarterly earnings surprise and stock returns.

main advantage of the Foster (1977) model is that it can be estimated without the Box–Jenkins ARIMA software.

Currently the main use of quarterly earnings time-series models is in tests of market efficiency examining post-earnings-announcement drift (see below). In other capital markets research, researchers almost invariably use analysts' or management forecasts of earnings. As seen below, these forecasts are not only easily available, but they are more accurate and more highly associated with security returns.

4.1.2.2.3. Properties of components of earnings. There are at least three reasons for researchers' interest in the properties of earnings components. First, to examine whether earnings components are incrementally informative beyond earnings in their association with security prices.[45] This research is generally aimed at evaluating standards that require earnings components to be disclosed and fundamental analysis. Conclusions about the incremental association or information content of earnings components hinge on the accuracy of the proxies for the unexpected portion of the earnings components, which creates a demand for the time-series properties of earnings components.

Second, accruals and cash flows are the two most commonly examined components of earnings. Operating accruals represent accountants' attempt to transform operating cash flows into earnings that are more informative about firm performance and thus make earnings a more useful measure for contracting and/or in fundamental analysis or valuation. However, self-interested managers might use accounting discretion opportunistically and manipulate accruals, which would distort earnings as a measure of firm performance. Tests of accrual management hypotheses based on positive accounting theory examine accounting accruals' properties. These tests provide a motivation for research in the time-series properties of accruals and cash flows and other earnings components (e.g., current and non-current accruals, operating and investing cash flows, etc.).

Finally, interest in the time-series properties of earnings components also arises because summing the forecasts of the components might yield a more accurate forecast of earnings. The logic here is similar to that underlying the aggregation of quarterly earnings forecasts to improve the accuracy of annual earnings forecasts. The difference is that the aggregation of components is contemporaneous (i.e., cross-sectional) whereas the aggregation of quarterly forecasts is temporal. In both cases the assumption is that there is a loss of information in aggregation.

4.1.2.2.4. Current status and future directions for research in earnings components. There is an active interest in research on the properties of earnings components because of both positive accounting research and

[45] See, for example, Lipe (1986), Rayburn (1986), Wilson (1986, 1987), Livnat and Zarowin (1990), Ohlson and Penman (1992), Dechow (1994), and Basu (1997).

fundamental analysis. Early research on the properties of accruals assumed naïve models (e.g., DeAngelo, 1986; Healy, 1985), but progress has been made since (e.g., Jones, 1991; Kang and Sivaramakrishnan, 1995; Dechow et al., 1995). I believe that modeling earnings components' properties using the nature of economic transactions and the accounting recording of those transactions is likely to be more fruitful than simply fitting time-series models on earnings components (see Guay et al., 1996; Healy, 1996). Dechow et al. (1998a) represent one attempt at modeling the time-series properties of accruals, operating cash flows, and earnings with sales as the starting point or primitive. The economic modeling of accruals or earnings components will not necessarily provide the best fit for the historical data, but it might have predictive power and ability to explain managerial behavior better than purely statistical time-series models.

4.1.2.3. Management forecasts. Management forecasts have many labels, including earnings warnings, earnings pre-announcements, and management's earnings forecasts. Earnings warnings and pre-announcements precede earnings announcements and typically convey bad news. Management's earnings forecasts are often soon after earnings announcements and do not necessarily communicate bad news to the market. Since management forecasts are voluntary, there are economic motivations for the forecasts. A detailed discussion of the economic issues surrounding management forecasts appears in the Healy and Palepu (2001) and Verrecchia (2001) review papers. A few examples of the economic issues include the following: (i) the threat of litigation influencing management's decision to issue voluntary forecasts and forecasts of bad news (e.g., Skinner, 1994; Francis et al., 1994; Kasznik and Lev, 1995); (ii) the effect of management's concern about the proprietary cost of disclosure on the nature of management forecasts (e.g., Bamber and Cheon, 1998); and (iii) the timing of management forecasts and the timing of insider buying and selling of company stocks (Noe, 1999). In this review, I only summarize the extant research on the properties of management forecasts. The summary describes the main findings and the hypotheses tested in the literature.

Early research on management forecasts appears in Patell (1976), Jaggi (1978), Nichols and Tsay (1979), Penman (1980), Ajinkya and Gift (1984), and Waymire (1984). They collectively show that management forecasts have information content. Specifically, management forecast releases are associated with significant increases in return variability (see e.g., Patell, 1976) and there is a positive association between the unexpected component of the management forecast and security returns around the forecast date (e.g., Ajinkya and Gift, 1984; Waymire, 1984).

One of the hypotheses for voluntary management forecasts is that through the forecasts management aligns investors' expectations with the superior information that the management possesses (Ajinkya and Gift, 1984). This expectation-adjustment hypothesis implies that management forecasts are superior to market expectations of earnings at the time of management forecasts. However, previous evidence in Imhoff (1978) and Imhoff and Paré (1982) suggested management forecasts are not systematically more accurate than analysts' forecasts. Evidence consistent with the superiority of management vis-à-vis analysts' forecasts as a proxy for the market's prevailing expectation appears in Waymire (1984). Recent research examines issues like the relation between various types, precision, and credibility of management forecasts and security price changes (e.g., Pownall et al., 1993; Baginski et al., 1993; Pownall and Waymire, 1989; Bamber and Cheon, 1998). Overall, the evidence suggests that management forecasts have information content and the information content is positively correlated with a number of determinants of the quality of the management forecasts.

4.1.2.4. Analysts' forecasts. There is a huge empirical and theoretical literature on analysts' forecasts. I focus on the properties of analysts' forecasts and some determinants of these properties. I do not review the research that examines why analysts forecast earnings, the determinants of the number of analysts following a firm, and the consequences of analysts' following on the properties of security returns. Some of these issues are examined in Verrecchia (2001) and Healy and Palepu (2001). I recognize that the issues n ot examined here also affect the properties of analysts' forecasts, but nevertheless I consider those beyond the scope of my review of the capital markets research.

Buy- and sell-side analysts issue earnings forecasts. Most research in accounting examines sell-side analysts' forecasts because these are publicly available. Analysts from brokerage houses and investment-banking firms in the financial services industry issue sell-side forecasts. Buy-side analysts are typically employed by mutual funds and pension funds and issue forecasts primarily for internal investment decision-making purposes. Like most of the research on analysts' forecasts, I review the research on sell-side analysts' forecasts.

Analysts' forecasts research can be broadly divided into two categories. The first category examines properties of consensus analysts' forecasts. A consensus forecast is the mean or median of the analysts' forecasts of (either quarterly or annual or long-term) earnings of an individual firm. An example of research in this category would be "Are analysts' forecasts optimistic?" The second category focuses on the properties of individual analysts' forecasts either in the cross section or temporally. This category examines questions like "What are the determinants of an individual analyst's forecast accuracy?" and "Does skill affect the accuracy of an analyst's forecast?" There is overlap between these two areas of research, so the discussion is sometimes applicable to both.

4.1.2.4.1. Analysts' forecasts compared to time-series forecasts. Early research examines the accuracy of analysts' forecasts and their association with security returns, and compares these properties with time-series forecasts of earnings. Brown and Rozeff (1978) were the first to document superior accuracy of analysts' forecasts over time-series forecasts of quarterly earnings. Subsequent research offers conflicting evidence (see Collins and Hopwood (1980) and Fried and Givoly (1982) for confirming the evidence in Brown and Rozeff (1978), whereas Imhoff and Paré (1982) for contradictory evidence) and also raises the question of whether analysts' superiority stemmed from their timing advantage (i.e., access to more recent information) over time-series models. Brown et al. (1987a, b) test for both accuracy and association with security returns in comparing the quality of analysts' forecasts against time-series forecasts of quarterly earnings. They show that, even after controlling for the timing advantage, analysts' forecasts are more accurate and modestly more highly associated with stock returns than time-series forecasts. O'Brien (1988), however, documents conflicting evidence in which an autoregressive model forecast is more highly associated with returns than I/B/E/S forecasts. The conflicting evidence notwithstanding, in recent years it is common practice to (implicitly) assume that analysts' forecasts are a better surrogate for market's expectations than time-series forecasts. The issues of current interest are whether analysts' forecasts are biased, the determinants of the biases, and whether the market recognizes the apparent biases in pricing securities.

4.1.2.4.2. Optimism in analysts' forecasts. Many studies report evidence that analysts' forecasts are optimistic,[46] although the optimism appears to be waning in recent years (see Brown, 1997, 1998; Matsumoto, 1998; Richardson et al., 1999). There are at least three hypotheses consistent with the decline in analyst optimism: (i) analysts are learning from evidence of past biases (see Mikhail et al. (1997), Jacob et al. (1999), and Clement (1999) for mixed evidence on the effect of experience on learning); (ii) analysts' incentives have changed; and (iii) the quality of data used in the research examining analysts' forecast properties has improved (e.g., suffers less from survivor biases or selection biases).

4.1.2.4.3. Estimating bias in analysts' forecasts. Forecast optimism is inferred from a systematic positive difference between the forecast and actual earnings per share. The optimism has been documented using Value Line, I/B/E/S, and Zacks data sources for analysts' forecasts (Lim, 1998). The estimates of analyst optimism vary across studies in part because of differences in research designs, variable definitions, and time periods examined. Consider, for example, the following three recent studies that report properties of I/B/E/S

[46] Examples include Barefield and Comiskey (1975), Crichfield et al. (1978), Fried and Givoly (1982), Brown et al. (1985), O'Brien (1988), Stickel (1990), Abarbanell (1991), Ali et al. (1992), Brown (1997, 1998), Lim (1998), Richardson et al. (1999), and Easterwood and Nutt (1999).

analysts' forecasts: Lim (1998), Brown (1998), and Richardson et al. (1999). Each uses over 100,000 firm-quarter observations and analyzes I/B/E/S forecasts from approximately the same time period from 1983 or 1984 to 1996 or 1997.

Lim (1998, pp. 9–10) uses "the median of the unrevised estimates of a quarter's earnings across all brokerage firms", although the use of the mean of analysts' forecasts is not uncommon in the literature (see, for example, Chaney et al., 1999).[47] Richardson et al. (1999) use individual analyst's forecast and average the forecast errors each month, whereas Brown (1998) reports results using only the most recent analyst forecast. Lim (1998) calculates forecast errors as the difference between the earnings forecast and actual earnings per share as reported on Compustat, based on the evidence in Philbrick and Ricks (1991) that actual earnings reported by I/B/E/S suffers from an "alignment problem". In contrast, Brown (1998) and Richardson et al. (1999) use I/B/E/S actual earnings "for comparability with the forecast" (Richardson et al., 1999, p. 7).

Previous research also differs in its treatment of outliers. Lim (1998) excludes absolute forecast errors of $10 per share or more, while Brown (1998) winsorizes absolute forecast errors greater than 25 cents per share and Degeorge et al. (1999) delete absolute forecast errors greater than 25 cents per share. Richardson et al. (1999) delete price-deflated forecast errors that exceed 10% in absolute value. Brown (1998), Degeorge et al. (1999), and Kasznik and McNichols (2001) do not use a deflator in analyzing analysts' forecast errors, whereas Lim (1998) and Richardson et al. (1999) deflate forecast errors by price. Analysis without a deflator implicitly assumes that the magnitude of undeflated forecast error is not related to the level of earnings per share (i.e., forecast errors are not heteroskedastic). In contrast, use of price deflation implicitly assumes that the deviation of the actual from forecasted earnings depends on the level of earnings per share or price per share and that price deflation mitigates heteroskedasticity.

4.1.2.4.4. Evidence of bias. Notwithstanding the research design differences, the evidence in most of the studies suggests analysts' optimism. This conclusion should be tempered by the fact that the forecast samples examined in various studies are not independent. Lim (1998) finds an average optimistic bias of 0.94%. of price. The bias is considerably higher at 2.5% of price for small firms and it is 0.53% of price for large market capitalization stocks. He also reports that the bias is pervasive in that it is observed every year and in every market

[47] Note that even if the distribution of actual earnings might be skewed, the distribution of analysts' forecasts for a given firm need not be skewed, so the use of the mean or median of analysts' forecasts might not make much difference. Evidence in O'Brien (1988) indicates that median forecasts are slightly smaller than the mean.

capitalization decile of sample firms, and it is observed in both newly covered and not newly covered securities by analysts.

While the forecast biases reported in Lim (1998) seem both statistically and economically large, Brown (1998) reports a mean bias of only a cent per share in the most recent analyst's forecast. His annual analysis from 1984 to 1997 reveals a range of bias from 2.6 cents per share optimism in 1993 to 0.39 cents per share pessimism in 1997. Richardson et al. (1999) also find that the bias declines dramatically, from 0.91% of the price to 0.09% of price, as the forecast horizon is shortened from one year to one month (also see O'Brien, 1988). Like Brown (1998), Richardson et al. also report that the bias has turned from optimism to pessimism in recent years. Abarbanell and Lehavy (2000a) take issue with this conclusion. They argue that forecast data providers like First Call, Zacks, and IBES have increasingly changed the definition of reported earnings to earnings from continuing operations and now require analysts to forecast earnings from continuing operations. Abarbanell and Lehavy (2000a) conclude that this change "plays a dominant role in explaining the recent declines in apparent forecast optimism and increases in the incidence of zero and small pessimistic forecast errors".

In most studies the median forecast bias is quite small (e.g., 0.01% in Lim, 1998), which suggests that extreme observations hugely influence the results, i.e., skewness of the earnings distribution drives the results. Consistent with earnings skewness, Gu and Wu (2000) and Abarbanell and Lehavy (2000b) find that a small number of forecast error observations disproportionately contributes to the observed bias.

4.1.2.4.5. Potential research design problems. Despite the apparently compelling evidence, I remain somewhat skeptical of the evidence of analysts' forecast bias for several reasons. First, forecast earnings and actual earnings against which the forecast is being compared do not always seem to be the same (see I/B/E/S data definitions), especially when Compustat actuals are used (see Sabino, 1999). Analysts generally forecast earnings without special items and other one-time gains and losses. I/B/E/S apparently adjusts the actual reported earnings number for special items and/or one-time gains and losses to back out the earnings number the firm would have reported consistent with the earnings number analysts were forecasting (see for details, Sabino, 1999; Abarbanell and Lehavy, 2000a). This procedure seems subjective and whether it contributes to the observed bias (or noise) is worthy of investigation.

Second, the coverage of data has improved dramatically through the years and the degree of bias has declined steadily (see evidence in Brown, 1997, 1998; Richardson et al., 1999). Is the evidence of bias related to the improvement in the coverage of firms in the data bases? Third, are there survival biases in the data? Survival bias might arise not simply because firms go bankrupt, but mostly because of mergers and acquisitions. Finally, what is the effect of mixing stale forecasts with recent forecasts? Evidence suggests recent forecasts are less biased than forecasts issued earlier. However, not all analysts revise their forecasts, so the median forecast at any point in time is for a sample of recent and stale forecasts. What is the contribution to the bias arising from stale forecasts? Is analysts' proclivity to revise forecasts diminished if a firm is performing poorly? This would impart an optimistic bias as a result of using stale forecasts (see Affleck-Graves et al., 1990; McNichols and O'Brien, 1997). Analysis in Richardson et al. (1999), which examines forecast bias as a function of the horizon, appears to be a step in the right direction.

4.1.2.4.6. Bias in long-horizon forecasts. In addition to quarterly earnings forecasts, there is a large body of recent research that examines properties of long-horizon analysts' forecasts. Long-horizon forecasts are generally forecasts of growth over two-to-five years. Analysis of long-term earnings growth forecasts also reveals that these are generally optimistic (e.g., LaPorta, 1996; Dechow and Sloan, 1997; Rajan and Servaes, 1997). An emerging body of research examines analysts' long-term forecasts in tests of market efficiency (see below). I defer the discussion of some of the properties of analysts' long-term forecasts to the tests of market efficiency section of the paper.

4.1.2.4.7. Economic determinants of forecast bias. Evidence of optimism in analysts' forecasts has led to many studies proposing and testing hypotheses to explain the optimistic bias. The hypotheses fall in two broad categories. First, there are economic incentives based explanations for analysts' forecast optimism. Second, a behavioral cognitive-bias explanation for analysts' bias is proposed.

Incentives-based explanations: First, an important economic incentive motivating "sell-side" analysts to issue optimistic earnings forecasts is the compensation they receive for their services to the corporate finance arm of an investment-banking firm.[48] The corporate finance division derives revenues mainly from services related to securities issues and merger-and-acquisition activities. Sell-side analysts' optimistic forecasts help the corporate finance division generate business. The deterrent to analysts from issuing overly optimistic forecasts is that a portion of their annual compensation and their reputation, and thus human capital, are an increasing function of forecast accuracy and a decreasing function of forecast bias.[49] One prediction of the hypothesis here is that analysts working for an investment-banking firm doing business with the client firm (called affiliated analysts) would issue more optimistic forecasts than unaffiliated analysts. Lin and McNichols (1998a),

[48] See Adair (1995), Ali (1996), Dechow et al. (1999), Dugar and Nathan (1995), Hansen and Sarin (1996), Hunton and McEwen (1997), Lin and McNichols (1998a,b), Michaely and Womack (1999), and Rajan and Servaes (1997).

[49] Consistent with this hypothesis, Mikhail et al. (1999) document a significant relation between analyst turnover and relative forecast accuracy.

Michaely and Womack (1999), Dugar and Nathan (1995), and Dechow et al. (1999), among others, offer evidence consistent with the hypothesis.

An alternative interpretation for the observed bias in affiliated analysts' forecasts is as follows. The determination of affiliated analysts is not exogenous. Suppose there are N analysts, and all of them are assumed to issue unbiased forecasts. Assume furthermore that they independently issue N forecasts at time t for a firm i. Firm i's management is interested in an investment-banking relation with one of the analyst's firm because it would like to issue new equity. Firm i might retain the investment-banking firm of the analyst issuing the highest of the N forecasts. That is, the firm's choice of the investment-banking analyst is likely in part a function of who is most bullish about the firm's prospects.[50] If the N forecasts were issued independently and since all the analysts are assumed to issue unbiased forecasts *on average*, the order statistic of the cross-sectional distribution of analysts' forecasts (or a forecast from the high end of the distribution) selected by the firm's management will ex post appear optimistic. I believe the challenge is to discriminate between the above explanation and the incentive-based opportunistic-forecast explanation.

Second, Lim (1998) and Das et al. (1998) argue that analysts might issue optimistic forecasts to gain increased access to information from management, especially in cases where the information asymmetry between the management and the investment community is high. Analysts' investment in developing better relations with firms' management improves the flow of information from managers as well as helps obtain more investment banking and brokerage business, and potentially more brokerage commissions from clients. Lim (1998) and Das et al. (1998) recognize that forecast bias is bad, but management might reward optimism by funneling information to the analyst. This information is helpful in improving forecast accuracy. The benefit to analysts is greatest when prior uncertainty is high. So analysts trade-off bias against information from management, which reduces the variance of the forecast error. This leads to an interior equilibrium, rather than a corner solution of huge optimistic bias.[51] The hypothesis also generates a cross-sectional prediction that the bias would be increasing in variables that proxy for prior uncertainty and information asymmetry (e.g., firm size, and growth opportunities). Evidence in Lim (1998) and Das et al. (1998) is consistent with the hypothesis.

[50] While this provides an incentive for all analysts to be optimistic, recall that I have assumed unbiased forecasts. The argument I make here is unchanged even if the analysts are on average assumed to make optimistically biased forecasts. If this were the case, the affiliated analyst is expected to appear more optimistically biased than the rest.

[51] See Laster et al. (1999) for a similar argument using publicity from their forecasts traded-off against accuracy as a motivation for analysts' optimistic bias.

Third, Gu and Wu (2000) hypothesize that the observed forecast bias results from analysts' incentives in the presence of earnings skewness. They argue that optimistic bias is rational and expected because analysts strive to minimize mean absolute forecast error. The median of a skewed distribution minimizes the mean absolute forecast error. Thus, if the realized earnings distribution is negatively skewed and if analysts seek to minimize the absolute forecast error, not mean squared error, then forecasts will be optimistically biased. Evidence in Gu and Wu (2000) is consistent with their skewness explanation. While Gu and Wu (2000) offer an interesting explanation, in their setting both optimistic and pessimistic biases are explained so long as analysts forecast median earnings. Therefore, if skewed earnings distribution suggests extreme surprising outcomes, then in good economic periods analysts ex post turn out to be pessimistic and they ex post turn out to be optimistic in bad economic times. Gu and Wu (2000) cannot discriminate between the above explanation and their hypothesis that analysts have an incentive to forecast the median.

Finally, Abarbanell and Lehavy (2000b) propose that it is management's incentive to take earnings baths that largely contributes to the observed optimistic bias in analysts' forecasts. That is, unlike the previous explanations, Abarbanell and Lehavy (2000b) argue that the bias has nothing to do with analysts' incentives or cognitive biases (see below). Instead, they show that earnings management observations disproportionately impact the estimated bias, which prior research seeks to explain on the basis of analysts' incentives and/or cognitive biases.

Cognitive-bias explanations: Cognitive-bias explanations for analysts' optimism have been proposed mainly to explain anomalous security-return evidence that suggests market inefficiency in long-horizon returns. Evidence of apparent market overreaction to past good and bad price performance (i.e., a profitable contrarian investment strategy) prompted a cognitive bias in analysts' forecasts as an explanation. Drawing upon the behavioral theories of Tversky and Kahneman (1984) and others, DeBondt and Thaler (1985, 1987, 1990), Capstaff et al. (1997), and DeBondt (1992) propose a cognitive-bias explanation for analysts' forecast optimism. Specifically, they hypothesize that analysts systematically overreact to (earnings) information, which imparts an optimistic bias in analysts' forecasts. However, in order for an optimistic bias in analysts' forecasts to arise, there must be some asymmetry in overreaction such that analysts' overreaction to good news is not fully offset by their overreaction to bad news. Elton et al. (1984) argue that analysts overestimate firms performing well and Easterwood and Nutt (1999) document evidence that analysts overreact to good earnings information, but underreact to bad earnings information. The source of asymmetry in the analysts' overreaction is not fully understood in the literature. The asymmetry also makes it difficult to explain the post-earnings-announcement drift because reversal in the reaction to good news earnings is not observed.

Research also examines whether there is a cognitive-bias-induced overreaction and optimism in analysts' forecasts (see Klein, 1990; Abarbanell, 1991) as well as whether the apparent security-return overreaction[52] is a result of the market believing analysts' cognitive-bias-induced overreacting and biased forecasts (e.g., LaPorta, 1996; Dechow and Sloan, 1997). Klein's (1990) evidence is inconsistent with overreaction in analysts' forecasts and Abarbanell (1991) infers underreaction to earnings information, which is consistent with the post-earnings-announcement drift. In recent work, Abarbanell and Lehavy (2000b) fail to find evidence consistent with cognitive bias inducing optimistic bias in analysts' forecasts. I defer the security-return evidence to Section 4 where I discuss research on market efficiency with respect to analysts' long-horizon forecasts.

Other explanations: In addition to the above incentives-based and cognitive-bias-related explanations for analysts' optimism, at least three other explanations are offered in the literature. These are (see Brown, 1998): herd behavior (Trueman, 1994); low earnings predictability (Huberts and Fuller, 1995); and analysts prefer to withhold unfavorable forecasts (Affleck-Graves et al., 1990; McNichols and O'Brien, 1997).

4.1.2.4.8. Properties of individual analyst's forecasts. Research in this area almost invariably has a descriptive component that documents properties of individual analyst's forecasts. Other research analyzes properties of individual analyst's forecasts in the context of analysts' economic incentives in issuing earnings forecasts, i.e., the costs and benefits of issuing accurate or biased forecasts. The latter is more interesting, but also more difficult.

Research on the properties of individual analysts' forecasts can be categorized into three streams. First, there is research on cross-sectional variation in and determinants of analysts' forecast accuracy. Second, research examines whether analysts' forecasts are efficient in using all the information available at the time of their forecasts. Third, there is research on systematic differences in the properties of analysts' forecasts between groups of analysts (e.g., affiliated versus unaffiliated analysts), which might be related to differential economic incentives facing the groups of analysts.

4.1.2.4.9. Differential forecast accuracy and its determinants. The early literature fails to find differential forecast accuracy among analysts (see Brown and Rozeff, 1980; O'Brien, 1990; Butler and Lang, 1991). Failure to control for the confounding effect of forecast recency on forecast accuracy contributed to the lack of finding significant differential forecast accuracy. Using larger data sets and better controls for forecast horizon, Sinha et al. (1997) conclude that analysts differ in terms of their forecast accuracy. They show that even in hold

[52] See DeBondt and Thaler (1985, 1987), Chan (1988), Ball and Kothari (1989), Chopra et al. (1992), Ball et al. (1995), and Fama and French (1995) for research examining whether investors and the stock market overreact to information over long horizons.

out samples (i.e., an ex ante analysis), superior forecasters based on past performance outperform other analysts in forecast accuracy (also see Stickel (1992), for the forecast superiority of the *Institutional Investor* All American Research Team vis-à-vis other analysts). Sinha et al. also find that poor performers do not necessarily repeat poor performance. Their evidence is consistent with economic Darwinism in that superior forecasters survive, but poor performers are possibly weeded out in the marketplace.

Recent examples of research examining the determinants of analyst forecast superiority include Mikhail et al. (1997), Jacob et al. (1999), and Clement (1999). The evidence in these studies suggests that experience (or learning), the size of the brokerage firm that an analyst works for, and the complexity of the analyst's task (number of firms and industries followed by an analyst) affect forecast accuracy. The evidence on experience appears mixed in part because of data problems. For example, data are available only since 1984, so even if some analysts were experienced at the start of the data availability year, they are coded as no more experienced as a novice. In addition, inferences about the effect of long experience are confounded by potential survivor bias problems.

4.1.2.4.10. Efficiency of analysts' forecasts. A number of studies show that analysts' forecasts are inefficient in the sense that they do not fully incorporate past information available at the time of their forecasts. Evidence in Lys and Sohn (1990), Klein (1990), and Abarbanell (1991) suggests that analysts underreact to past information reflected in prices. There is evidence of serial correlation in forecast revisions of individual analysts surveyed by Zacks Investment Research (see Lys and Sohn, 1990), in the Value Line forecasts (see Mendenhall, 1991) and in the I/B/E/S consensus forecasts (see Ali et al., 1992). This research examines whether analysts' underreaction to past information and/or earnings information is a potential explanation for the post-earnings-announcement drift (also see Abarbanell and Bernard, 1992).

The inefficiency of analysts' forecasts in incorporating available information in revising their forecasts raises the question of an analyst's incentive to provide an accurate forecast. Stated differently, is the cost of incorporating all the information outweighed by potential benefits? This requires better knowledge of (or proxies for) the cost and reward structure of a financial analyst.

4.1.2.4.11. Differences in forecast accuracy across classes of analysts. Recent research examines whether economic incentives motivate different classes of analysts (e.g., analysts affiliated with a brokerage firm that has an investment-banking relation with the firm whose earnings are being forecast versus unaffiliated analysts). This research, discussed earlier, examines both differences in forecast accuracy across the classes of analysts and security price performance in an attempt to ascertain whether capital markets are fixated on biased analysts' forecasts. I will revisit the issues surrounding market efficiency below.

4.1.3. Methodological issues and capital markets research

There are several issues involved in drawing statistical inferences in capital markets research. Although econometric in nature, some methodological research appears in the accounting literature because it addresses issues that are unique to capital markets research in accounting. The uniqueness often stems either from the properties of accounting data or from choice of research design (e.g., levels regressions). There is a voluminous body of research that examines econometric issues germane to capital markets research. These issues are important and have a tremendous bearing on the inferences we draw from the statistical analysis presented in the research. However, to keep the review focused, I survey this research only by way of listing the main issues and refer the reader to the relevant literature for technical details. The main issues include:

(i) bias in test statistics because of cross-correlation in the data or regression residuals (see Schipper and Thompson, 1983; Collins and Dent, 1984; Sefcik and Thompson, 1986; Bernard, 1987; Christie, 1987; Kothari and Wasley, 1989; Brav, 2000; Mitchell and Stafford, 2000);
(ii) price and return regression models (see Lev and Ohlson, 1982; Christie, 1987; Landsman and Magliolo, 1988; Kothari and Zimmerman, 1995; Barth and Kallapur, 1996; Barth and Clinch, 1999; Easton, 1998; Brown et al., 1999; Holthausen and Watts, 2001); and
(iii) comparing the information content of alternative models, e.g., comparing the association of earnings versus cash flows with stock returns (see Davidson and MacKinnon, 1981; Cramer, 1987; Vuong, 1989; Dechow, 1994; Biddle et al., 1995; Biddle and Seow, 1996; Dechow et al., 1998b; Ball et al., 2000).

4.1.4. Models of discretionary and non-discretionary accruals

4.1.4.1. Motivation. I review methodological research on models of discretionary and non-discretionary accruals because of their preeminent role in researchers' ability to draw correct inferences in capital markets and other research in accounting. Discretionary accruals and earnings management are used synonymously in the literature. Schipper (1989) defines earnings management as "purposeful intervention in the external reporting process, with the intent of obtaining some private gain to managers or shareholders". The discretionary accrual models split total accruals into a discretionary component, which serves as a proxy for earnings management, and a non-discretionary portion. The non-discretionary accrual together with operating cash flows is the non-discretionary portion of reported earnings. At least three streams of research use discretionary accrual models.

First, discretionary accrual models are used in tests of contracting- and political-cost-based hypotheses about management's incentives to manipulate accounting numbers (i.e., opportunistic use of accruals). Alternatively, this research hypothesizes that firms choose accounting policies or include discretionary accruals in earnings to convey management's private information about the firm's prospects or to more accurately reflect the firm's periodic performance, i.e., the efficient contracting use of accruals (see Holthausen and Leftwich, 1983; Watts and Zimmerman, 1990; Holthausen, 1990; Healy and Palepu, 1993). This body of research is usually not in the capital markets area.

Second, using market efficiency as a maintained hypothesis, many studies test the efficient contracting and opportunism hypotheses by correlating earnings components with stock returns. This research is frequently aimed at testing the information content or association with security returns of new mandated recognition or disclosure standards of accounting. Examples of this research include studies examining whether banks' disclosures of fair values of investments and loans contain value-relevant information (see, e.g., Barth, 1994; Barth et al., 1996; Nelson, 1996). Alternatively, research examines properties of voluntarily disclosed accounting data to test the efficient contracting and opportunism hypotheses (e.g., Beaver and Engel, 1996; Wahlen, 1994). Beaver and Venkatachalam (1999) is an example of research that simultaneously tests the information content and opportunism hypotheses, i.e., it allows for both non-strategic noise and opportunistic accrual manipulation.

Third, a recent popular area of research tests the joint hypothesis of market inefficiency and accrual manipulation with a capital market motivation, e.g., an incentive to manipulate accruals upward in periods prior to stock issues (see Dechow et al., 1996; Jiambalvo, 1996). Recent developments in financial economics and accounting, which are suggestive of informational inefficiency of the capital markets, have fueled this research. The research tests whether there is a positive association between current manipulated (or discretionary) accruals and subsequent risk-adjusted abnormal stock returns. Examples of research in this area include Sloan (1996), Teoh et al. (1998a–c), Rangan (1998), and Ali et al. (1999).

4.1.4.2. Discretionary accrual models. There are five well-known time-series models of discretionary accruals in the literature.[53] These are: the DeAngelo (1986) model, the Healy (1985) model, the industry model used in Dechow and Sloan (1991), the Jones (1991) model, and the modified-Jones model by Dechow et al. (1995). Of these only the Jones and modified-Jones models are commonly used in research in part because they outperform the rest in terms of specification and power (see Dechow et al., 1995). Thomas and Zhang (1999)

[53] Strictly speaking, they are models of non-discretionary accruals and the residual (or the intercept plus the residual) from each model is an estimate of discretionary accruals.

dispute Dechow et al.'s finding and conclude "Only the Kang-Sivaramakrishnan model, which is coincidentally the least popular model, performs moderately well." Kang and Sivaramakrishnan (1995) employ an instrumental variable approach to estimate discretionary accruals.

Moreover, cross-sectional estimation of the Jones model (see DeFond and Jiambalvo, 1994; Subramanyam, 1996b) has replaced the original time-series formulation of the model in terms of recent application. DeFond and Jiambalvo (1994), Subramanyam (1996b) and other studies have legitimized the cross-sectional estimation. Their evidence suggests the performance based on cross-sectional estimation is no worse than that using time-series estimation of the Jones and modified-Jones models. Cross-sectional estimation imposes milder data availability requirements for a firm to be included for analysis than time-series estimation. This mitigates potential survivor bias problems. The precision of the estimates is also likely higher in cross-sectional estimation because of larger sample sizes than the number of time-series observations for an individual firm. The downside of cross-sectional estimation is that cross-sectional variation in the parameter estimates is sacrificed. However, conditional cross-sectional estimation is a good remedy for the problem (see previous discussion in the context of time-series properties of annual earnings forecasts in Section 4.1.2, and Fama and French, 2000; Dechow et al., 1999).

4.1.4.3. Evaluation of discretionary accruals models. An influential study by Dechow et al. (1995) evaluates the power and specification of alternative discretionary accrual models. Their conclusion that the "modified version of the model developed by Jones (1991) exhibits the most power in detecting earnings management" (Dechow et al., 1995, p. 193) serves as the basis for the widespread use of the modified-Jones model. Dechow et al. (1995, p. 193) also conclude that, while "all of the models appear well specified when applied to a random sample", "all models reject the null hypothesis of no earnings management at rates exceeding the specified test levels when applied to samples of firms with extreme financial performance". Finally, Dechow et al. (1995, p. 193) find that "the models all generate tests of low power for earnings management…".

Since earnings management studies almost invariably examine samples of firms that have experienced unusual performance, the most relevant conclusion from Dechow et al. (1995) is that the discretionary accrual models are seriously misspecified. The misspecification arises because the magnitude of normal accruals, i.e., non-discretionary or expected accruals, is correlated with past (and contemporaneous) firm performance. The dependence arises for two reasons. First, as discussed in Section 4.1 on the time-series properties of earnings, firm performance conditional on past performance does not follow a random walk. Second, both operating accruals and operating cash flows are strongly mean reverting (see Dechow (1994) for evidence, and Dechow et al.

(1998a, b) for a model that explains the correlation structure), which means these variables are not serially uncorrelated. However, none of the five discretionary accrual models used in the literature explicitly captures accruals' serial correlation property, so estimated discretionary accruals are biased and contaminated with non-discretionary accruals. Evidence in Guay et al. (1996), who use market-based tests, and Hansen (1999), who examines the behavior of future earnings, suggests that the extent of the non-discretionary accrual component in estimated discretionary accruals is large. Thomas and Zhang's (1999) conclusion is still stronger. They infer that the commonly used models "provide little ability to predict accruals".

I now turn attention to power of the tests that use discretionary accruals. Power of a test is the frequency with which the null hypothesis is rejected when it is false. In assessing the power of the discretionary accrual models, there are two relevant issues. First, if a test is misspecified (i.e., rejection frequency under the null exceeds the significance level of the test, e.g., 5%), statements about the power of the test are not particularly meaningful. Second, assuming that the estimated discretionary accruals are adjusted for bias due to past performance or other reasons, I would argue that the discretionary accrual models yield tests of high, not low power. This conclusion contrasts with Dechow et al. (1995). They examine the power of the tests using individual securities, i.e., sample size is one. Since almost all research studies use samples in excess of 50–100, assuming independence, the standard deviation of the mean discretionary accrual is an order of magnitude smaller than that in Dechow et al. (1995).[54] Therefore, in most research settings, the power is considerably higher than reported in Dechow et al. (1995). Not surprisingly, the null of zero discretionary accruals is often rejected in empirical research.

4.1.4.4. Future research: Better models of discretionary accruals and better tests. The misspecification of and bias in the discretionary accrual models suggest that inferences about earnings management might not be accurate. Accruals should be modeled as a function of a firm's immediate past economic performance, so that discretionary accruals can be more accurately isolated (see Kaplan, 1985; McNichols and Wilson, 1988; Guay et al., 1996; Healy, 1996; Dechow et al., 1998a). Shocks to a firm's economic performance affect normal accruals as well as serve as a strong motivation to managers to manipulate accruals both opportunistically and to convey information. This complicates the researcher's task of separating discretionary from non-discretionary accruals.

Collins and Hribar (2000b) point to another problem in identifying not only discretionary accruals, but total accruals as well. They show that a researcher's

[54] Even if the standard deviation is estimated with a correction for cross-sectional dependence, it is likely to be considerably smaller than that for a sample of one firm as in Dechow et al. (1995).

estimate of total accruals using the balance sheet approach instead of taking information directly from a cash flow statement is economically significantly biased in the presence of mergers and acquisitions and discontinued operations.[55] Precise information on cash flows and accruals has become available only after the Statement of Financial Accounting Standard No. 95 became effective in 1987, and many research studies use the balance sheet approach even in the recent period. The misestimation of total accruals increases the error in estimating discretionary accruals and potentially biases the estimated discretionary accrual. If the test sample firms are more active in mergers and acquisitions or have discontinued operations more frequently than the control sample firms, then Collins and Hribar (2000b) analysis suggests the inferences might be incorrect. Their replication of the studies examining seasoned equity offering firms' accrual manipulation reveals that the bias in estimated discretionary accruals largely accounts for the apparent manipulation documented in Teoh et al. (1998a) and elsewhere.

Another complicating factor is whether discretionary accruals are motivated by managerial opportunism or efficient contracting considerations. Subramanyam (1996b) reports results of the tests of estimated discretionary accruals' association with returns and with future earnings and cash flow performance. He concludes that discretionary accruals are on average informative, not opportunistic.[56] In contrast, portfolios representing firms with extreme amounts of accruals, which are likely to be flagged as extreme discretionary accrual portfolios, are suggestive of accrual manipulation with a motivation to (successfully) fool capital markets (see Sloan, 1996; Xie, 1997; Collins and Hribar, 2000a, b). Because the opportunism and efficient contracting motivations are likely linked to managers' incentives and firm performance, it behooves researchers to link the development of a discretionary accrual model to firm performance.

Simultaneous with the development of better economic models of discretionary accruals, improved tests using discretionary accruals are required. The demand for better tests arises for at least three reasons. First, research using discretionary accruals frequently examines multi-year performance, whereas methodological studies like Dechow et al. (1995) examine discretionary accrual performance over only one year. Second, test statistics calculated assuming cross-sectional independence might be misspecified especially when a researcher examines performance over multi-year horizons. See Brav (2000), for evidence on bias in tests of long-horizon security-return performance using

[55] Also see Drtina and Largay (1985), Huefner et al. (1989), and Bahnson et al. (1996).

[56] However, Subramanyam (1996b) finds that the coefficient on discretionary accruals is smaller than that on non-discretionary accruals, which is consistent with discretionary accruals being partially opportunistic or that they are less permanent than non-discretionary accruals.

tests that ignore positive cross-sectional dependence (also see Collins and Dent, 1984; Bernard, 1987).

Third, test statistics for multi-year performance might be misspecified because long-horizon performance is likely right skewed (or might exhibit some other form of non-normality) and not all sample firms survive, so there might be a survivor bias. While a *t*-test using a large sample size is quite robust to non-normality, the combination of skewness (or other forms of non-normality) and cross-sectional dependence might contribute to test misspecification. Use of Bootstrap standard errors would be an option that is worth examining to tackle problems arising from both non-normality and survivor biases.

Fourth, the percentage of firms surviving the multi-year test period in a typical research study is considerably smaller than 100%. For example, Teoh et al. (1998c) study a sample of 1514 IPOs for a six-year post-IPO period. In their tests based on the return-on-sales performance measure using a matched-pair sample, the number of firms surviving in the sixth post-IPO year is only 288, i.e., 19% of the original sample (see Teoh et al., 1998c, Table 2, panel C). Such a large reduction in sample size is not unique to the Teoh et al. (1998c) study. Surprisingly, however, there is no systematic evidence in the literature on whether such a large degree of attrition imparts a bias. Moreover, in a matched-pair research design, is the attrition due more often to the lack of survival of test firms or matched control firms? Does this matter?

Finally, evidence in Barber and Lyon (1996) suggests that use of a performance-matched control firm yields unbiased measures of abnormal operating performance in random and non-random samples. Use of performance-matched samples is common in research examining discretionary accruals. However, a systematic study of the specification and power of the tests of discretionary accruals using performance-matched control firm samples is missing in the literature.

4.1.4.5. Capital market research implications. Of direct relevance in this review of the capital markets literature is the question whether capital market studies are affected by problems with the discretionary accrual models. I believe they are. Let me give one example. Consider the hypothesis in Aharony et al. (1993), Friedlan (1994), Teoh et al. (1998b, c), and other studies that in the years leading up to an IPO, management biases financial performance upward through positive discretionary accruals.

First, management's IPO decision is endogenous. It is likely to be taken in the light of superior past and expected future economic performance and a need for cash for investments to meet the anticipated demand for the company's products and services. However, high growth is mean reverting. One reason is that a portion of high growth often results from transitory earnings due to a non-discretionary (or neutral) application of GAAP. Thus, a portion of the subsequent performance reversal is expected and may not be due to discretionary accruals.

Second, the popularly used modified-Jones model treats all of the increase in accounts receivables as discretionary (see Teoh et al., 1998c; Dechow et al., 1995).[57] Thus, legitimate revenue growth on credit is treated as discretionary or fraudulent (see Beneish, 1998). This means, since extreme revenue growth is mean reverting, the modified-Jones model exacerbates the bias in estimated discretionary accrual in the post-IPO period.

The above example suggests the possibility of bias in estimated discretionary accruals (also see Beneish, 1998). More careful tests are warranted to draw definitive conclusions. In addition to documenting evidence of discretionary accruals, researchers correlate the estimated discretionary accruals with contemporaneous and subsequent security returns to test market efficiency. I defer to Section 4.4 a discussion of potential consequences of misspecified discretionary accrual models for inferences about the market's fixation on reported accounting numbers in the context of tests of market efficiency. As noted above, the capital market motivation for accrual manipulation has assumed great importance in the light of evidence suggesting capital markets might be informationally inefficient.

4.2. Alternative accounting performance measures

Starting with Ball and Brown (1968), many studies use association with stock returns to compare alternative accounting performance measures like historical cost earnings, current cost earnings, residual earnings, operating cash flows, and so on. A major motivation for research comparing alternative performance measures is perceived deficiencies in some of the performance measures. For example, Lev (1989), the AICPA Special Committee on Financial Reporting (1994), also known as the Jenkins Committee, and compensation consultants like Stern, Stewart & Company (Stewart, 1991) all argue that the historical cost financial reporting model produces earnings of "low quality" vis-à-vis firm performance.

Researchers' explicit or implicit use of the term "earnings quality" is either in the context of examining whether earnings information is useful to investors for valuation or in evaluating managers' performance. Capital-markets research typically assumes that an accounting performance measure serves

[57] Teoh et al. (1998c, p. 192) describe their estimation of discretionary accruals as follows: "…we first estimate expected current accruals by cross-sectionally regressing current (not total) accruals on only the change in sales revenues. The expected current accruals is calculated using the estimated coefficients in the fitted equation after subtracting the change in trade receivables from the change in sales revenues. The residual of current accruals is the abnormal current accruals".

either the managerial performance measure role or the valuation information role. A managerial performance measure indicates the value added by the manager's efforts or actions in a period, whereas a measure designed to provide information useful for valuation gives an indication of the firm's economic income or the change in shareholders' wealth. The former has a contracting motivation and the latter has an informational or valuation motivation. Although I expect the performance measure with the contracting motivation to be positively correlated with the performance measure designed with a valuation motivation, I do not expect the two to be the same (see discussion below). Therefore, I believe the research design comparing alternative performance measures should be influenced by the assumed choice of the objective.

4.2.1. Review of past research

Early research on association studies (e.g., Ball and Brown, 1968), which is reviewed in Section 3, firmly establishes that earnings reflect some of the information in security prices. However, this early research did not perform statistical tests comparing alternative performance measures, since the primary concern was to ascertain whether there is any overlap between earnings information and the information reflected in security prices.

In the 1980s several studies statistically compared stock returns' association with earnings, accruals, and cash flows. This research includes long-window association studies by Rayburn (1986), Bernard and Stober (1989), Bowen et al. (1986, 1987), and Livnat and Zarowin (1990) and short-window tests by Wilson (1986, 1987). Apart from providing a formal test, their motivation is that previous research used a relatively crude measure of cash flows. They also use more sophisticated expectation models to more accurately isolate the unexpected components of earnings (accruals) and cash flows, because returns in an efficient market only reflect the unanticipated components. The conclusion from most of these studies is that there is incremental information in accruals beyond cash flows.

In this heavily researched area of the relative information content of earnings and cash flows, Dechow's (1994) innovation is in developing cross-sectional predictions about the conditions that make earnings relatively more informative about a firm's economic performance than cash flows (also see Dechow et al., 1998a). Dechow (1994) argues that the emphasis in previous research on unexpected components of the performance measures is misplaced. She views performance measures as primarily serving a contracting purpose. Therefore, she is not interested in a research design that (i) attempts to obtain the most accurate proxy for the anticipated component of a performance measure and (ii) correlates the unanticipated component with stock returns. She argues that managers' compensation contracts almost invariably specify only one summary performance variable (e.g., earnings) and that the contracts rarely specify it in terms of the innovation in the variable (e.g., unexpected earnings). Dechow (1994) therefore forcefully argues that tests evaluating alternative performance measures should seek to identify the best alternative measure, regardless of whether each measure provides incremental association.[58]

4.2.2. Current interest

Recent research examines new performance measures that the FASB requires to be disclosed (e.g., comprehensive income compared to primary earnings per share by Dhaliwal et al., 1999). Alternatively, research compares different measures advocated by compensation consultants like Stern Stewart & Company against earnings (e.g., EVA compared against earnings by Biddle et al., 1997) or measures that have evolved in different industries (e.g., Vincent (1999) and Fields et al. (1998) examine alternative performance measures used by real estate investment trusts, REITs). Evidence from these studies suggests that performance measures that have evolved voluntarily in an unregulated environment (e.g., performance measures in the REIT industry) are more likely to be incrementally informative than those mandated by regulation (e.g., comprehensive income).

4.2.3. Unresolved issues and future research

4.2.3.1. Correlation with returns as a criterion. Research evaluating alternative performance measures frequently uses association with security returns as the criterion to determine the best measure. Going back to Gonedes and Dopuch (1974), a long-standing issue has been whether association with stock returns is the right test. Holthausen and Watts (2001) offer an in-depth analysis of the issue as well. Research evaluating alternative performance measures must recognize that the objective of a particular performance measure should influence the choice of a test. Consider the scenario in which the performance measure and financial statements are geared towards facilitating debt contracts. It is not clear that a performance measure that seeks to measure the change in the value of the firm's growth options, which would be reflected

[58] Dechow (1994) proposes the Vuong (1989) test, which, in substance, is a test of difference between the adjusted explanatory powers of two models, each with one (set of) explanatory variable(s), but the same dependent variable in both the models. Following Dechow (1994), the Vuong (1989) test has become the industry standard. However, there are alternatives to the Vuong test, as developed in Biddle et al. (1995), or the Davidson and MacKinnon (1981) non-nested J-test. Biddle and Seow (1996) claim that the Biddle et al. (1995) test's specification and power are at least as good as or better than the Vuong and J-tests in the presence of heteroskedastic and cross-correlated data (see Dechow et al., 1998b). Another alternative is to compare *r*-squares of two models with or without the same dependent variable using the standard error of the *r*-square as derived in Cramer (1987). This approach is helpful in making comparisons across countries (see for example, Ball et al., 2000) or across industries.

in the change in the firm's market capitalization, is of greatest interest to the firm's debt-holders.

As another example, if the objective of a performance measure is to report the net value of the delivered output in the past period, then it may not necessarily correlate highly with stock returns (see, for example, Lee, 1999; Barclay et al., 1999). The reason is that return for a period reflects the consequences of only the unanticipated component of the period's delivered output and revisions in expectations about future output. Once we accept that highest correlation with returns is neither a necessary nor a sufficient condition in comparing alternative performance measures, then incremental information content of a measure becomes a questionable criterion in evaluating alternative performance measures.

4.2.3.2. Level or unanticipated component of a performance measure. As noted earlier, Dechow (1994) argues that most management compensation contracts use only one accounting performance measure and that the measure is not the unexpected component of the performance variable. She therefore advocates against using the unexpected component of the performance measure. This suggests correlating the level of the performance measure with the level of price. Use of beginning-of-the-period price as a deflator for both dependent and independent variables is motivated by the econometric benefits (e.g., fewer correlated omitted variables, lesser heteroscedasticity and reduced serial correlation) that follow from using price as a deflator (see Christie, 1987). However, Ohlson (1991), Ohlson and Shroff (1992), and Kothari (1992) show that, because price embeds expectations about future performance, it serves not only as a deflator with econometric benefits, but it in effect correlates returns with the unexpected component of the performance measure. Therefore, if the objective is to focus on the total performance measure, not just its unexpected component, then should it be correlated with returns or prices? Correlation with prices indeed correlates the entire performance measure with prices because current price contains information in the surprise as well as the anticipated components of the performance measure (Kothari and Zimmerman, 1995).[59] The down side of correlating prices with a performance measure is that there can be severe econometric problems due to heteroscedasticity and correlated omitted variables (see Gonedes and Dopuch, 1974; Schwert, 1981; Christie, 1987; Holthausen, 1994; Kothari and Zimmerman, 1995; Barth and Kallapur, 1996; Skinner, 1996; Shevlin, 1996; Easton, 1998; Holthausen and Watts, 2001).

[59] For other advantages of using price regressions, also see Lev and Ohlson (1982) and Landsman and Magliolo (1988).

4.2.3.3. Correlation with future cash flows. An important stated objective of financial accounting standards is that financial information should be helpful to users in assessing the amount, timing, and uncertainty of future cash flows (see FASB, 1978). An operational interpretation of this criterion is to compare performance measures on the basis of their correlation with future cash flows. Some recent research examines earnings' correlation with future cash flows (see Finger, 1994; Dechow et al., 1998a; Barth et al., 1999). If a researcher employs correlation with future cash flows as the criterion to evaluate alternative performance measures, then the performance measure's correlation with prices would serve as a complementary test. The benefit of using price is that it contains information about expected future cash flows in an efficient market, which means the vector of expected future cash flows is collapsed into a single number, price. Of course, the trade-off is econometric problems in using price-level regressions (see Holthausen and Watts, 2001) and the effect of discount rates on price, holding cash flows constant.

4.3. Valuation and fundamental analysis research

This section begins with a discussion of the motivation for research on fundamental analysis (Section 4.3.1). Section 4.3.2 explains the role of fundamental analysis as a branch of capital markets research in accounting. Section 4.3.3 describes the dividend discounting, earnings capitalization, and residual income valuation models that are used frequently in accounting research. This section also reviews the empirical research based on these valuation models. Section 4.3.4 reviews the fundamental analysis research that examines financial statement ratios to forecast earnings and to identify mispriced stocks.

4.3.1. Motivation for fundamental analysis

The principal motivation for fundamental analysis research and its use in practice is to identify mispriced securities for investment purposes. However, even in an efficient market there is an important role for fundamental analysis. It aids our understanding of the determinants of value, which facilitates investment decisions and valuation of non-publicly traded securities. Regardless of the motivation, fundamental analysis seeks to determine firms' intrinsic values. The analysis almost invariably estimates the correlation between the intrinsic value and the market value using data for a sample of publicly traded firms. The correlation between market values and intrinsic value might be estimated directly using intrinsic values or indirectly by regressing market values on determinants of the intrinsic value. In this section, I examine the latter. The last step in fundamental analysis is to evaluate the success or failure of intrinsic valuation on the basis of the magnitude of risk-adjusted returns to a trading strategy implemented in periods subsequent to intrinsic valuation. This is a test of market efficiency and I discuss research on this topic in Section 4.4.

4.3.2. Is fundamental analysis accounting research?

To better answer the question whether research on fundamental analysis should be considered as part of accounting research,[60] first compare the information set in financial statements with the set incorporated in market values. Since market value is the discounted present value of expected future net cash flows, forecasts of future revenues, expenses, earnings, and cash flows are the crux of valuation. Lee (1999, p. 3) concludes that the ''essential task in valuation is forecasting. It is the forecast that breathes life into a valuation model''. However, in most economically interesting settings (e.g., IPOs, high-growth firms, and efficiency enhancing and/or synergy motivated mergers), financial statements prepared according to current GAAP are likely to be woefully inadequate as summary statistics for the firm's anticipated future sales, and therefore, for predicted future earnings information that is embedded in the current market values. Therefore, unless current accounting rules are changed dramatically, it is unlikely that financial statements in themselves will be particularly useful or accurate indicators of market values.

The reliability principle that underlies GAAP is often cited as the reason why financial statements do not contain forward-looking information that affects market values. For example, Sloan (1998, p. 135) surmises ''It seems that it is the reliability criterion that makes the difference between the myriad of variables that can help forecast value and the much smaller subset of variables that are included in GAAP.'' While the reliability principle is important, I believe the revenue recognition principle is just as, if not more, important. The revenue recognition principle reduces financial statements to answering the question ''What have you done for me lately?'' Thus, even if future revenue were to be reliably anticipated (at least a big fraction of it can be for many firms), still *none* of it would be recognized. Since market values and changes in those values depend crucially on news about future revenues, current GAAP financial statements are unlikely to be particularly timely indicators of value.

In spite of a lack of timely information in financial statements, I emphasize the following. First, lack of timeliness in itself does not imply a change in GAAP with respect to the revenue recognition principle (or the reliability principle) is warranted; I am merely describing current GAAP. There are economic sources of demand for historical information in financial statements and therefore for the revenue recognition principle, but that is beyond the

[60] This question might be asked of some other research as well (e.g., market efficiency research in accounting). However, my casual observation is that this question is raised more frequently in the context of fundamental analysis.

scope of this review. Second, there is still some information conveyed by financial reports that is not already in the public domain, as seen from the event study research on the information content of accounting. The association study and the earnings response coefficient literatures seek to ascertain whether accounting captures some of the information that affects security prices and how timely are accounting reports in reflecting that information. As discussed earlier, one concern in this literature is whether GAAP and/or managerial discretion render accounting numbers devoid of value-relevant information.

Given the historical nature of information in financial statements, meaningful fundamental analysis research requires accounting researchers to expand the definition of capital markets research to include research using forecasted earnings information for fundamental analysis. Lee (1999) offers a spirited defense of this viewpoint. He concludes (p. 17) "User-oriented research, such as valuation, is definitely a step in the right direction" for accounting researchers. I concur. However, such research has to move beyond reporting descriptive statistics and evidence of the success of trading strategies into proposing theories and presenting empirical tests of the hypotheses derived from the theories.

Students of fundamental analysis and valuation research should have an understanding of alternative valuation models and fundamental analysis techniques both from the perspective of fulfilling the demand for valuation in an efficient market and intrinsic valuation analysis designed to identify mispriced securities. Below I summarize valuation models and empirical research evaluating the models. I follow this up with fundamental analysis research like Ou and Penman (1989a, b), Lev and Thiagarajan (1993), and Abarbanell and Bushee (1997,1998). Whether abnormal returns can be earned using intrinsic value calculation or fundamental analysis is deferred to the next section on tests of market efficiency.

4.3.3. Valuation models

For fundamental analysis and valuation, the accounting literature relies on the dividend-discounting model or its transformation, like the earnings (capitalization) model or the residual income model. An ad hoc balance sheet model is also popular in the literature (e.g., Barth and Landsman, 1995; Barth, 1991, 1994; Barth et al., 1992). It implicitly relies on the assumption that a firm is merely a collection of separable assets whose reported amounts are assumed to be noisy estimates of their market values. The balance sheet model is used primarily to test value relevance in the context of evaluating financial reporting standards, which is not the primary focus of my review (see Holthausen and Watts, 2001). Moreover, when used, the balance sheet model is typically augmented to also include earnings as an additional variable, which makes it empirically similar to the transformed dividend-discounting models. I therefore only discuss the dividend-discounting model and its accounting-variable-based transformations.

4.3.3.1. Dividend-discounting and earnings capitalization models. This model is generally attributed to Williams (1938). The dividend-discounting model defines share price as the present value of expected future dividends discounted at their risk-adjusted expected rate of return. Formally,

$$P_t = \sum_{k=1}^{\infty} \mathrm{E}_t[D_{t+k}] / \prod_{j=1}^{k} (1 + r_{t+j}), \tag{18}$$

where P_t is the share price at time t, $\sum$ is the summation operator, $\mathrm{E}_t[D_{t+k}]$ is the market's expectation of dividends in period $t+k$, $\prod$ is the product operator, and r_{t+j} is the risk-adjusted discount rate that reflects the systematic risk of dividends in period $t+j$.

As seen from Eq. (18), price depends on the forecasts of future dividends and the discount rates for future periods. Gordon (1962) makes simplifying assumptions about both the dividend process and discount rates to derive a simple valuation formula, known as the Gordon Growth model. Specifically, if the discount rate, r, is constant through time and dividends are expected to grow at a constant rate $g<r$, then

$$P_t = \mathrm{E}_t(D_{t+1})/(r-g). \tag{19}$$

Since future dividends can be rewritten in terms of forecasted values of future earnings and future investments, the dividend-discounting model can be reformulated. Fama and Miller (1972, Chapter 2) is an excellent reference for making the basic transition from the dividend-discounting model to an earnings capitalization model.[61] Fama and Miller make several points that are helpful in understanding the drivers of share price. First, value depends on the forecasted profitability of current and forecasted future investments, which means dividend policy per se does not affect firm value, only a firm's investment policy affects value (Miller and Modigliani, 1961). Fama and Miller (1972) entertain dividend signaling to the extent that a change in dividends conveys information about the firm's investment policy and in this sense mitigates information asymmetry.[62]

Second, the growth rate, g, in Eq. (19) depends on the extent of reinvestment of earnings into the firm and the rate of return on the investments. However, reinvestment itself does not increase market value today unless the return on

[61] For a more sophisticated treatment that allows for a changing discount rate, see Campbell and Shiller (1988a, b), Fama (1977, 1996), and Rubinstein (1976).

[62] See Ross (1977), Bhattacharya (1979), Asquith and Mullins (1983), Easterbrook (1984), Miller and Rock (1985), Jensen (1986), and Healy and Palepu (1988), for some of the literature on dividend signaling.

investments in the future exceeds the discount rate or the cost of capital, r. That is, if the expected return on investments in all future periods exactly equals r, then share price is simply X_{t+1}/r, where X_{t+1} is forecasted earnings for the next period. This valuation is obtained regardless of the degree of expansion either through reinvestment or through issuance of new equity. Fama and Miller (1972, p. 90) refer to this valuation as "the capitalized value of the earnings stream produced by the assets that the firm currently holds". Share value will be higher than X_{t+1}/r only if the firm has opportunities to invest in projects that are expected to earn an above-normal rate of return (i.e., return in excess of r).

Third, capitalization of forecasted earnings generally yields incorrect valuation because future earnings also reflect growth due to reinvestment (i.e., plow back of earnings) and investments financed by new issuance of equity. So, the transformation from a dividend-discounting model to an earnings capitalization model requires an adjustment to exclude the effect of reinvestment on future earnings, but include any effect on future earnings as a result of earning an above-normal rate of return (i.e., the effect of growth opportunities on earnings).

Earnings capitalization models are popular in accounting and much of the earnings response coefficient literature relies on them (see Beaver, 1998; Beaver et al., 1980). In earnings response coefficient applications of earnings capitalization models, forecasted earnings are either based on time-series properties of earnings (e.g., Beaver et al., 1980; Kormendi and Lipe, 1987; Collins and Kothari, 1989) or analysts' forecasts (e.g., Dechow et al., 1999). This literature finesses the reinvestment effect on earnings by assuming that future investments do not earn above-normal rates of returns, which is equivalent to assuming a 100% dividend–payout ratio (e.g., Kothari and Zimmerman, 1995). The marginal effect of growth opportunities is accounted for in the earnings response coefficient literature by using proxies like the market-to-book ratio, or through analysts' high forecasted earnings growth. The hypothesis is that such growth opportunities will have a positive marginal effect on earnings response coefficients (e.g., Collins and Kothari, 1989) because growth stocks' prices are greater than X_{t+1}/r, the no-growth valuation of a stock.

4.3.3.2. Residual income valuation models. The Ohlson (1995) and Feltham and Ohlson (1995) residual income valuation models have become hugely popular in the literature.[63] Starting with a dividend-discounting model, the residual income valuation model expresses value as the sum of current book

[63] Several critiques of the Ohlson and Feltham–Ohlson models appear in the literature. These include Bernard (1995), Lundholm (1995), Lee (1999), Lo and Lys (2001), Sunder (2000), and Verrecchia (1998).

value and the discounted present value of expected abnormal earnings, defined as forecasted earnings minus a capital charge equal to the forecasted book value times the discount rate. Ohlson (1995) and others (e.g., Bernard, 1995; Biddle et al., 1997) point out that the concept of residual income valuation has been around for a long time.[64] However, Ohlson (1995) and Feltham and Ohlson (1995) deserve credit for successfully reviving the residual income valuation idea, for developing the ideas more rigorously, and for impacting the empirical literature.

The Ohlson (1995) model imposes a time-series structure on the abnormal earnings process that affects value. The linear information dynamics in the model (i) specifies an autoregressive, time-series decay in the current period's abnormal earnings, and (ii) models "information other than abnormal earnings" into prices (Ohlson, 1995, p. 668). The economic intuition for the autoregressive process in abnormal earnings is that competition will sooner or later erode above-normal returns (i.e., positive abnormal earnings) or firms experiencing below-normal rates of returns eventually exit. The other information in the Ohlson model formalizes the idea that prices reflect a richer information set than the transaction-based, historical-cost earnings (see Beaver et al., 1980).

The Feltham and Ohlson (1995) model retains much of the structure of the Ohlson (1995) model except the autoregressive time-series process. The Feltham–Ohlson residual income valuation model expresses firm value in terms of current and forecasted accounting numbers, much like the dividend-discounting model does in terms of forecasted dividends or net cash flows. Forecasted abnormal earnings can follow any process and they reflect the availability of other information. This feature enables the use of analysts' forecasts in empirical applications of the Feltham–Ohlson model and is sometimes claimed to be an attractive feature of the valuation model vis-à-vis the dividend-discounting model. For example, in comparing the applications of the dividend-discounting model to the residual income valuation model, Lee et al. (1999) conclude that "practical considerations, like the availability of analysts' forecasts, makes this model easier to implement" than the dividend-discount model (also see Bernard, 1995, pp. 742–743). The illusion of ease arises because, assuming clean surplus, one can value the firm directly using abnormal earnings forecasts, rather than backing out net cash flows from pro forma financial statements. Abnormal earnings forecasts are the difference between (analysts') forecasts of earnings and a capital charge,

[64] The predecessor papers of the residual valuation concept include Hamilton (1777), Marshall (1890), Preinreich (1938), Edwards and Bell (1961), Peasnell (1982), and Stewart (1991).

i.e., $E_t[X_{t+k} - r\,BV_{t+k-1}]$. Using abnormal earnings forecasts, the share price at time t, P_t, is expressed as[65]

$$P_t = BV_t + \sum_{k=1}^{\infty} E_t[X_{t+k} - r\,BV_{t+k-1}]/(1+r)^k, \tag{20}$$

where BV_t is the book value of equity at time t, $E_t[.]$ the expectation operator where the expectation is based on information available at time t, X_t the earnings for period t, and r the risk-adjusted discount rate applicable to the equity earnings (or cash flows).

While Eq. (20) expresses price in terms of forecasted book values and abnormal earnings, those forecasts have precisely the same information as forecasts of dividends, which are implicit in analysts' forecasts of earnings. Stated differently, the residual income valuation model is a transformation of the dividend-discounting model (see Frankel and Lee, 1998; Dechow et al., 1999; Lee et al., 1999).

In addition to the apparent ease of implementation, Bernard (1995) and others argue that another appealing property of the residual income valuation model is that the choice of accounting method does not affect the model's implementation. If a firm employs aggressive accounting, its current book value and earnings would be high, but its forecasted earnings will be lower and the capital charge (or normal earnings) would be higher. Therefore, lower forecasted future abnormal earnings offset the consequences of aggressive accounting that appear in current earnings. Unfortunately, the elegant property that the effect of the management's choice of accounting methods on earnings in one period is offset by changes in forecasted earnings has three unappealing consequences. First, it renders the Feltham–Ohlson model devoid of any accounting content, just as a dividend-discounting model is not particularly helpful for financial reporting purposes. The accounting content is lost because the model does not offer any guidance or predictions about firms' choice of accounting methods or properties of accounting standards, notwithstanding the frequent use of the term conservative and unbiased accounting in the context of the residual income model. This point is discussed in detail in Lo and Lys (2001), Sunder (2000), Verrecchia (1998), and Holthausen and Watts (2001).

Second, from a practical standpoint of an analyst, even though reduced future abnormal earnings offset the effect of aggressive accounting methods, an analyst must forecast future abnormal earnings by unbundling current earnings into an aggressive-accounting-method-induced component and remaining regular earnings.

[65] The pricing equation is misspecified in the presence of complex, but routinely encountered, capital structures that include preferred stock, warrants, executive stock options etc. I ignore such misspecification in the discussion below.

Third, the interpretation of abnormal earnings is clouded. Some researchers interpret expected abnormal earnings as estimates of economic rents (Claus and Thomas, 1999a, b; Gebhardt et al., 1999). However, the choice of accounting methods mechanically affects the estimates of expected abnormal earnings, so those estimates by themselves are not an indication of economic rents. For example, a firm choosing the pooling of interest method of accounting for a merger will have higher expected "abnormal" earnings compared to an otherwise identical firm that uses the purchase method of accounting for mergers. In contrast, America Online is expected to report an amortization charge of approximately $2 billion per year for next 25 years as a result of its merger with Time Warner, which will be accounted for as a purchase transaction.

4.3.3.3. Empirical applications and evaluation of valuation models. All valuation models make unrealistic assumptions. This feature is common to most theoretical models, like the Ohlson (1995) model that imposes a particular structure on the abnormal earnings process and other information. It is fruitless to criticize one or more of these models on the basis of the realism of the assumptions.[66] Assuming efficient capital markets, one objective of a valuation model is to explain observed share prices. Alternatively, in an inefficient capital market, a good model of intrinsic or fundamental value should predictably generate positive or negative abnormal returns. Therefore, in the spirit of positive science, it is worthwhile examining which of these models best explains share prices and/or which has the most predictive power with respect to future returns. In this section, I evaluate models using the former criteria, whereas the next section focuses on the models' ability to identify mispriced securities.

Several recent studies compare the valuation models' ability to explain cross-sectional or temporal variation in security prices (see Dechow et al., 1999; Francis et al., 1997, 1998; Hand and Landsman, 1998; Penman, 1998; Penman and Sougiannis, 1997, 1998; Myers, 1999).[67] Two main conclusions emerge from these studies. First, even though the residual income valuation model is identical to the dividend-discounting model, empirical implementations of the dividend-discounting model yield value estimates do a much poorer job

[66] Lo and Lys (2001), in the spirit of Roll's (1977) critique of the CAPM, argue that the Feltham and Ohlson (1995) and Ohlson (1995) models are not testable. Any test of the models is a joint test of the model (or the model's assumptions) and that the model is descriptive of the market's pricing of stocks.

[67] In an influential study, Kaplan and Ruback (1995) evaluate discounted cash flow and multiples approaches to valuation. Since they do not examine earnings-based valuation models, I do not discuss their study.

of explaining cross-sectional variation in market values than earnings capitalization models (e.g., Francis et al., 1997; Penman and Sougiannis, 1998). Second, the traditional implementation of the dividend-discounting model by capitalizing analysts' forecasts of earnings is just about as successful as the residual income valuation model (e.g., Dechow et al., 1999; Lee et al., 1999; Liu et al., 2000). I discuss and explain the two conclusions below.

The poor showing of the dividend-discounting model, the first conclusion stated above, appears to be a consequence of inconsistent application of the model in current research (see Lundholm and O'Keefe (2000) for an in-depth discussion). Consider the implementation of the model in Penman and Sougiannis (1998) and Francis et al. (1997) with a five-year horizon for dividend forecasts plus terminal value. The dividend forecasts for the five years generally account for a small fraction of current market value. This is not surprising because dividend yield is only a few percent. The terminal value is estimated assuming a steady-state growth in dividends beyond year five. It is common to assume the steady-state growth rate, g, to be either zero or about 4%. Both Penman and Sougiannis (1998) and Francis et al. (1997) report results using $g = 0$ or 4% in perpetuity.

The inconsistent application of the dividend-discount model arises because if $g = 0$, then the forecasted dividend in period 6 should be the earnings for period 6. FD_{t+6} should equal forecasted earnings for year 6 because once the no-growth assumption is invoked, the need for investments diminishes compared to that in the earlier growth periods. That is, there is no longer a need to plow earnings back into the firm to fund investments for growth. Investments roughly equal to depreciation would be sufficient to maintain zero growth in steady state. Therefore, cash available for distribution to equityholders will approximate earnings, i.e., the payout ratio will be 100%. Thus, assuming a zero growth in perpetuity will typically result in a huge permanent increase in dividends from year 5 to year 6, with dividends equal to earnings in years 6 and beyond. Instead, both Penman and Sougiannis (1998) and Francis et al. (1997) use $FD_{t+5}(1 + g)$, where FD_{t+5} is the forecasted dividend for year 5. Naturally, they find that dividend capitalization models perform poorly.[68] However, if the implications of the zero-growth assumption are applied consistently to the dividend discounting and the residual income valuation models, the fundamental value estimate from both models will be identical.[69] Similar logic applies to other growth rate assumptions.

Francis et al. (1997, Tables 3 and 4) do report results using the dividends = earnings assumption to calculate the terminal value, but their

[68] Additional misspecification is possible because earnings are eventually paid to both common and preferred stockholders, but the abnormal earnings valuation model is implemented without full consideration to preferred shareholders.

[69] See Lundholm and O'Keefe (2000) and Courteau et al. (2000) for further details on this point.

approach is confounded by the fact that they use Value Line's five-year-ahead forecast of the price–earnings multiple. Ironically, either because of the implicit assumption of dividends = earnings or because Value Line is skilled in forecasting the future price–earnings multiple, the value estimates in Francis et al. that implicitly use the dividends = earnings assumption for terminal value, are more accurate than all other models. The former explanation is more likely because otherwise a trading strategy based on the Value Line forecasts would yield huge abnormal returns.

The second conclusion from the empirical literature on valuation models is that simple earnings capitalization models with ad hoc and/or restrictive assumptions do as well as the more rigorous residual income valuation models in explaining cross-sectional variation in prices. The economic intuition underlying the residual income valuation model is appealing. In the spirit of the model, empirical applications generally assume that above-normal rates of returns on investments will decay and there is a careful attempt to account for the wealth effects of growth through reinvestment. Still, Dechow et al. (1999) find a simple model that capitalizes analyst's next period earnings forecast in perpetuity (i.e., a random walk in forecasted earnings and 100% dividend payout, both ad hoc assumptions) does better than the residual income valuation model.[70,71] What explains this puzzle?

To understand the lack of improved explanatory power of the more sophisticated valuation models, consider the variance of the independent variable, forecasted earnings. Forecasted earnings have two components: normal earnings (= the capital charge) and expected abnormal earnings. Since the present value of normal earnings is the book value, which is included as an independent variable, the normal earnings component of forecasted earnings serves as an error in the independent variable that uses forecasted earnings to explain prices. However, for annual earnings data, most of the variance of forecasted earnings is due to expected abnormal earnings. Use of a constant discount rate across the sample firms further reduces the variance accounted for by normal earnings in the residual income valuation model applications (Beaver, 1999).[72] Therefore, in spite of the fact that forecasted earnings are contaminated by normal earnings, which contributes to misestimated

[70] The improved explanatory power of fundamental values estimated using analysts' forecasts vis-à-vis historical earnings information highlights the important role of other information that influences expectations of future earnings beyond the information in past earnings (e.g., Beaver et al., 1980).

[71] Kim and Ritter (1999) find that IPOs are best valued using forecasted one-year-ahead earnings per share and Liu et al. (2000) present similar evidence comparing multiples of forecasted earnings against more sophisticated valuation models.

[72] However, substituting a firm-specific discount rate is unlikely to make a big difference. Use of firm-specific discount rate is not without a cost: discount rates are notoriously difficult to estimate and existing techniques estimate the rates with a large standard error (see Fama and French, 1997).

persistence in the context of valuation, the resulting errors-in-variables problem is not particularly serious. The variance of the measurement error is small relative to the signal variance, i.e., the variance of forecasted earnings minus normal earnings. In addition, any error in estimating the cost of capital employed to calculate normal earnings diminishes the benefit of adjusting forecasted earnings for normal earnings.

While controlling for normal earnings is not helpful in the above context, as an economic concept it rests on solid grounds. The preceding discussion is not intended to discourage the use of discount rates or risk adjustment. It simply highlights one context where the payoff to the use of risk adjustment is modest. Over long horizons, risk adjustment is potentially more fruitful.

There are at least three other empirical attempts (Myers, 1999; Hand and Landsman, 1998, 1999) to test Ohlson's (1995) linear information dynamics valuation model. All three studies as well as Dechow et al. (1999) find evidence inconsistent with the linear information dynamics. I do not think one learns much from rejecting the linear information dynamics of the Ohlson model. Any one-size-fits-all description of the evolution of future cash flows or earnings for a sample of firms is likely to be rejected. While an autoregressive process in residual income as a parsimonious description is economically intuitive, there is nothing in economic theory to suggest that all firms' residual earnings will follow an autoregressive process at all stages in their life cycle. A more fruitful empirical avenue would be to understand the determinants of the autoregressive process or deviations from that process as a function of firm, industry, macroeconomic, or international institutional characteristics. The conditional estimation attempts in Fama and French (2000) and Dechow et al. (1999) to parameterize the autoregressive coefficient (discussed in Section 4.1.2) are an excellent start.

4.3.3.4. Residual income valuation models and discount rate estimation. An emerging body of research uses the dividend-discounting model and the Feltham–Ohlson residual income valuation model to estimate discount rates. This research includes papers by Botosan (1997), Claus and Thomas (1999a, b), and Gebhardt et al. (1999). The motivation for this research is twofold.

First, there is considerable debate and disagreement among academics and practitioners with respect to the magnitude of the market risk premium (see Mehra and Prescott, 1985; Blanchard, 1993; Siegel and Thaler, 1997; Cochrane, 1997) and whether and by how much it changes through time with changing riskiness of the economy (Fama and Schwert, 1977; Keim and Stambaugh, 1986; Fama and French, 1988; Campbell and Shiller, 1988a; Kothari and Shanken, 1997; Pontiff and Schall, 1998). The market risk premium is the difference between the expected return on the market portfolio of stocks and the risk-free rate of return. The historical average realized risk premium has been about 8% per year (Ibbotson Associates, 1999).

Second, the cost of equity capital of an individual firm is a function of both the market risk premium and its relative risk (e.g., beta of the equity in the context of the CAPM). In spite of a vast body of research in finance and economics, the dust has still not settled on the set of priced risk factors. In addition, estimates of a security's sensitivity to priced factors, i.e., estimates of relative risks, are notoriously noisy. Therefore, the state-of-the-art estimate of cost of equity (relative risk times the risk premium plus the risk-free rate) is extremely imprecise (see Fama and French, 1997; Elton, 1999).

Research that uses the Feltham–Ohlson model to estimate equity discount rates attempts to improve upon the cost of equity estimates obtained using the traditional methods in finance. The empirical approach to estimating the cost of equity using the Feltham–Ohlson model is quite straightforward. It seeks to exploit information in analysts' forecasts and current prices, rather than that in the historical time series of security prices, to estimate discount rates. Gebhardt et al. (1999) note that practitioners have long attempted to infer discount rates from analysts' forecasts (e.g., Damodaran, 1994; Ibbotson, 1996; Gordon and Gordon, 1997; Madden, 1998; Pratt, 1998), but that the same approach is not popular among academics.

In an efficient market, price is the discounted present value of the sum of the book value and the discounted present value of the forecasted residual income stream. Analysts' forecasts of earnings and dividend–payout ratios are used to forecast the residual income stream. The cost of equity then is defined as the discount rate that equates the price to the fundamental value, i.e., the sum of book value and the discounted residual income stream. An analogous approach can be employed to infer discount rates using forecasts of future dividends.

Since the information used in the residual income valuation model is identical to that needed for the dividend-discount model, discount rates backed out of a dividend-discount model should be exactly the same as those from the residual income valuation model. However, studies using earnings-based valuation models to back out market risk premiums or equity discount rates claim that earnings-based valuation models yield better estimates of discount rates than using the dividend-discount model. For example, Claus and Thomas (1999a, b, p. 5) state: "Although it is isomorphic to the dividend present value model, the abnormal earnings approach uses other information that is currently available to reduce the importance of assumed growth rates, and is able to narrow considerably the range of allowable growth rates by focusing on growth in rents (abnormal earnings), rather than dividends."

The striking conclusion from the Claus and Thomas (1999a, b) and Gebhardt et al. (1999) studies is that their estimate of the risk premium is only about 2–3%, compared to historical risk premium estimated at about 8% in the literature. In line with the small risk premium, the studies also find that cross-sectional variation in the expected rates of return on equity that would capture differences in firms' relative risks is also quite small. However, Gebhardt et al. (1999) show that the variation in their estimates of costs of equity is correlated with many of the traditional measures of risk. This increases our confidence in the estimated discount rates.

The attempts to estimate the market risk premium and costs of equity address an important question. The intuition for why the estimated discount rates are less dispersed is that rational forecasts are less variable than actual data.[73] Therefore, estimates of discount rates using forecast data are also expected to be less volatile than those obtained using ex post data. While it is appealing to use forecast data to estimate discount rates, there is also a downside, and hence, I think it is premature to conclude that the risk premium is as low as 2–3% for at least two reasons.

First, it is possible that forecasted growth, especially the terminal perpetuity growth rate, used in the abnormal earnings valuation model is too low. The lower the forecasted growth, mechanically the lower the discount rate must be in order for the price-equal-to-the-fundamental-value identity to hold.

Second, the earnings-based fundamental valuation approach used to estimate discount rates assumes market efficiency. However, the same approach is also employed to conclude that returns are predictable and that the market is currently overvalued (e.g., Lee et al. (1999), and many other academics and practitioners). That is, assuming forecasts are rational and accurate estimates of discount rates are used, Lee et al. and others conclude that equities are predictably mispriced. Ironically, another body of research uses the residual income valuation model to conclude that analysts' forecasts are biased, and that the market is naively fixated on analysts' forecasts, and therefore returns are predictable (e.g., Dechow et al., 1999, 2000).

In summary, of the three variables in the valuation model—price, forecasts, and discount rates—two must be assumed correct to solve for the third. Using different combinations of two variables at a time, research has drawn inferences about the third variable. Because the assumptions in the three sets of research are incompatible, the conclusions are weak. Research on stock mispricing relative to fundamental valuation, properties of analysts' forecasts, and market's naïve reliance on analysts' forecasts provides evidence on potential settings where the model fails or the market's pricing is inconsistent with that based on the valuation model. That is, the evidence is inconsistent with the joint hypothesis of the model and market efficiency. These are tests of market efficiency that I review in the next section. A fruitful avenue for future research would be to provide further evidence on the relation between estimated discount rates and subsequent returns (see Gebhardt et al., 1999).

[73] See Shiller (1981) for using this argument in the context of testing the rationality of the stock market. Shiller's work led to a huge literature in finance and economics on examining whether stock markets are excessively volatile.

4.3.4. Fundamental analysis using financial ratios

This stream of research has two objectives. First, it uses information in financial ratios to forecast future earnings more accurately than using other methods (e.g., time-series forecasts and/or analysts' forecasts). Second, it identifies mispriced securities. The underlying premise is that the financial-ratio-based model predicts future earnings better than the alternatives and this superior predictive power is not reflected in current share prices (i.e., market are inefficient).

4.3.4.1. Earnings prediction. There is a long-standing interest in earnings prediction in the accounting literature (see Section 4.1.2). Below I focus on forecasts of future earnings and accounting rates of returns using financial ratios. There is a long history of practitioners and academics interpreting univariate ratios like the price–earnings multiple and price-to-book ratio as leading indicators of earnings growth (see, for example, Preinreich, 1938; Molodovsky, 1953; Beaver and Morse, 1978; Cragg and Malkiel, 1982; Peasnell, 1982; Penman, 1996, 1998; Ryan, 1995; Beaver and Ryan, 2000; Fama and French, 2000). The economic logic for the predictive power of price–earnings and price-to-book ratios with respect to future earnings is straightforward. Price is the capitalized present value of a firm's expected future earnings from current as well as future expected investments, whereas current earnings only measure the profitability of realized revenues from current and past investments. Price thus has information about the firm's future profitability, which contributes to the predictive ability of price–earnings and price-to-book ratios with respect to future earnings growth. In addition to the predictive ability stemming from the forward-looking information in prices about future earnings, the ratio-based earnings prediction literature also examines the role of transitory earnings and accounting methods in forecasting earnings.

Ou and Penman (1989a, b) initiated rigorous academic research on earnings prediction based on a multivariate analysis of financial ratios. The main idea is to examine whether combining information in individual ratios about future earnings growth can yield more accurate forecasts of future earnings. Ou and Penman use statistical procedures to reduce a large number of financial ratios to a subset that is most effective in forecasting future earnings. In holdout samples, they show that the forecasting model using the subset of the ratios outperforms time-series models of annual earnings in terms of forecast accuracy and contemporaneous association with stock returns.

Several extensions of Ou and Penman's earnings prediction research appear in the literature. For example, the innovation in Lev and Thiagarajan (1993) and Abarbanell and Bushee (1997, 1998) is that, unlike Ou and Penman (1989a, b), they use "*a priori* conceptual arguments to study any of their" ratios

(Abarbanell and Bushee, 1998, p. 22). They demonstrate that the earnings prediction signals in variables like growth in accounts receivables relative to sales growth and gross margin rate are incrementally associated with contemporaneous stock returns and are significantly helpful in predicting future earnings.

Other ratio-based earnings prediction approaches typically seek to exploit the information in prices about future earnings. For example, Penman (1996, 1998) develops techniques that combine the information in price–earnings ratios and price-to-book ratios that is superior to using any one ratio to forecast future earnings or the return on equity. Presence of transitory earnings contaminates price–earnings ratio as an indicator of growth. This weakness in price–earnings ratios is in part remedied by also using the price-to-book ratio, which signals growth in book equity and future returns on equity and because it is relatively unaffected by current transitory earnings. Penman (1998) presents empirical evidence on the benefits of combining the information in price–earnings and price-to-book ratios for earnings prediction. Specifically, using historical data, Penman (1998) estimates optimal weights on price–earnings and price-to-book ratios to forecast one- and three-year-ahead earnings. The evidence suggests moderate forecasting gains from optimal weighting of information in the two ratios.

Another example of ratio-based earnings prediction research is Beaver and Ryan (2000). They decompose "bias" and "lag" components of the price-to-book ratios to forecast future book returns on equity. Bias in the book-to-market ratio arises when a firm uses conservative accounting such that its book value of equity is expected to be persistently below the share price. Beaver and Ryan define lag as the time it takes for book values to catch up with stock prices in reflecting a given economic gain or loss. Consistent with economic intuition, Beaver and Ryan (2000) predict an inverse relation between bias and future return on equity, i.e., high book-to-market ratio forecasts low earnings growth. The horizon over which bias is helpful in predicting the return on equity depends on lag or the speed with which book values adjust to reflect an economic gains and losses. If the lag is short-lived, then the prediction horizon is also short. Evidence in Beaver and Ryan is broadly consistent with their predictions.

A final example of ratio-based earnings prediction research is Penman and Zhang (2000). They study the interaction of changes in growth and conservative accounting practices like expensing of research and development and marketing costs. The interaction is helpful in forecasting future earnings because extreme changes in growth are mean reverting and the effect is noticeable in the case of firms that are intensive in research and development and marketing or LIFO inventory reserves, etc. They predict and find that firms exhibiting extreme changes in research and development and marketing expenditures and LIFO reserves exhibit a rebound in their return on net assets.

Penman and Zhang label this phenomenon as the predictive ability of earnings quality.

4.3.4.2. Summary. The ratio-based earnings prediction literature focuses on the forecasting power of financial ratios with respect to future earnings. Empirical evidence is generally consistent with the ratios' ability to predict earnings growth. These models, however, rarely outperform analysts' forecasts of earnings, especially forecasts over long horizons. The primary interest in the ratio-based forecasting models is the lure of above-normal investment returns from simple, cheaply implementable models.

4.3.4.3. Return prediction. A large number of the ratio-based earnings prediction studies also examine whether trading strategies that exploit information about earnings growth earn above-normal rates of return. For example, Ou and Penman (1989a, b), Lev and Thiagarajan (1993), Abarbanell and Bushee (1998), Piotroski (2000), and Penman and Zhang (2000) demonstrate that the information in the earnings prediction signals is helpful in generating abnormal stock returns (see the next section), which suggests market inefficiency with respect to financial statement information.

4.4. Tests of market efficiency: overview

In this section, I discuss the empirical literature in accounting on tests of market efficiency. The review is deliberately narrowly focused on empirical issues. I do not examine market efficiency topics like the definition of market efficiency and tests of mean reversion in aggregate stock returns. These topics are important and essential for understanding the market efficiency research in accounting, but are beyond the scope of my review. Fortunately, several excellent surveys of the market efficiency literature exist. I encourage interested researchers to read Ball (1978, 1992, 1994), Fama (1970, 1991, 1998), LeRoy (1989), MacKinlay (1997), and Campbell et al. (1997).

Market efficiency tests in the financial accounting literature fall into two categories: event studies and cross-sectional tests of return predictability (see Fama, 1991). Event studies examine security price performance either over a short window of few minutes to a few days (short-window tests) or over a long horizon of one-to-five years (long-horizon tests). Section 4.4.1 discusses the attractive features as well as research design and data problems in drawing inferences about market efficiency based on short- and long-window event studies. Section 4.4.2 surveys the empirical literature on event studies. I review event studies from the post-earnings-announcement drift literature in Section 4.4.2.1, studies of market efficiency with respect to accounting methods and method changes and functional fixation in Section 4.4.2.2, and studies on long-horizon returns to accrual management and analyst forecast optimism in Section 4.4.2.3.

Cross-sectional tests of return predictability (or anomalies studies) examine whether the cross section of returns on portfolios formed periodically using a specific trading rule are consistent with a model of expected returns like the CAPM. These are tests of the joint hypothesis of market efficiency and the equilibrium expected rate of return model employed by the researcher. Section 4.4.3 reviews the literature on cross-sectional tests of return predictability. Section 4.4.3.1 summarizes results of tests of the market's (mis)pricing of earnings yields and accounting accruals and Section 4.4.3.2 discusses findings from tests of long-horizon returns to fundamental analysis.

4.4.1. Issues in drawing inferences from event studies

Event studies are tests of market efficiency. They test the impact, speed, and unbiasedness of the market's reaction to an event. In an efficient capital market, a security's price reaction to an event is expected to be immediate and subsequent price movement is expected to be unrelated to the event-period reaction or its prior period return. The modern literature on event studies originates with Fama et al. (1969) and Ball and Brown (1968), who examine security return behavior surrounding stock splits and earnings announcements.[74] Since then hundreds of event studies have been conducted in the legal, financial economics, and accounting literatures. There are two types of event studies: short-window event studies and long-horizon post-event performance studies. The inferential issues for the short-window event studies are straightforward, but they are quite complicated for the long-horizon performance studies. I discuss the salient issues of each type of study below.

4.4.1.1. Short-window event studies. Short-window event studies provide relatively clean tests of market efficiency, in particular when sample firms experience an event that is not clustered in calendar time (e.g., earnings announcement day returns or merger announcement day returns). The evidence from short-window event studies is generally consistent with market efficiency. The evidence using intra-day, daily, and weekly returns to wide-ranging events like earnings announcements, accounting irregularities, mergers, and dividends suggests the market reacts quickly to information releases. In some cases, the reaction appears incomplete and there is a drift, which contradicts market efficiency.

In a short-window test, researchers face few problems of misestimating the expected return over the short event window (e.g., Brown and Warner, 1985). Expected market return per day is about 0.05%, so the misestimation in a

[74] The first published event study is Dolley (1933). Like Fama et al. (1969), it examines the event-period price effects of stock splits.

security's return due to risk mismeasurement (e.g., Scholes and Williams, 1977; Dimson, 1979) in most cases is likely to be less than 0.01–0.02% per day.[75] This is small relative to an average abnormal return of 0.5% or more that is commonly reported in event studies.[76]

One concern in assessing the significance of the average market reaction in the event period is that the event might induce an increase in return variability (e.g., Beaver (1968) reports increased return variability around earnings announcements). Tests that fail to account for the increased return variability excessively reject the null hypothesis of zero average abnormal return (e.g., Christie, 1991; Collins and Dent, 1984). Use of the cross-sectional standard deviation of event period abnormal returns greatly mitigates the potential problem arising from an event-induced increase in return variability.

4.4.1.2. Long-horizon event studies. A long-horizon event study tests whether one-to-five-year returns following an event are systematically non-zero for a sample of firms. These studies assume that the market can overreact or underreact to new information and that it can take a long time to correct the misvaluation because of continued apparently irrational behavior and frictions in the market. The source of underreaction and overreaction is human judgment or behavioral biases in information processing. There is a systematic component to the behavioral biases so that in the aggregate the pricing implications of the biases do not cancel out, but manifest themselves in security prices deviating systematically from those implied by the underlying fundamentals. Several recent studies model the price implications of human behavioral biases to explain apparent long-horizon market inefficiency (e.g., Barberis et al., 1998; Daniel et al., 1998; Hong and Stein, 1999; DeBondt and Thaler, 1995; Shleifer and Vishny, 1997).

Recent evidence in the finance and accounting literature suggests huge apparent abnormal returns spread over several years following well-publicized events like initial public offerings, seasoned equity issues, and analysts' long-term forecasts. Collectively this research poses a formidable challenge to the efficient markets hypothesis. However, before we conclude that markets are grossly inefficient, it is important to recognize that long-horizon event studies suffer from at least three problems: risk misestimation, data problems, and the lack of a theory of market inefficiency as the null hypothesis. For an in-depth

[75] An implicit assumption is that the event does not cause the sample securities' beta risks to increase by an order of magnitude. See Ball and Kothari (1991) for stocks' daily beta risk in event time over 21 days centered around earnings announcements and Brennan and Copeland (1988) for evidence on risk changes around stock split announcements.

[76] The real danger of failing to reject the null hypothesis of no effect when it is false (i.e., a type II error) in a short-window event study stems from uncertainty about the event day (see Brown and Warner, 1985).

discussion of conceptual and empirical problems in drawing inferences from long-horizon tests of market efficiency, see Barber and Lyon (1997), Kothari and Warner (1997), Fama (1998), Lyon et al. (1999), and Loughran and Ritter (2000).

4.4.1.2.1. Risk measurement and risk factors. Misestimation of risk can produce economically and statistically significant magnitudes of apparent abnormal returns because the post-event return measurement period is long. Risk misestimation can arise because sensitivity to a risk factor is measured incorrectly or because a relevant risk factor is omitted from the model of expected returns. Random errors in estimating stocks' risks are not a serious problem because almost all the studies examine performance at a portfolio level.[77] Risk misestimation is a problem, however, if the misestimation is correlated across the stocks in a portfolio. This scenario is plausible because of the endogenous nature of economic events, i.e., the subset of firms experiencing an economic event is not random with respect to the population of firms. Typically unusual performance precedes an event and risk changes are associated with past performance (e.g., French et al., 1987; Chan, 1988; Ball and Kothari, 1989; Ball et al., 1993, 1995).

With regards to potential bias in estimated abnormal performance because of omitted risk factors, the finance literature has not quite settled on the risk factors priced in stock valuations as well as the measurement of the risk factors. Thus, for potential reasons of both risk mismeasurement and omitted risk factors, misestimation of securities' expected returns in a long-horizon event study is a serious concern. Stated differently, discriminating between market inefficiency and a bad model of expected returns is difficult in long-horizon event studies.

4.4.1.2.2. Data problems. A variety of data problems afflict long-horizon event studies and make it difficult to draw definitive inferences about market efficiency. (i) Survivor and data-snooping biases can be serious in long-horizon performance studies, especially when both stock-price and financial accounting data are used in the tests, as is common in many long-horizon market efficiency tests in accounting (see Lo and MacKinlay, 1990; Kothari et al., 1995, 1999b). Since many studies analyze financial and return data for the surviving subset of the sample firms, inferential problems arise due to potential survivor biases in the data. It is not uncommon to observe 50% or more of the initial sample of firms failing to survive the long horizon examined in the study.

(ii) Problems of statistical inferences arise in long-horizon performance studies. Sample firms' long-horizon returns tend to be cross-correlated even if

[77] Random errors in risk estimation and thus in abnormal return estimation can be a serious problem if the researcher correlates estimated abnormal returns with firm-specific variables like financial data and proxies for trading frictions. The random error weakens the correlation and thus the test's power.

the event is not perfectly clustered in calendar time (Bernard, 1987; Brav, 2000). Long-horizon return data are highly right skewed, which poses problems in using statistical tests that assume normality (see Barber and Lyon, 1997; Kothari and Warner, 1997; Brav, 2000). Because of the statistical properties of return data, the literature raises questions whether the appropriate return measure is buy-and-hold returns or monthly returns cumulated over a long period (see Roll, 1983; Blume and Stambaugh, 1983; Conrad and Kaul, 1993; Fama, 1998; Mitchell and Stafford, 2000). Loughran and Ritter (2000) discuss additional inference problems that arise because the timing of events is endogenous. For example, we witness IPO waves either because there are periods of good investment opportunities and/or because issuers believe the market is overvalued. As a result, it is possible that misvalued event firms contaminate the benchmark portfolios (e.g., market, size, and book-to-market portfolios) and inferences from market efficiency tests are flawed.

(iii) Skewness of financial variables (returns and or earnings) coupled with non-randomness in data availability and survivor biases can produce apparent abnormal performance and a spurious association between ex ante information variables like analysts' growth forecasts and ex post long-horizon price performance (see Kothari et al., 1999b). As noted above, in long-horizon studies, it is not uncommon to encounter data availability for less than 50% of the initial sample either because post-event financial data are unavailable or because firms do not survive the post-event long horizon. If this decline in sample size is not random with respect to the original population of firms experiencing an event, then inferences based on the sample examined by a researcher can be erroneous. Kothari et al. (1999b) present evidence to suggest both skewness in financial data and non-random survival rates in samples drawn from CRSP, Compustat, and IBES databases.

Long-horizon market inefficiency studies generally report larger magnitudes of abnormal returns for subsets of firms. These subsets of firms often consist of small market capitalization stocks, stocks that trade at low prices with relatively large proportionate bid–ask spreads, stocks that are not traded frequently (i.e., illiquid stocks), and stocks that are not closely followed by analysts and other information intermediaries in the market (Bhushan, 1994). The pronounced indication of market inefficiency among stocks with high trading frictions and less information in the market is interpreted as prices being set as if the market naïvely relies on biased analyst forecasts. While this is possible, there is at least one alternative explanation. The data problems discussed above are likely more prevalent in samples where we observe the greatest degree of apparent inefficiency. Careful attention to data problems will help discriminate between competing explanations for evidence that currently is interpreted as market inefficiency.

4.4.1.3. A theory of market inefficiency and specification of the null hypothesis. In addition to potential risk measurement and data problems discussed above, there is another challenge in drawing definitive conclusions about market efficiency. While much of the research concludes market inefficiency, further progress will be made if researchers develop a theory that predicts a particular return behavior and based on that theory design tests that specify market inefficiency as the null hypothesis. Researchers should then design powerful tests that fail to reject that null hypothesis. An excellent example of such research is Bernard and Thomas (1990), who specify stock-price behavior under a naïve earnings expectation model as well as a sophisticated earnings expectation model. However, there is still a need for a well-developed theory of naïve investor behavior that can be subjected to empirical testing in other contexts or a theory that would be helpful in explaining observed return behavior in contexts such as those discussed below.

Currently the null of market efficiency is rejected regardless of whether positive or negative abnormal return (i.e., under- or over-reaction) is observed. A theory of market inefficiency should specify conditions under which market under- and over-reaction is forecasted. For example, why does the market overreact to accruals in annual earnings (as in Sloan, 1996), but underreact to quarterly earnings information as seen from the post-earnings announcement drift? What determines the timing of abnormal returns in the long-horizon studies? For example, why does Frankel and Lee's (1998, Table 8 and Fig. 2) fundamental valuation strategy, which is designed to exploit mispricing, produce relatively small abnormal returns in the first 18 months, but large returns in the following 18 months? Sloan (1996, Table 6) finds that more than half of the three-year hedge portfolio return (i.e., lowest minus the highest accrual decile portfolio) return is earned in the first year and a little less than one-sixth of the three-year return is earned in the third year of the investment strategy.

Some have priors that the inefficiency would be corrected quickly, whereas others argue it can take a long time. For example, W. Thomas (1999, p. 19) in his analysis of the market's ability to process information about the persistence of the foreign component of earnings, states: "... I proceed under the assumption that mispricing is more likely to cause only a short-term relation with abnormal returns while unidentified risk is more likely to cause a short- and long-term relation with abnormal returns." If transaction costs, institutional holdings, and other related characteristics are an impediment to speedy absorption of information in stock prices, then long-horizon studies should test whether there is a positive relation between the horizon over which abnormal returns are earned and proxies for the information environment. If large stocks earn abnormal returns for several years, I would interpret that as damaging to the market inefficiency hypothesis.

Another important reason for the demand for a theory of market inefficiency is to understand what might cause markets to be inefficient (i.e., why might prices deviate systematically from economic fundamentals?). Several empirical studies document that intrinsic values estimated using the residual income model predict future returns (see Lee (1999), and discussion below for summaries). However, the residual income model or the dividend-discount model provides little guidance in terms of why we should expect to predict future returns using estimated intrinsic values. Such a prediction requires a theory for why and where prices would deviate systematically from intrinsic values so the theory can be tested empirically.[78] The theory would either use investors' behavioral biases or trading frictions to predict deviations of security prices from their intrinsic values. Accounting researchers' efforts on fundamental analysis and tests of market efficiency would be more fruitful if some energy is channeled into the development and tests of theories of inefficiency.

4.4.1.4. Summary. Long-horizon performance studies and tests of market efficiency are fraught with methodological problems. The problems in data bases, potential danger of researchers engaging in data snooping, non-normal statistical properties of data, and research design issues collectively weaken our confidence in the conclusion that markets are grossly inefficient in processing information in news events quickly and unbiasedly. I foresee considerable research that attempts to overcome the problems faced in long-horizon tests so that we can draw more definitive conclusions about market efficiency. Capital markets researchers in accounting should exploit their knowledge of institutional details and financial data and design more creative long-horizon tests of market efficiency. However, the challenges in designing better tests also underscore the need for a sophisticated training in cutting-edge research in finance and econometrics.

4.4.2. Evidence from event studies

Short-window tests: Like the evidence in the financial economics literature, most of the evidence from short-window event studies in the capital markets literature in accounting is consistent with market efficiency. However, some evidence suggests market inefficiency. This is discussed in the context of post-earnings-announcement drift and functional fixation.

Evidence suggests the market's reaction to news events is immediate and unbiased. Consider the market's reaction to earnings announcements as reported in two illustrative studies: Lee (1992) and Landsman and Maydew

[78] The parallels here are Jensen and Meckling's (1976) agency theory to explain deviations from the Modigliani and Miller (1958) and Miller and Modigliani (1961) no-effects predictions for corporate finance in frictionless markets, and Watts and Zimmerman's (1978) contracting and political cost hypotheses to explain firms' preference among alternative accounting methods in informationally efficient capital markets.

(1999). Lee (1992) uses intra-day return and trading volume data. He observes a statistically significant price reaction of the same sign as the earnings surprise. The reaction occurs within 30 min of the earnings announcement, with no statistically discernible price effect thereafter. Investors' trading volume reaction reported in Lee (1992) is also short lived: less than 2 h for large trades and a few hours for small trades. Landsman and Maydew (1999) analyze the market's reactions to earnings announcements over three decades. They too find that the stock return volatility and trading volume are significantly greater on earnings announcement days, but the activity reverts to normal conditions immediately thereafter.

The above findings reinforce previous evidence in Beaver (1968) and May (1971) using weekly price and trading volume data around annual and quarterly earnings announcement dates and Patell and Wolfson's (1984) intraday return analysis around earnings announcements. Other research offers a variety of refinements to suggest that the market predictably discriminates between different types of news announcements and the information content of those announcements. For example, several studies report an inverse relation between the information content (i.e., price and trading volume reaction) of earnings announcements and transaction costs and pre-disclosure (or interim) information (see Grant, 1980; Atiase, 1985, 1987; Bamber, 1987; Shores, 1990; Lee, 1992; Landsman and Maydew, 1999). Others examine the effects of audit quality, seasonality, accrual errors in first three quarters versus the fourth quarter, transitory earnings, etc. on the stock price reaction to earnings announcements (e.g., Teoh and Wong, 1993; Salamon and Stober, 1994; Freeman and Tse, 1992) and find evidence generally consistent with rationality in the cross-sectional variation in the market's response.

Long-horizon tests: There has been a surge of research on long-horizon tests of market efficiency in recent years. Collectively this research reports economically large abnormal returns following many events. As noted earlier, there are methodological questions about this evidence. I review the evidence of long-horizon abnormal performance following earnings announcements, accrual management, analysts' forecast optimism, and accounting method changes.

4.4.2.1. Post-earnings-announcement drift. Post-earnings-announcement drift is the predictability of abnormal returns following earnings announcements. Since the drift is of the same sign as the earnings change, it suggests the market underreacts to information in earnings announcements. Ball and Brown (1968) first observe the drift. It has been more precisely documented in many subsequent studies.[79] The drift lasts up to a year and the magnitude is both statistically and

[79] See Jones and Litzenberger (1970), Brown and Kennelly (1972), Joy et al. (1977), Watts (1978), Foster et al. (1984), Rendleman et al. (1987), Bernard and Thomas (1989, 1990), Freeman and Tse (1989), Mendenhall (1991), Wiggins (1991), Bartov (1992), Bhushan (1994), Ball and Bartov (1996), and Bartov et al. (2000), among others.

economically significant for the extreme good and bad earnings news portfolios. A disproportionate fraction of the drift is concentrated in the three-day periods surrounding future quarterly earnings announcements, as opposed to exhibiting a gradually drifting abnormal return behavior. Because of this characteristic and because almost all of the drift appears within one year, I characterize the drift as a short-window phenomenon, rather than a long-horizon performance anomaly. The profession has subjected the drift anomaly to a battery of tests, but a rational, economic explanation for the drift remains elusive.

The property of the drift that is most damaging to the efficient market hypothesis is documented in detail in Rendleman et al. (1987), Freeman and Tse (1989), and Bernard and Thomas (1989, 1990). Collectively, these studies show that the post-earnings-announcement abnormal returns are consistent with the market acting as if quarterly earnings follow a seasonal random walk process, whereas the true earnings process is more complicated. In particular, the true process might be more accurately described as a seasonally differenced first-order auto-regressive process with a seasonal moving-average term to reflect the seasonal negative autocorrelation (Brown and Rozeff, 1979). A large fraction of the drift occurs on subsequent earnings announcement dates and the drift consistently has the predicted sign for the extreme earnings portfolios. These properties diminish the likelihood of an efficient markets explanation for the drift.

Numerous studies seek to refine our understanding of the drift. Ball and Bartov (1996) show that the market is not entirely naïve in recognizing the time-series properties of quarterly earnings. However, their evidence suggests the market underestimates the parameters of the true process. So, there is predictability of stock performance at subsequent earnings announcement dates. Burgstahler et al. (1999) extend the Ball and Bartov (1996) result by examining the market's reaction to special items in earnings. Their results also suggest the market only partially reflects the transitory nature of special items. Soffer and Lys (1999) dispute Ball and Bartov's (1996) results. Using a two-stage process to infer investors' earnings expectations, Soffer and Lys (1999, p. 323) "are unable to reject the null hypothesis that investors' earnings expectations do not reflect any of the implications of prior earnings for future earnings". Abarbanell and Bernard (1992) conclude that the market's failure to accurately process the time-series properties of earnings is due in part to dependence in analysts' forecast errors (also see Lys and Sohn, 1990; Klein, 1990; Abarbanell, 1991; Mendenhall, 1991; Ali et al., 1999).

Research attempting to understand whether the market's earnings expectations are naïve has used security prices to infer the expectations. While this approach has many desirable properties, J. Thomas (1999) warns of the danger of incorrect inferences and Brown (1999) proposes an alternative approach examining whether the time-series properties of analysts' forecasts exhibit the naïve property. If not, then the search for alternative explanations for the observed security return behavior gains credibility.

Bhushan (1994) shows that the magnitude of the drift is positively correlated with the degree of trading frictions, which makes commercial attempts to exploit the drift economically less attractive. Bartov et al. (2000) examine whether the magnitude of the drift is decreasing in investor sophistication, as proxied for by the extent of institutional ownership in a stock (see Hand, 1990; Utama and Cready, 1997; Walther, 1997; El-Gazzar, 1998). Brown and Han (2000) examine predictability of returns for the subset of firms whose earnings exhibit first-order auto-regressive property, which is far less complex than the Brown and Rozeff (1979) model. They conclude that the market fails to recognize the autoregressive earnings property only for firms that have relatively less pre-disclosure information (i.e., small firms with relatively unsophisticated investors). Even in these cases, they find the drift ifs asymmetric in that the drift is observed for large positive, but not negative, earnings surprises.[80]

Attempts to explain the drift on the basis of transaction costs and investor sophistication, in my opinion, are not entirely satisfying. Since a non-trivial fraction of the drift shows up on one-to-three-quarters-ahead earnings announcement days, there is a substantial opportunity for a number of market participants to exploit the mispricing, at least in the case of stocks experiencing good earnings news. Many of these market participants likely engage in trades in similar stocks for other reasons, so the marginal transaction costs to exploit the drift are expected to be small. Risk mismeasurement is also unlikely to explain the drift because the drift is observed in almost every quarter and because it is concentrated in a few days around earnings announcements.

Another stream of research in the accounting and finance literature examines whether the post-earnings announcement drift (or the earnings-to-price effect) is incremental to or subsumed by other anomalies (see Fama and French (1996), Bernard et al. (1997), Chan et al. (1996), Raedy (1998), Kraft (1999), and discussion in Section 4.4.3). The anomalies examined include the size, book-to-market, earnings-to-price, momentum, industry, trading volume, long-term contrarian investment strategy, past sales growth, and fundamental analysis effects, and combinations of these effects.[81] Kraft (1999) concludes

[80] Since Brown and Han (2000) focus on a relatively small fraction (20%) of the population of firms, their tests might have lower power.

[81] The following studies report evidence on the anomalies: Banz (1981) on the size effect; Basu (1977, 1983) on the earnings-to-price effect; Rosenberg et al. (1985) and Fama and French (1992) on the book-to-market effect; Lakonishok et al. (1994) on the sales growth (or value-versus-glamour) and cash-flow-to-price effects; DeBondt and Thaler (1985, 1987) on the long-term contrarian effect; Jegadeesh and Titman (1993) and Rouwenhorst (1998) on the short-term momentum effect; Moskowitz and Grinblatt (1999) on the industry-factor effects to explain the momentum effect; Lee and Swaminathan (2000) on the momentum and trading volume effects; and Lev and Thiagarajan (1993) and Abarbanell and Bushee (1997, 1998) on the fundamental analysis effect.

that other anomalies or the Fama–French three-factor model (see Fama and French, 1993) do not subsume the drift, whereas evidence in Fama and French (1996) suggests that their three-factor model explains the earnings-to-price effect.

4.4.2.1.1. Summary. The post-earnings announcement drift anomaly poses a serious challenge to the efficient markets hypothesis. It has survived a battery of tests in Bernard and Thomas (1989, 1990) and many other attempts to explain it away. It appears to be incremental to a long list of anomalies that are inconsistent with the joint hypothesis of market efficiency and an equilibrium asset-pricing model. The survival of the anomaly 30 years after it was first discovered leads me to believe that there is a rational explanation for it, but evidence consistent with rationality remains elusive.

4.4.2.2. Accounting methods, method changes and functional fixation

4.4.2.2.1. Research design issues. Capital markets research has long examined whether the stock market is efficient with respect to cross-sectional differences in firms' use of accounting methods and to changes in accounting methods. Since most accounting method choices do not in themselves create a cash flow effect, tests of market efficiency with respect to accounting methods have been an easy target. However, this has proved to be one of the more difficult topics. Firms' choice of accounting methods and their decisions to change methods are not exogenous. Cross-sectional differences in firms' accounting method choice potentially reflect underlying economic differences (e.g., differences in investment–financing decisions, growth opportunities, debt and compensation contracts, etc.; see Watts and Zimmerman, 1986, 1990). The economic differences contribute to variations in the expected rates of return and price–earnings multiples. Therefore, an assessment of the pricing of accounting effects is clouded by the effect of underlying economic differences among the firms.

Accounting method change events also have their pros and cons in testing market efficiency. Managers' decisions to change accounting methods typically follow unusual economic performance and accounting method changes might be associated with changes in the firms' investment and financing decisions. For example, Ball (1972), Sunder (1975), and Brown (1980) find that the average earnings and stock-return performance of firms switching to income-decreasing LIFO inventory method are above normal in the period leading up to the inventory accounting method change. Since changes in economic performance and changes in investment and financing decisions are generally associated with changes in expected rates of return, accurate assessment of long-horizon risk-adjusted performance following accounting method changes is tricky. Another practical problem with an event study approach to accounting method changes is that many firms do not publicly announce the accounting method change, so there can be considerable uncertainty associated with the date the market learns about the method change.[82]

Another problem is that surprise announcements of accounting method changes themselves often convey information that causes market participants to reassess firm value.[83] For example, the market frequently greets firms' announcements of changes in capitalization and revenue recognition policies with large price swings (e.g., on March 18, 1992, Chambers Development Co. experiences a –63% stock price reaction to its announcement that it would expense instead of capitalize development costs; see Revsine et al., 1999, pp. 19–23). Some academics and the financial press interpret the reaction as the market's fixation on reported accounting numbers because the accounting method change in itself did not affect the firm's cash flow for the accounting period. The reasoning is only partially right in that the accounting method change might easily have influenced the market's expectation of future cash flows. Thus, in order to interpret the market's reaction to accounting method changes as consistent with market efficiency, one must model changes in cash flow expectations concurrent with the accounting method change and other cash flow effects arising from contracting, tax, and/or regulatory considerations.

4.4.2.2.2. Evidence: accounting method differences. A large body of literature examines whether the market is mechanically fixated on reported earnings. The conclusion that emerges from this literature is that broadly speaking the market rationally discriminates between non-cash earnings effects arising from the use of different accounting methods. However, an unresolved and contentious question is whether there is a modest degree of inefficiency. I believe the evidence is fairly strong that managerial behavior is consistent with the market behaving as if it is functionally fixated on reported accounting numbers, but that the security price behavior itself is at worst only modestly consistent with functional fixation.

Beaver and Dukes (1973) is probably the first study to examine whether the stock market rationally recognizes the non-cash effects of accounting methods on reported earnings in setting security prices. They compare the price–earnings ratios of firms using accelerated and straight-line depreciation methods. Consistent with market efficiency, they find that accelerated depreciation firms' price–earnings ratios exceed those of straight-line depreciation method firm. Moreover, the difference more or less disappears once the straight-line depreciation method firms' earnings are restated to those obtained under the accelerated depreciation method. Additional analysis also reveals

[82] With increasing pressure on firms to publicly disclose accounting events like method changes and the decreasing costs of electronically searching for the information, it is easier in today's environment to precisely identify the announcement date of an accounting method change.

[83] See the literature on signaling and voluntary disclosure.

that the accelerated and straight-line depreciation samples of firms did not exhibit statistically or economically significant differences in systematic risk or earnings growth (see Beaver and Dukes, 1973, Table 2).

Many other studies examine market efficiency with respect to accounting method differences. Lee (1988) and Dhaliwal et al. (2000) examine differences in price–earnings ratios between LIFO and non-LIFO firms. Dukes (1976) shows that the market values research and development costs as an asset even though they are expensed for reporting purposes (also see Lev and Sougiannis, 1996; Aboody and Lev, 1998). Evidence also suggests that the market began to reflect pension liabilities even before they appeared on financial statements (Dhaliwal, 1986) and a firm's risk reflects the debt equivalence of operating leases (see Lipe (2000, Section 2.3.2) for a summary of evidence).

While there is considerable evidence consistent with market efficiency, some discordant notes coexist. Vincent (1997) and Jennings et al. (1996) examine stock prices of firms using the purchase and pooling-of-interests accounting methods for mergers and acquisitions. They find that firms using the purchase accounting method are disadvantaged. The authors compare the price–earnings ratios of the firms using the pooling method to those using the purchase method. For this comparison, they restate earnings numbers of the pooling method firms as if these firms used the purchase accounting method. They find that the price–earnings ratios of the pooling method firms are higher than the purchase accounting method users.

The Vincent (1997) and Jennings et al. (1996) evidence is consistent with the conventional wisdom among investment bankers that Wall Street rewards reported earnings and thus prefers pooling-of-interests earnings. Regardless of whether the conventional wisdom is valid in terms of security price behavior, it appears to have a real effect on the pricing of acquisitions accounted for using the pooling or purchase method. Nathan (1988), Robinson and Shane (1990), and Ayers et al. (1999) all report that bidders pay a premium for a transaction to be accounted for as pooling of interests. Lys and Vincent (1995) in their case study of AT&T's acquisition of NCR, conclude that AT&T spent about $50 to possibly as much as $500 million to account for the acquisition using the pooling method.

To complement the analysis of pricing and premium magnitudes in pooling and purchase accounting, researchers also examine long-horizon returns following merger events accounted for using the pooling and purchase methods. Hong et al. (1978) and Davis (1990) are early studies of acquirers' post-merger abnormal returns. They examine whether abnormal returns to acquirers using the purchase method are negative, consistent with the market reacting negatively to goodwill amortization after the merger. Neither study finds evidence of the market's fixation on reported earnings.

Rau and Vermaelen (1998) and Andrade (1999) reexamine post-merger performance of pooling and purchase method users employing state-of-the-art techniques to estimate long-horizon abnormal returns and using larger samples of mergers from recent decades. They reach somewhat opposite conclusions. Rau and Vermaelen (1998) compare the post-merger returns of a third of the acquirers reporting the largest earnings impact of merger accounting against the middle and lowest third of the acquirers ranked according to the merger earnings impact. The post-merger one-, two-, or three-year returns for the three samples are not statistically different from zero or different from each other. Andrade (1999) also examines the post-merger performance, but uses regression analysis with controls for a large number of confounding variables. He finds a positive and statistically significant 18-month abnormal return effect attributable to the merger-accounting impact on earnings. However, the effect is "one order of magnitude smaller than implied by practitioners' views" (Andrade, 1999, Abstract). He therefore concludes that "it makes little sense for managers to expend time, effort, and resources in structuring the deal so as to improve its impact on reported EPS" (Andrade, 1999, p. 35).

Andrade (1999) also analyzes merger announcement-period returns to test whether the market reaction is increasing in the merger-accounting-earnings effect. He observes a statistically significant, but economically small positive impact of merger accounting earnings. This is weakly consistent with functional fixation. Hand (1990) advances an "extended" version of the functional fixation hypothesis. It argues that the likelihood that the market is functionally fixated is decreasing in investor sophistication. Hand (1990) and Andrade (1999) find evidence consistent with extended functional fixation in different types of accounting event studies.[84] This is similar to the negative relation between the magnitude of post-earnings-announcement drift and investor sophistication discussed earlier in this section.

Summary: Differences in accounting methods (e.g., purchase versus pooling accounting for mergers and acquisitions) can produce large differences in reported financial statement numbers without any difference in the firm's cash flows. We do not observe systematic, large differences in the prices of firms employing different accounting methods. This rules out noticeable magnitudes of market fixation on reported financial statement numbers. There is some evidence, however, to suggest that over long horizons differences in accounting methods produce measurable differences in risk-adjusted stock returns. Whether these abnormal returns suggest a modest degree of market in efficiency or they are a manifestation of the problems in accurately measuring long-horizon price performance is unresolved.

[84] See Ball and Kothari (1991) for theory and evidence that calls into question the extended functional fixation hypothesis.

4.4.2.2.3. Accounting method changes. Accounting method changes are distinct from accounting method differences in that method changes are the consequence of a deliberate action to change a method at a point in time and are thus amenable to an event study centered on the event of accounting method change. In contrast, accounting method differences between firms can persist indefinitely so long as firms continue with their respective accounting methods. Thus, there is no accounting event and therefore samples of firms with accounting method differences are typically not amenable to an event study.

Some of the earliest capital markets research analyzes accounting method changes as a means of testing market efficiency (see, for example, Ball, 1972; Kaplan and Roll, 1972; Archibald, 1972; Sunder, 1973, 1975). Collectively this research examines security returns at the time of and surrounding accounting method changes. Conclusions from this research are that the announcement effects of accounting method changes are generally small and the long-horizon performance of firms making accounting method changes is inconclusive with respect to the efficient markets hypothesis. The lack of conclusive results is because of cash flow effects of some method changes (e.g., switch to and from LIFO inventory method) and the endogenous and voluntary nature of accounting method changes. Therefore, there are information effects and potential changes in the determinants of expected returns associated with the method changes. In addition, much progress has been made in estimating the long-horizon performance in an event study (see Barber and Lyon, 1997; Kothari and Warner, 1997; Barber et al., 1999).

Many studies examine the stock-price effects of accounting method changes. Studies on firms' switch to and from LIFO inventory method are particularly popular; see, for example, Ricks (1982), Biddle and Lindahl (1982), Hand (1993, 1995). Evidence from these studies remains mixed. However, with the exception of Dharan and Lev (1993), a study that carefully re-examines long-horizon stock-price performance around accounting method changes using state-of-the-art long-horizon performance measurement techniques is sorely missing from the literature. Such a study would be timely in part because the long-horizon market inefficiency hypothesis has acquired currency in academic as well as practitioner circles.

4.4.2.3. Long-horizon returns to accrual management and analyst forecast optimism

4.4.2.3.1. The logic. Several studies examine long-horizon stock market efficiency with respect to accrual management and analysts' optimistic earnings growth forecasts. The crux of the argument is that information from firms' owners and/or managers and financial analysts about firms' prospects (e.g., earnings growth) reflects their optimism and that the market behaves naively in that it takes the optimistic forecasts at face value.

Firms' owners and managers and financial analysts have an incentive to issue optimistic forecasts.[85] Owners and managers issuing new equity can reap benefits if the issue price is inflated. Owners and managers are hypothesized to attempt to inflate the price of initial public offerings or seasoned equity offerings by influencing the market's expectations of future earnings. Toward this end, they manipulate upward reported earnings through discretionary accounting accruals.

Financial analysts' incentive to issue optimistic forecasts stems from the fact that the investment-banking firms they work for derive benefits from investment banking and brokerage business of the client firms. Optimistic forecasts potentially generate greater business from the clients. In addition, optimistic forecasts might induce client managements to share private information with the financial analysts.

The cost of accrual management and optimistic forecasts is a loss of credibility and reputation for accuracy in the event that accrual management and forecast optimism are detected. In addition, there is the potential danger of facing lawsuits and civil and criminal penalties for fraud in the event of an eventual decline in share prices when future earnings realizations suggest forecast optimism. Owners, managers, and financial analysts must trade off the potential benefits against the costs. The benefits from accrual manipulation and analysts' optimism obviously depend in part on the success in inflating security prices. The market's failure to recognize the optimistic bias in accruals and analysts' forecasts requires a theory of market inefficiency that is still being developed and tested in the literature. There are at least three reasons for systematic mispricing of stocks resulting from the market's naïve reliance on optimistic information. They are the presence of frictions and transaction costs of trading, limits on market participants' ability to arbitrage away mispricing, and behavioral biases that are correlated among market participants (e.g., herd behavior). Capital markets research testing market efficiency primarily examines whether there is evidence of accrual manipulation and forecast optimism and whether securities are systematically mispriced. The literature in accounting is yet to develop theories of market inefficiency, which have begun to appear in the finance and economics journals.

4.4.2.3.2. Evidence. Several studies present challenging evidence to suggest that discretionary accruals in periods immediately prior to initial public offerings and seasoned equity offerings are positive.[86] Evidence in these studies also suggests the market fails to recognize the earnings manipulation, which is inferred on the basis of predictable subsequent negative long-horizon price

[85] Managers' incentives are assumed to be aligned with owners' incentives. In an IPO, this assumption is descriptive because managers are often also major owners and/or managers have substantial equity positions typically in the form of stock options.

[86] See Teoh et al. (1998a–c), Teoh and Wong (1999), and Rangan (1998).

performance. Negative, statistically significant cross-sectional association between ex ante estimated accrual manipulation and stocks' ex post price performance exists, which violates market efficiency.

A well-developed literature examines whether analysts' forecasts are optimistic at the time of initial or seasoned equity offerings. Hansen and Sarin (1996), Ali (1996), and Lin and McNichols (1998a) fail to find optimism in short-term analysts' forecasts around equity offerings. Lin and McNichols (1998a) and Dechow et al. (2000) hypothesize that analysts' long-term forecasts might be optimistic because the market places less emphasis on the accuracy of long-term forecasts and long-term forecasts are more relevant for valuation than short-term forecasts. The Lin and McNichols (1998a) and Dechow et al. (2000) evidence on long-term forecast optimism is conflicting: Lin and McNichols (1998a, Table 2, p. 113) report negligible optimistic bias (lead analysts forecast 21.29% growth versus unaffiliated analysts forecast 20.73% growth), whereas the Dechow et al. (2000, Table 2, p. 16) evidence suggests a large bias (affiliated analysts 23.3% versus unaffiliated analysts 16.5%). Dechow et al. argue that stocks' long-horizon negative performance following seasoned equity offerings is due to the market's naïve fixation on analysts' optimistic long-term earnings growth forecasts. They show that the bias in analysts' long-term growth forecasts is increasing in the growth forecast, and post-equity-offer performance is negatively related to the growth rate at the time of the equity offers. Unlike Dechow et al., Lin and McNichols (1998a) do not find a difference in future returns.

Research also examines whether analysts affiliated with the investment-banking firm providing client services are more optimistic in their earnings forecasts and stock recommendations than unaffiliated analysts' forecasts. Rajan and Servaes (1997), Lin and McNichols (1998a), and Dechow et al. (2000) all report that affiliated analysts issue more optimistic growth forecasts than unaffiliated analysts. Similarly, Michaely and Womack (1999) and Lin and McNichols (1998a, b) find that affiliated analysts' stock recommendations are more favorable than unaffiliated analysts' recommendations.

4.4.2.3.3. Assessment of the evidence. The body of evidence in this area challenges market efficiency. However, there are several research design issues that are worth addressing in future research. Many of these are discussed elsewhere in the review. First, as discussed in the context of discretionary accrual models (Section 4.1.4), estimation of discretionary accruals for non-random samples of firms like IPO firms and seasoned equity offering firms is problematic. Long horizons further complicate the tests. In addition, the evidence in Collins and Hribar (2000b) that previous findings of accrual manipulation in seasoned equity offering firms using the balance sheet method might be spurious is damaging to the market inefficiency hypothesis not only because of problems in estimating discretionary accruals but also for the following logical reason. Consider the evidence in Teoh et al. (1998a) that estimated discretionary accruals of seasoned equity offering firms are negatively correlated with subsequent returns. Collins and Hribar (2000b) show that the estimated discretionary accruals are biased (i.e., accrual manipulation result is spurious) and that the bias is correlated with the seasoned equity offering firms' merger and acquisition activity. This means subsequent abnormal returns are unrelated to management's discretionary accruals, and instead appear to be correlated with firms' merger and acquisition activity. Thus, either the market is fixated on discretionary accruals or the market commits systematic errors in processing the valuation implications of merger and acquisition activity. As always, the possibility of some other phenomenon driving the return behavior following seasoned equity offerings exists.

Second, the association between ex ante growth forecasts or other variables and ex post performance variables might be spuriously strengthened because of survivor biases and data truncation (see Kothari et al. (1999b), and discussion earlier in this section).

Third, long-horizon performance measurement is problematic. Techniques that recognize long-horizon issues should be used to estimate abnormal performance (e.g., the Carhart (1997) four-factor model or the Fama and French (1993) three-factor model, or the Daniel et al. (1997) characteristic-based approach). Some argue that the three- and four-factor models in the finance literature are empirically motivated and lack a utility-based theoretical foundation. More importantly, these models might over-correct for the systematic component in stock returns in that returns to factors like book-to-market might indicate systematic mispricing, i.e., market inefficiency (see, e.g., Dechow et al., 2000). Even if empirically motivated factors were to merely capture systematic mispricing (rather than represent compensation for risk), it is important to control for these factors in estimating abnormal returns. The reason is straightforward. Researchers typically test whether a treatment variable or an event generates abnormal performance. If similar performance is also produced by another variable, like firm size to book to market, then it becomes less plausible that the observed performance is attributable to the treatment variable or the event. Abnormal performance can be realized by simply investing in potentially many stocks of similar characteristics regardless of whether or not they experience the event studied by the researcher.

Finally, classification of affiliated and unaffiliated analysts is not exogenous. As discussed in the section on the properties of analysts' forecasts, it is possible that firms choose those investment bankers whose analysts are (genuinely) most optimistic (i.e., give the highest forecasts) from among all the analysts.[87] So, we expect the affiliated analysts to have larger forecast errors than the

[87] If my assumption is not descriptive of the process of selection of an affiliated analyst investment-banking firm, the criticism is not applicable.

unaffiliated analysts. Therefore, the evidence that affiliated analysts' forecasts are more biased than unaffiliated analysts' forecasts is not particularly helpful. Research must attempt to demonstrate that analysts bias their forecasts upward because of the lure of investment-banking business (i.e., demonstrate causality).

4.4.3. Cross-sectional tests of return predictability

Cross-sectional tests of return predictability differ from event studies in two respects. First, to be included in the analysis, firms need not experience a specific event like seasoned equity issue. Second, return predictability tests typically analyze returns on portfolios of stocks with specific characteristics (e.g., quintile of stocks reporting largest ratios of accruals to total assets or extreme analysts' forecasts) starting with a common date each year, whereas the event date in event studies is typically not clustered in calendar time.

Cross-sectional return predictability tests of market efficiency almost invariably examine long-horizon returns, so they face the problems discussed previously. Four problems are worth revisiting. First, expected return mismeasurement can be serious in long-horizon tests. Second, researchers typically focus on stocks exhibiting extreme characteristics (e.g., extreme accruals) that are correlated with unusual prior performance, so changes in the determinants of expected return are likely to be correlated with the portfolio formation procedure. Third, survival bias and data problems can be serious, in particular if the researcher examines extreme performance stocks. Finally, since there is perfect clustering in calendar time, tests that fail to control for cross-correlation likely overstate the significance of the results.

There are two types of cross-sectional return predictability tests frequently conducted in accounting: predictability tests that examine performance on the basis of univariate indicators of market's mispricing (e.g., earnings yield, accruals, or analysts' forecasts) and tests that evaluate the performance of multivariate indicators like the fundamental value of a firm relative to its market value (e.g., Ou and Penman, 1989a, b; Abarbanell and Bushee, 1997, 1998; Frankel and Lee, 1998; Piotroski, 2000). Both sets of tests provide strong evidence challenging market efficiency. Both univariate and multivariate indicators of mispricing generate large magnitudes of abnormal performance over a one-to-three-year post-portfolio-formation periods. The focus of future research should be to address some of the problems I have discussed above in reevaluating the findings of the current research from return-predictability tests. I summarize below the evidence from the two types of return-predictability tests.

4.4.3.1. Return predictability using univariate indicators of mispricing. Early tests of return predictability using univariate indicators of mispricing used earnings yield (e.g., Basu, 1977, 1983). This evidence attracted considerable attention in the literature and the evidence from the earnings yield and other anomalies eventually led to multi-beta CAPM models like the Fama–French three-factor (i.e., market, size, and book-to-market) model or Carhart (1997) four-factor model that also includes momentum as a factor.

The recent flurry of research in return-predictability tests examines whether indicators other than earnings yield generate long-horizon abnormal performance. Examples of this research include the Lakonishok et al. (1994) tests based on cash flow yield and sales growth; the LaPorta (1996) and Dechow and Sloan (1997) tests of market overreaction stemming from analysts' optimism; and the Sloan (1996), Collins and Hribar (2000a, b) and Xie (1999) tests of the market's overreaction to extreme accrual portfolios.

The theme most common in this literature is that the market overreacts to univariate indicators of firm value and it corrects itself over a long horizon. The overreaction represents market participants' naïve fixation on reported numbers and their tendency to extrapolate past performance. However, because there is mean reversion in the extremes (e.g., Brooks and Buckmaster, 1976), the market's initial reaction to extreme univariate indicators of value overshoots fundamental valuation, and thus provides an opportunity to earn abnormal returns.[88]

While many of the univariate indicators of return-predictability suggest market overreaction, using both cash flow and earnings yield as indicators of market mispricing suggests market underreaction. One challenge is to understand why the market underreacts to earnings, but its reaction to its two components, cash flows and accruals, is conflicting. Previous evidence suggests that the market underreacts to cash flow and overreacts to accruals. Recently research has begun to address these issues theoretically as well as empirically. For example, Bradshaw et al. (1999) examine whether professional analysts understand the mean reversion property of extreme accruals. They find that analysts do not incorporate the mean reversion property of extreme accruals in their earnings forecasts. Bradshaw et al. (1999, p. 2) therefore conclude "investors do not fully anticipate the negative implications of unusually high accruals". While Bradshaw et al.'s explanation is helpful in understanding return predictability using accruals, it would be of interest to examine whether similar logic can explain the cash flow and earnings yield anomalies. Extreme earnings and cash flows are also mean reverting. What is predicted about analysts' forecasts with respect to these two variables and how does that explain the market's underreaction to earnings?

[88] Variations of the overreaction and extrapolation of past performance arguments appear in the following studies. Lakonishok et al. (1994) in the context of past sales growth and current cash flow and earnings yield; Sloan (1996) in the context of accruals; and LaPorta (1996) and Dechow and Sloan (1997) in the context of analysts' forecasts.

While much evidence suggests market over- and under-reaction, other studies are inconsistent with such market behavior. For example, Abarbanell and Bernard (2000) fail to detect the stock market's myopic fixation on current performance, i.e., market overreaction. Ali et al. (1999) undertake a different approach to understand whether market participants' naïveté contributes to cross-sectional return predictability using accruals. As several researchers hypothesize in the post-earnings-announcement drift literature, Ali et al. (1999) test whether returns to the accruals strategy are greater in magnitude for the high transaction cost, low analyst following, and low institutional ownership stocks. The literature hypothesizes these characteristics proxy for low investor sophistication, so a given level of accrual extremity in these stocks should yield greater magnitudes of abnormal returns than high investor sophistication stocks. Ali et al. (1999) do not find significant correlation between investor sophistication and abnormal returns. Zhang (2000) draws a similar conclusion in the context of market's fixation on analyst forecast optimism and auto-correlation in forecast revisions. These findings make it less likely that returns to the accrual strategy and apparent return reversals following analysts' optimistic forecasts arise from investors' functional fixation. The evidence makes it more likely that the apparent abnormal returns represent compensation for omitted risk factors, statistical and survival biases in the research design, biases in long-horizon performance assessment, or period-specific nature of the anomaly. Naturally, further research is warranted.

4.4.3.2. Return predictability using multivariate indicators of mispricing. Ou and Penman (1989a, b) use a composite earnings change probability measure called *Pr*. They estimate the *Pr* measure from a statistical data reduction analysis using a variety of financial ratios. The *Pr* measure indicates the likelihood of a positive or negative earnings change. Ou and Penman (1989a, b) report positive abnormal returns to the *Pr*-measure-based fundamental strategy.

The Ou and Penman (1989a, b) studies attracted a great deal of attention in the literature. They rejuvenated fundamental analysis research in accounting, even though their own findings appear frail in retrospect. Holthausen and Larcker (1992) find that the *Pr* strategy does not work in a period subsequent to that examined in Ou and Penman (1989a, b). Stober (1992) and Greig (1992) interpret returns to the *Pr* strategy as compensation for risk. Stober (1992) reports that abnormal performance to the *Pr* strategy continues for six years and Greig (1992) finds that size subsumes the *Pr* effect.

Lev and Thiagarajan (1993), Abarbanell and Bushee (1997, 1998), and Piotroski (2000) extend the Ou and Penman analysis by exploiting traditional rules of financial-ratio-based fundamental analysis to earn abnormal returns. They find that the resulting fundamental strategies pay double-digit abnormal returns in a 12-month period following the portfolio-formation date. The conclusion of the market's sluggish adjustment to the information in the ratios is strengthened by the fact that future abnormal returns appear to be concentrated around earnings announcement dates when the earnings predictions of the analysis come true (see Piotroski, 2000).

Frankel and Lee (1998), Dechow et al. (1999), and Lee et al. (1999) extend the multivariate fundamental analysis to estimating stocks' fundamental values and investing in mispriced stocks as suggested by their fundamental values. They use the residual income model combined with analysts' forecasts to estimate fundamental values and show that abnormal returns can be earned.[89]

5. Summary and conclusions

In this paper I review research on the relation between capital markets and financial statement information. I use an economics-based framework of demand for and supply of capital markets research in accounting to organize the paper. The principal sources of demand for capital markets research are fundamental analysis and valuation, tests of market efficiency, the role of accounting in contracts and in the political process, and disclosure regulation. In summarizing past research, I critique existing research as well as discuss unresolved issues and directions for future research. In addition, I offer a historical perspective of the genesis of important ideas in the accounting literature, which have greatly influenced future accounting thought in the area of capital markets research. An exploration of the circumstances, forces, and concurrent developments that led to significant breakthroughs in the literature will hopefully guide future accounting researchers in their career investment decisions.

Ball and Brown (1968) heralded capital markets research into accounting. Key features of their research, i.e., positive economics championed by Milton Friedman, Fama's efficient markets hypothesis, and the event study research design in Fama et al. (1969), were the cornerstones of the economics and finance research taking place concurrently at the University of Chicago. History repeated itself with Watts and Zimmerman's positive accounting theory research in the late 1970s. While the above are just two examples, many other developments in accounting are also influenced by concurrent research and ideas in related fields. The important conclusion here is that rigorous training in and an on-going attempt to remain abreast of fields beyond accounting will enhance the probability of successful, high-impact research.

[89] Lee et al. (1999) results are also somewhat frail in that they fail to find abnormal returns unless they use information in the short-term risk-free rates in calculating fundamental values. Since fundamental analysis never emphasized the importance of, let alone the need of, information in short-term interest rates, I interpret their evidence as not strong.

Section 4 surveys empirical capital markets research. The topics include methodological research (e.g., earnings response coefficients, time series and analysts' forecasts, and models of discretionary accruals); research examining alternative performance measures; valuation and fundamental analysis research; and finally, accounting research on tests of market efficiency. The areas of greatest current interest appear to be research on discretionary accruals, influence of analysts' incentives on the properties of their forecasts, valuation and fundamental analysis, and tests of market efficiency. The revival of interest in fundamental analysis is rooted in the mounting evidence that suggests capital markets might be informationally inefficient and that prices might take years before they fully reflect available information. Fundamental valuation can yield a rich return in an inefficient market. A large body of research demonstrates economically significant abnormal returns spread over several years by implementing fundamental analysis trading strategies. Evidence suggesting market inefficiency has also reshaped the nature of questions addressed in the earnings management literature. Specifically, the motivation for earnings management research has expanded from contracting and political process considerations in an efficient market to include earnings management designed to influence prices because investors and the market might be fixated on (or might over- or under-react to) reported financial statement numbers.

Evidence of market inefficiency and abnormal returns to fundamental analysis has triggered a surge in research testing market efficiency. Such research interests academics, investors, and financial market regulators and standard setters. The current rage is examination of long-horizon security price performance. However, this research is methodologically complicated because of skewed distributions of financial variables, survival biases in data, and difficulties in estimating the expected rate of return on a security. Progress is possible in testing market efficiency if attention is paid to the following issues. First, researchers must recognize that deficient research design choices can create the false appearance of market inefficiency. Second, advocates of market inefficiency should propose robust hypotheses and empirical tests to differentiate their behavioral-finance theories from the efficient market hypothesis that does not rely on investor irrationality. The above challenges in designing better tests and refutable theories of market inefficiency underscore the need for accounting researchers trained in cutting-edge research in economics, finance, and econometrics.

Perspectives on Recent Capital Market Research

William H. Beaver
Stanford University

I. INTRODUCTION

The purpose of my remarks is to provide one perspective on major areas of capital markets research that have made important contributions to our understanding of accounting numbers, with an emphasis on those published during the past ten years. I do not intend these remarks to be a survey;[1] instead, I select the five research areas I believe have made the greatest contribution to our knowledge over the past ten years. These areas illustrate the degree to which capital market research has become interconnected. My remarks address why these areas are important, briefly summarize what we have learned, highlight some of the links between these areas, and raise some unresolved issues. Within each area, I identify major issues and some of the key papers, but I do not attempt to be comprehensive. In the process, I have sacrificed depth for breadth.

The five areas I have selected are market efficiency, Feltham-Ohlson modeling, value relevance, analysts' behavior, and discretionary behavior. The first two areas, market efficiency and Feltham-Ohlson modeling, are basic platforms that permit us to organize our thinking about the role of accounting in capital markets. The last three areas are applications that incorporate some form of accounting structure or individual behavior.

II. MARKET EFFICIENCY

Market efficiency is, of course, an important field of study. Much of the regulation of financial reporting is premised on the notion that once firms make accounting data publicly available, the implications will be widely appreciated and reflected in security prices. If the market is inefficient, then financial reporting and disclosure are not as effective, at least with respect to prices fully reflecting that information. Questions for regulators then arise as to whether altering the presentation of the data could mitigate this deficiency.

If investors trade in an efficient market, then they can rely on prices reflecting a rich set of the total mix of information, including financial statement information, and they need

---

[1] Kothari (2001) provides an excellent recent survey of capital markets research.

Editor's Note: The Executive Committee of the American Accounting Association has recommended the commission of a series of Presidential Research Lectures, to be delivered at annual meetings of the Association. To encourage broad dissemination, the Committee has requested that *The Accounting Review* publish this lecture given at the 2001 American Accounting Association Annual Meeting in Atlanta, GA.

Author's Note: I am pleased and honored to be the third Presidential Lecturer, following two distinguished colleagues, Shyam Sunder two years ago and Bill Kinney last year. I thank Mary Barth, Wayne Landsman, Maureen McNichols, and Stephen Ryan for many helpful suggestions on earlier drafts of this paper.

not process all of that information directly. In other words, investors become indirect beneficiaries of that information, even if they do not literally process it themselves. Efficient capital markets also have implications for resource allocation and production efficiency, so it is not surprising that market efficiency was one of the earliest areas studied.

Market efficiency is also of interest to researchers because, if they can assume market efficiency in the research design, then researchers can draw a different (and potentially more powerful) set of inferences. Assumptions about market efficiency affect the researchers' choice of the length of the window over which to compute abnormal returns in an event study. Market efficiency also affects the interpretations the researcher places on observed associations between security prices and accounting numbers.

There was a time when we thought that the issue of market efficiency with respect to publicly available data was "resolved." Early capital markets studies largely supported market efficiency. Both Ball and Brown (1968) and Beaver (1968) examined the post-announcement behavior of security returns and tentatively concluded that market efficiency was a reasonable approximation of the empirical results. Early studies examined changes in accounting methods (Archibald 1972; Ball 1972) and reached similar conclusions. Researchers also examined differences in accounting methods (e.g., Beaver and Dukes 1973) and concluded that the market prices behaved in a manner consistent with market efficiency.

Recent studies have reexamined market efficiency, and several have concluded that capital markets are inefficient with respect to at least three areas: post-earnings announcement drift, market-to-book ratios and its refinements, and contextual accounting issues.

Post-Earnings Announcement Drift

Post-earnings announcement drift was one of the first areas to suggest that markets may not be efficient with respect to accounting data. Several studies (Foster et al. 1984, among others) found evidence of post-earnings announcement drift in spite of attempts to control for at least some of the confounding factors. One reason for the finding of post-announcement drift is that the availability of daily return data enhances the power of the tests relative to prior research that used only weekly or monthly return data. The post-announcement drift studies culminated in Bernard and Thomas's (1989, 1990) research, which is an econometric tour de force. Their studies represent a classic example of excellent research design. The studies tenaciously pursue competing explanations, such as transaction costs vs. omitted risk factors, and find them lacking in many respects. Moreover, their studies, along with Freeman and Tse (1989), also explicitly develop an alternative hypothesis as to the nature of the market inefficiency and establish that the subsequent abnormal returns tend to cluster around subsequent earnings announcement dates. Their evidence that the abnormal returns are associated with some inefficient processing of earnings announcements is compelling.

An important extension is Abarbanell and Bernard (1992), whose study examines the question of whether a portion of the post-earnings announcement drift is attributable to the behavior of analysts' earnings forecasts and deficiencies in their processing of accounting data. This study reaches two important conclusions:

(1) The analysts' forecasts appear to underestimate the persistency in earnings, and forecast errors based on analysts' forecasts are serially correlated. If analysts efficiently processed information, then the unconditional expected value of the forecast error would be zero, and the expected serial correlation would be zero.

(2) This phenomenon explains some, but not all, of the post-earnings announcement drift. We would not expect analysts' behavior to be the complete explanation because post-earnings announcement drift is most pronounced in the small capitalization firms, which are not as heavily followed as larger capitalization firms are. Bartov et al. (2000) suggest that institutional holdings are also an important explanatory variable. In a further extension, Bhattacharya (2001) concludes that trade size, a proxy for less wealthy and less informed investors, may also be a factor. These studies represent a key link between market efficiency and the role of information and financial intermediaries.

Studies of post-earnings announcement drift are particularly compelling because earnings changes and earnings forecast errors have lower serial correlation than other candidates for market efficiency, such as market-to-book ratios. High serial correlation raises suspicion that the variable is a proxy for an omitted factor that is priced by the market.

Market-to-Book Ratios and Extensions

A second area of research is abnormal returns associated with portfolio strategies based on market-to-book ratios. Two early studies in this area are Fama and French (1992) and Lakonishok et al. (1994). The negative association between market-to-book ratios and subsequent returns appears to be significant and persistent and not explainable by conventional risk measures or their proxies. This is a controversial area; Fama (1991), among others, suggests that market-to-book ratios may represent some (otherwise unidentified) pricing factor, and Fama and French (1992) have posited a three-factor pricing model that includes the market-to-book ratio. As a result, recent market efficiency tests control for the market-to-book ratio and still find evidence of abnormal returns.

Major extensions of this work refine the market-to-book analysis by computing market-to-value ratios. At its simplest level, the argument for the market-to-book ratio as being a measure of market inefficiency is that the market prices either fail to reflect some factor related to the underlying value, which is reflected in book value, or that they include some factor unrelated to the underlying value. For example, high market-to-book ratio stocks represent so-called "glamour" stocks that are overpriced. From this perspective, one can extend the concept of value to include accounting "fundamentals" in addition to book value. Two major examples are Frankel and Lee (1998) and Dechow et al. (1999). Both studies employ modeling motivated by Feltham-Ohlson to predict the intrinsic value based on book value, earnings, and analysts' earnings forecasts. Both studies conclude that market-to-value ratios are associated with even higher subsequent abnormal returns than are the simpler market-to-book ratio strategies, which is consistent with these value estimates' being better proxies for underlying fundamentals and, hence, being better able to identify overpriced and underpriced stocks. As with research on post-earnings announcement drift, the abnormal returns here appear to be more prevalent in small capitalization stocks.

In another extension of the market-to-book research, Dechow and Sloan (1997) find that stock prices appear to reflect naively analysts' biased forecasts of future earnings growth, and reliance on analysts' earnings growth forecasts can explain over half of the higher returns associated with pursuing "contrarian" (e.g., market-to-book and price-earnings-based) strategies.

Contextual Accounting Issues

A key feature of the previous two areas is that they require little, if any, knowledge of the distinctive characteristics of how financial statements are prepared. They are based on generic treatments of earnings and book value. Our comparative advantage as accounting researchers is in incorporating the richness of our knowledge of accounting institutions, reporting standards, and the composition of accounting numbers. Several recent studies have examined market efficiency based on some key feature of financial reporting.

Sloan (1996) is an excellent example of research that exploits our knowledge of one key feature: accrual accounting. Important aspects of the Sloan (1996) study are (1) an examination of the "consistency" between the weight placed on accruals and cash flow components in forecasting earnings and the implicit weight investors placed on the cash flow and accrual components of earnings in a valuation equation, and (2) the examination of portfolio strategies based on the magnitude of the accruals. Sloan (1996) concludes that capital markets overestimate the persistency of accruals and underestimate the persistency of cash flows from operations, because accruals are more subject to uncertainty of estimation and more subject to management and manipulation. Xie (2001) supports this conclusion by showing the mispricing documented by Sloan (1996) is largely due to abnormal accruals.

Moreover, in an attempt to address the "IPO puzzle," Teoh et al. (1998a, 1998b) and Teoh, Wong, et al. (1998) find that unusual accruals occur at Initial Public Offering dates and subsequently reverse. The accruals appear to be associated with at least a portion of the negative abnormal returns identified in the IPO research. These findings are consistent with those of Sloan (1996), as well as Xie (2001) and DeFond and Park (2001), that security prices do not fully reflect either the nature of accruals or their implications for future earnings and valuation.

However, not all accruals are associated with abnormal returns. Research also indicates that the supplemental disclosures with respect to specific accruals can permit capital markets to form unbiased estimates of the implications of the accrual for future earnings and hence for valuation. For example, Beaver and McNichols (2001) show that increased disclosure regarding the history of policy loss reserves in the property casualty insurance companies can make the accruals transparent to investors, and that revisions policy of loss accruals (development) are not associated with subsequent abnormal returns.

Unresolved Issues

The magnitude and length of the abnormal returns is surprising. For example, Frankel and Lee (1998) report that in the 36 months after portfolio formation, the abnormal returns associated with market-to-value strategies are 31 percent, whereas strategies that also exploit the predictability of analysts' forecasts are associated with abnormal returns of 45 percent.

There are several unresolved issues:

(1) How can widely disseminated and examined data used with simple portfolio strategies that require no knowledge of accounting be associated with abnormal returns? From an economic perspective, widely disseminated data are not likely candidates.

(2) How can studies of arcane disclosures (e.g., nonperforming loans and pensions, as in Beaver et al. [1989] and Barth et al. [1992]) find that such disclosures are apparently reflected in prices, yet more visible variables, such as earnings and book value, are not?

(3) How can studies of security returns in the very short run (e.g., intraday returns, as in Patell and Wolfson [1984]) show evidence of relatively rapid response (within hours, if not minutes), and yet have evidence of abnormal returns that appear to persist for years after the portfolio formation date?

(4) How can the body of research in aggregate show that prices both lead (e.g., Beaver et al. 1980; Beaver et al. 1987; Collins et al. 1997; Ryan 1995) and lag accounting data?

III. FELTHAM-OHLSON MODELING

For better or for worse, capital markets research is primarily empirical, rather than theoretical. One major exception is the modeling by Feltham and Ohlson (hereafter F-O). As one of the few attempts during the last ten years to develop a "theory of accounting" (i.e., a formal representation of value in terms of accounting numbers), the F-O approach is, in my opinion, one of the most important research developments in the last ten years (important articles are Ohlson [1995, 1999] and Feltham and Ohlson [1995, 1996]). F-O modeling is also one of the more controversial research areas in accounting. I will discuss the key features, empirical applications, major criticisms, and prospects for future research.

Key Features of F-O Modeling

One feature is the common set of assumptions that pervades the work. The assumptions include a valuation assumption that the value of equity is equal to the present value of expected future dividends, the clean surplus relation, and some form of a linear information dynamic. Feltham and Ohlson have derived a rich set of implications from these parsimonious assumptions.

In contrast to prior attempts to link accounting data and equity value, the F-O approach is neither a theory of information nor a theory of measurement. However, it permits a representation of the value of equity in terms of accounting numbers (most prominently, book value and expected abnormal earnings), relying essentially on the present value of expected dividends and clean surplus relation assumptions.

The F-O approach provides a role for many important features of the accounting system, including clean surplus, book value as well as earnings, transitory components of earnings, conservatism, and delayed recognition. For example, we can clearly see a progression in adding key features of the financial-reporting system. Early modeling assumed unbiased accounting and the clean surplus relation, while later extensions incorporated conservative accounting (Feltham and Ohlson 1995; Zhang 2000). Feltham-Ohlson alter the assumptions regarding the linear information dynamics to allow for "other information." In doing so, the model provides a role for information that is currently known and reflected in price, but is reflected with a lag in the accounting numbers. The model provides a representation for delayed recognition. By enriching the linear information dynamics, Feltham and Ohlson (1996) construct a theory of depreciation, which distinguishes between two potential sources of conservatism: accelerated depreciation and positive net present value projects. Ohlson (1999) decomposes earnings into permanent and transitory components. In the process, he clearly distinguishes between the concepts of forecasting relevance and the time-series persistence of an earnings component, and he demonstrates how each relevance concept affects valuation relevance of that earnings component. Extensions alter the linear information assumptions to incorporate additional conditioning variables (e.g., different decompositions of earnings, such as cash flows and accruals, Barth et al. [1999]). Thus the F-O approach provides a potentially rich platform for further modifications of the linear information dynamics to address additional accounting issues of interest.

The F-O approach has stimulated considerable empirical research. Frankel and Lee (1998) and Dechow et al. (1999) use the approach in testing market efficiency, which is a very ambitious application of the model. Studies employing a combined book value and earnings approach that either literally relies on the F-O model or is motivated by it are Barth, Beaver, and Landsman (1996, 1998), Barth and Clinch (1998), Burgstahler and Dichev (1997), Aboody et al. (1999), Barth, Beaver, Hand, and Landsman (1999), Collins, Maydew, and Weiss (1997), and Collins, Pincus, and Xie (1999). Other empirical applications include direct tests of the F-O model (e.g., Myers 1999; Barth, Beaver, Hand, and Landsman 1999). Major findings of this literature include the following:

(1) Both book value and earnings are significant pricing factors.
(2) The relative importance of book value is inversely related to the financial health of the firm.
(3) The coefficient on earnings is lower for firms with low return on equity.
(4) The coefficient on positive earnings is positive and significant, while the coefficient on losses is insignificantly different from zero.
(5) Accrual vs. cash flow components of earnings are priced significantly differently from one another. In general, the accrual components are associated with a lower coefficient.

Criticisms of the Feltham-Ohlson Approach

One major criticism is that the model has no endogenous demand for accounting data, but how serious is this charge? The modeling can be informative without including an endogenous demand for accounting, and I believe the criticism is somewhat misplaced or misdirected. By analogy, the Capital Asset Pricing Model (CAPM) has no demand for financial institutions, yet we observe financial institutions empirically. What do we conclude? Do we conclude that the risk-return trade-off derived from the CAPM is of no interest or relevance to investors or to managers of financial institutions? I think not. The F-O models do not attempt to derive a demand for accounting. The F-O approach provides a framework for representing valuation in terms of accounting numbers, while taking accounting as given exogenously. This framework relates published accounting data to equity valuation, allows us to interpret the coefficients on the valuation equation, and allows us to relate the coefficients from the valuation equation to coefficients from the time-series of earnings equation. With contextual accounting arguments added to the general framework, researchers can predict how accounting numbers would relate to value (e.g., predictions on how the coefficients for the cash-flow and accrual components of earnings would be expected to differ in an earnings forecasting equation and a valuation equation).

Another criticism is that there is no information asymmetry, and that hence no strategic uses of accounting data arise within the F-O framework. To be sure, many financial-reporting issues arise out of concern over information asymmetry and incentives to "manage" the accounting numbers. For example, the research on analysts' behavior and discretionary behavior address issues of information asymmetry and incentives. However, the F-O approach is a beginning. As a prelude to developing models that incorporate information asymmetry and strategic uses of accounting data in valuation, it is helpful to start with a model of the relation between the valuation and accounting numbers in a nonstrategic setting. Moreover, not all issues of interest in accounting involve information asymmetry. A large body of research examines empirically the relation between valuation and publicly available accounting numbers in a nonstrategic setting (e.g., value-relevance studies). A conceptual framework, such as the F-O approach, guides the specification and interpretation of the empirical estimating equations.

Of course, it would also be desirable to have a theory where demand for accounting data is endogenous, and to have models of information asymmetry where incentives to report strategically are endogenous. However, it is unreasonable to expect the F-O model to be rich enough to encompass all issues of interest to accounting research. Parsimony is a virtue in modeling. The model focuses attention on specific variables of interest, and the trade-off between insight and comprehensiveness is common in modeling exercises.

Some aspects of the models are unsupported by the empirical data (e.g., Myers 1999; Joos 2000; Barth et al. 1999), such as the linearity properties and the consistency among the coefficients in the system of linear information dynamics and valuation equations. However, the conflicting evidence highlights one of the important features of the F-O framework. Most accounting research is conducted in "reduced form." In other words, we estimate intuitively plausible relations that we hope will allow us to predict the sign of the coefficient. Rarely do we predict the magnitude of the coefficient. Even more rare are opportunities to test structural relations among the coefficients across different equations in the system. The F-O models permit us to predict how the coefficients within and across equations in the system are related. In particular, the coefficients in the valuation equation are a function of the coefficients in the linear information dynamics equations.

Although it may seem disappointing that we can reject the null hypothesis that the predicted coefficients equal the empirically observed ones, it is progress to be in a position to specify a predicted relation among the coefficients. We make further progress by asking what modifications would permit a consistency between the systems of equations. Introducing nonlinearity in information dynamics is a likely candidate. For example, the F-O model does not incorporate bankruptcy or other option-related phenomena that might introduce nonlinearities into the relation. Research is currently underway to incorporate nonlinearities (Yee 2001).

The F-O modeling is one of the few attempts to pursue accounting theory. It is no coincidence that the terminology of accounting (e.g., *income*) is similar to that used in economics and finance. We could have called the difference between revenues and expenses by another name, but we did not. The semantics of accounting was chosen because income theory asserts that the resulting measure is an indicator of firm performance. Hence, it is natural to focus on a theory of measures of accounting net income and their relation to value.

Empirical studies applying the F-O framework often append a contextual accounting theory regarding differences in cash flows vs. accruals, the fair value of financial instruments, or the nature of pension obligations to guide the empirical predictions. Such contextual richness can help fill in some of the substance omitted from the parsimonious F-O representations. Once these contextual theories are appended, the combination of parsimonious modeling and contextual richness provides a rich basis for empirical testing. One of the major applications of the F-O models is the value-relevance literature.

IV. VALUE-RELEVANCE RESEARCH

Value relevance is major area of empirical research in the last ten years.[2] Holthausen and Watts (2001) identify 54 value-relevance studies, only three of which were published before 1990. Value-relevance research examines the association between a security price-based dependent variable and a set of accounting variables. An accounting number is termed "value relevant" if it is significantly related to the dependent variable.[3] Defined in this most

[2] A more complete review of the literature appears in Barth, Beaver, and Landsman (2001).

[3] Beaver (1998, 116), Ohlson (1995), and Barth (2000) provide closely related formal definitions. The key commonality is that an accounting amount is deemed value relevant if it is significantly associated with equity market value.

general sense, value-relevance research has a long history (Miller and Modigliani 1966); however, the term came into common usage in the early 1990s (Easton et al. 1993). Papers by Ohlson (1995, 1999) also use the term "value relevance," in a manner consistent with empirical studies. As with the other research areas, value-relevance research is controversial (Holthausen and Watts 2001; Barth, Beaver, and Landsman 2001).

In this paper I address some basic questions: What distinguishes value-relevance research from other capital market research? Why is timeliness not a key issue in many value-relevance studies? What is the conceptual foundation of the value-relevance studies? What have we learned? What is the role of value-relevance research? What are some major unresolved issues?

What Are the Distinctive Characteristics?

Value-relevance research has two major characteristics. The first is that, more than any of the other four areas discussed, value-relevance research demands an in-depth knowledge of accounting institutions, accounting standards, and the specific features of the reported numbers. This knowledge includes the stated objectives of financial reporting, criteria standard setters use, the basis for specific standards, and details of how to construct the accounting numbers under a given standard (pension reporting is an excellent example). Incorporating the accounting context gives value-relevance research its richness and provides a basis for empirical predictions (Barth 1991), and vividly illustrates accounting researchers' comparative advantage in examining relations between equity value and accounting numbers.

A second distinguishing characteristic is that timeliness of information is not an overriding issue. Although value relevance research encompasses event studies, it also includes studies that examine the relation between the *levels* of stock prices and the accounting data. The timing of the information is of primary concern in the event-study research design. Event studies examine the stock price reaction over short windows of time centered on the announcement date. They identify the date of the public disclosure of the item being studied and examine the price change (usually in percentage terms and adjusted for market-wide movements) surrounding the event date.

In contrast to event studies, levels studies identify drivers of value that may be reflected in price over a longer time period than assumed in event studies. For example, prices may reflect the information before the announcement date. The value-relevance research characterizes market value at a point in time as a function of a set of accounting variables, such as assets, liabilities, revenues, expenses, and net income. This research design does not address timeliness, in contrast to "event-study" research design.

Why Is Timeliness Not the Key Issue?

The accounting system recognizes events later than security prices do (e.g., Ryan 1995). Delayed recognition is a natural implication of accounting standards, such as the revenue recognition principle. Moreover, we know that earnings announcements are largely, but not entirely, preempted by the disclosure of other information (Ball and Brown 1968; Beaver 1968). Landsman and Maydew (2002) conclude this finding has not changed over the last 30 years. Imagine a world in which earnings is the only information relevant to the value of the firm. With no private information search or prior public disclosures that preempt the earnings announcement, we would observe large spikes in price changes at earnings announcement times, in response to the unexpected earnings. However, this prospect creates incentives for private information search to obtain prior information about the forthcoming accounting earnings. To the extent that private information and prior public announcements are reflected in prices before the public earnings announcement, the price reaction at the earnings announcement date is reduced. In the limit, a search for prior information can completely preempt the earnings announcement; however, such preemption does not eliminate the importance of reported earnings. The primary barrier to the complete preemption of earnings is the cost of obtaining the prior information. This cost includes not only the out-of-pocket cost of the information search, but also indirect costs imposed by the legal liability for selectively disseminating or obtaining nonpublicly available information. As the costs approach zero, the announcement effect can approach zero.

Models by Demski and Feltham (1994), McNichols and Trueman (1994), and Kim and Verrecchia (1994) formalize this process. For example, in Demski and Feltham (1994) the sole role of the information obtained before the earnings announcement is to provide information about forthcoming earnings. In short, these models imply there is more to the price-earnings relation than only the short-term price reactions at the announcement date. In fact, the magnitude of price change at the announcement date is informative about the costs of obtaining predisclosure information, but provides limited evidence about how value-relevant earnings are.

The informational approach states that a signal is informative only if the signal can alter beliefs conditional upon the other information available. This would require that the accounting number have some unique component that is not preempted by other information available prior to or simultaneous with the accounting number. This perspective is consistent with event study research designs, which control for other information publicly available prior to and concurrent with the accounting announcement.

However, accounting numbers are not unique representations of the underlying constructs they are designed to capture. It is often possible to find a vector of publicly available information that, collectively, is highly correlated with a particular accounting number. For example, the fair value of bank loans is a function of default risk and interest rate risk (Barth et al. 1996). Some linear combination of book value of the loans, proxies for default risk, and proxies for interest rate risk may be highly correlated with fair value measures, even if those measures "perfectly" capture the underlying construct. However, a key role of financial statements is to summarize relevant information parsimoniously and in a manner consistent with the underlying concept. It is informative to know how well accounting numbers play this role, even if vectors of competing proxies for the same underlying construct exist. In fact, if the accounting number (e.g., fair value of bank loans) is capturing the underlying construct, then we would expect other proxies for the construct (e.g., default risk and interest rate risk) to be correlated with the accounting number. Such correlation would indicate that the accounting number is capturing the underlying construct.

To choose another example, assume that an alternative set of data could produce a variable that is perfectly correlated with depreciation expense. Would this imply that one could exclude depreciation from the calculation of net income? Lambert (1996) concluded that the FASB probably would not exclude depreciation. The balance sheet and income statements are not intended to list only those assets, liabilities, revenues, and expenses not preempted by other publicly available information. The financial statements are intended instead to be "complete" within the constraints and definitions of generally accepted accounting principles. In this broader view of the role of financial statements, timeliness is only one dimension.

This broader view has implications for research design. For example, researchers often use first differences, rather than levels, of a stock-price-related dependent variable to mitigate some econometric problems, such as correlated omitted variables or serial dependency in the regression residuals (Landsman and Magliolo 1988). However, changing the form of the variable may fundamentally change the question addressed. One chooses the levels design when the problem is to determine what accounting numbers are reflected in firm value, whereas one chooses the first differences research design when the problem is to explain changes in value over a specific period of time. Hence, in the first differences formulation, the issue of timing of the information is important. Thus, if the researcher is interested in whether the accounting amount is timely, then examining changes in value can be the appropriate research design choice. However, for the reasons discussed earlier, researchers are interested in a variety of questions, many of which do not involve timeliness.

What Is the Conceptual Foundation of Value-Relevance Research?

The theoretical foundation of value-relevance studies is a combination of a valuation theory plus contextual accounting arguments that allow researchers to predict how accounting variables relate to the market value of equity. There are three major types of valuation models. The oldest is an earnings-only approach—Miller and Modigliani (1966) characterize value as the present value of permanent future earnings. The research of Landsman (1986), Barth (1991), and Barth et al. (1996) adopts a balance-sheet approach. The Feltham-Ohlson model discussed earlier represents firm value as a linear function of book value of equity and the present value of expected future abnormal earnings. Value-relevance studies have relied heavily on a combined book value and earnings approach (Barth, Beaver, and Landsman 2001).

However, the valuation assumption is only half the story. Value-relevance studies typically incorporate contextual accounting arguments to predict the relation between accounting variables and market value. For example, the prediction that pension assets and obligations are priced as if they are assets and obligations of the company is based on the conceptual argument offered by the FASB (among others) regarding the economic substance of the pension contract between the company and employees, under a defined benefit plan (Landsman 1986).

The predictions of the way fair value of financial instruments will be priced in a valuation equation draws upon conceptual arguments concerning relevance and reliability of fair value vis-à-vis historical costs. This is an accounting theory, albeit one couched in terms of measurement of specific assets or obligations rather than a global statement that unequivocally predicts how all assets and liabilities would be measured and priced. Although the lack of a general theory of accounting can frustrate researchers (and others), researchers can use contextual accounting arguments to aid in predicting valuation-accounting number relations.

What Have We Learned?

The hallmark of value-relevance studies is that their execution requires an investment in and understanding of the institutional details of the way financial statements are prepared and of contextual arguments regarding the properties of various measures. What we have learned relates to three questions regarding an accounting number: Is it priced (i.e., does it have a coefficient that is significantly different from zero)? Is it priced consistently with some theoretical value (e.g., for a balance sheet number, is its coefficient equal to 1)? Is a particular accounting number priced equal to or differently from similar accounting numbers (e.g., do all components of net income have the same valuation multiples)? Here are some examples of what we have learned.

Evidence indicates that unrecorded pension assets and liabilities (unrecorded but disclosed in the footnotes) are priced. Landsman (1986), Barth (1991), and Barth et al. (1992) find that the unrecognized portion of pension assets and liabilities is priced in a manner consistent with the capital market viewing pension assets as assets of the company and pension obligations as liabilities. Similar findings with respect to other post-retirement benefits (Amir 1993; Choi et al. 1997) are observed. Fair values of financial instruments are priced (Barth et al. 1996). However, the results are mixed with respect to the fair value of bank loans (Beaver and Venkatachalam 2000; Eccher et al. 1996; Nelson 1996). Moreover, Barth (1994a) shows that pricing multiples vary with the type of investment security in a manner related to the ease with which bank management can estimate the fair values.

Footnote information is often not as prominently displayed and may contain complex, arcane data (concerning such items as pension disclosures) that can be difficult to interpret. The pricing of footnote data is a nontrivial issue. The pricing of pension assets and obligations and the fair value of financial instruments is of interest in its own right. However, they are two prominent examples of the broader issue of whether footnote information is priced. Another example is nonperforming loans, which is footnote information on the default risk of bank loans. Empirical evidence indicates nonperforming loans are significant in explaining the value of bank common equity (Beaver et al. 1989; Wahlen 1994; Beaver and Engel 1996; Barth, Beaver, and Landsman 1996; Venkatachalam 1996).

The value-relevance literature also addresses questions relating to nonfinancial intangible assets. These studies generally find that intangible assets (e.g., capitalized software, brands, and goodwill) are priced (e.g., Aboody and Lev 1998; Barth, Clement, et al. 1998; Barth and Clinch 1998; Chambers et al. 1999). Studies also find that investors perceive research and development and advertising expenditures and bank core deposits as assets of the firm (e.g., Abdel-khalik 1975; Hirschey and Weygandt 1985; Bublitz and Ettredge 1989; Landsman and Shapiro 1995; Barth et al. 1996; Eccher et al. 1996; Lev and Sougiannis 1996; Healy et. al. 1997; Joos 2000). Barth and McNichols (1994) and Hughes (2000) find that unbooked environmental liabilities are also priced.

One would expect various components of earnings to be associated with different pricing multiples based on the persistence of that earnings component (Sloan 1996; Ohlson 1999). Empirical evidence indicates that the accrual components of earnings are not only less persistent than the cash-flow components in forecasting future earnings, but also that the accrual components are associated with a lower earnings multiple (Barth et al. 1999). Also for banks, earnings before security gains and losses is associated with a higher pricing multiple than security gains and losses (Barth et al. 1990).

The Role of Value-Relevance Research

Accounting research can play three roles:

(1) Research can help articulate the nature of the issues, and can provide a paradigm or language with which to frame the questions of interest. The paradigm of the value of information is not a predictive theory in itself, but provides a definitional and taxonomic framework for formulating the informational role of accounting numbers.
(2) Research can provide a theory. This theory can be normative, which leads to prescriptive statements, or positive, which provides hypotheses and testable predictions.
(3) Research can provide empirical evidence.

Empirical evidence is a signal from an information system. The study's research design describes the features of the information system. The researcher forms priors with respect to the relationships of interest (e.g., probabilities that either of two alternative hypotheses is true). The evidence is a signal that leads to a posterior distribution, which must differ from the prior for at least one possible signal for the research to be informative. As the power of the research design increases, the signals generated by the design become more informative.

Value-relevance research provides evidence as to whether the accounting numbers relate to value in the predicted manner. In the pension context, the predictions are based on contextual theory that pension assets are assets of the firm and pension obligations are obligations of the firm. A plausible prediction is that pension assets (obligations) are priced as assets (obligations). A study's findings represent only one of many possible outcomes. However, the subsequent discussions and the subsequent research conducted are informed by and conditioned on the observed evidence.

Unresolved Issues

Some of the unresolved issues affecting the inferences drawn from value-relevance research include market efficiency, econometric issues, and other purposes of financial statements. Does market efficiency affect interpretation of the results? I believe it does, but the findings are important even if markets are inefficient. Are the standard econometric issues more serious with respect to this research area than elsewhere? Most, if not all, of the econometric issues faced here are common to other areas of accounting research. Moreover, value-relevance research incorporates design features to mitigate these concerns. Finally, what other purposes of financial statements should be explored as a complement to the value relevance research? Accounting for contracting purposes is a major candidate (Watts and Zimmerman 1986).

V. RESEARCH ON ANALYSTS' BEHAVIOR

Another major research area is analysts' forecasting abilities and their coverage decisions. Analysts' behavior is important to accounting research, because analysts are among the major information intermediaries who use and interpret accounting data (Schipper 1991). As a result, security prices reflect the results of their analysis. Because the average prudent investor may lack the time, skill, or resources to analyze and interpret financial statements, analysts can be a major way in which accounting data become reflected in security prices. Efficient analysts' information processing can facilitate the efficiency of security prices, as well. If there are limitations and inefficiencies in the analysts' information processing, and if capital markets do not draw on other aspects of the total mix of information to circumvent analysts' limited information processing, then prices may not fully reflect the financial statement data. To the extent that analysts rely on a rich set of publicly available data, their forecasts can be a natural way to incorporate other information into the research design of valuation studies (e.g., via the application of the F-O models). An investigation of analysts' forecasts can assess the importance of accounting data relative to the total mix of information.

The history of analysts' forecasts is rich (Brown 1993). In some respects, it is the successor to the time-series of earnings literature (Beaver 1970; Ball and Watts 1972). The early literature focuses on which time-series model most accurately forecasts earnings. Identifying the process tells us something about the general characteristics of the accounting numbers (e.g., seasonality and adjacent quarter-to-quarter effects). Moreover, researchers use earnings forecasts derived from these models as inputs into other forms of research (e.g., we can use earnings forecast errors in security returns studies). Analysts' earnings forecasts are natural candidates for more accurate forecasts because they can reflect a richer information system than simply the past earnings series. One of the original purposes, learning about the features of the accounting system, has withered. However, the literature has examined issues beyond those related to finding the most accurate earnings forecast. Biases, processing limitations, and strategic considerations have been addressed.

What Have We Learned?

Much prior research has concluded that analysts' forecasts are optimistic (O'Brien 1988, among others), although there appears to be secular reduction in the optimistic bias (Brown 2001). The degree of bias is related to underwriter affiliation. Analysts employed by investment firms that are associated with the underwriting of the firm's securities issue more optimistic forecasts (Lin and McNichols 1998). Analysts' (initially optimistic) forecasts tend to be revised downward during the year (Kasznik and McNichols 2001). Analysts with better forecasting ability appear to have a higher probability of survival (Mikhail, Walther, and Willis 1999; Clement 1999).

Analysts' forecasts outperform the best statistical models (Brown et al. 1987a, among others), which is not surprising, since the analysts can use a richer information set than the past earnings series. However, a model that incorporates both statistically based forecasts and analysts' forecasts outperforms analysts' forecasts alone, which implies that the analysts' forecasts do not reflect all of the information in the past earnings series (Brown et al. 1987b). The forecast errors based on analysts' forecasts are serially correlated, which is also consistent with the idea that analysts' forecasts do not fully reflect all the available information (Dechow et al. 1999; Frankel and Lee 1998). This evidence is also consistent with analysts' underestimating the persistency of earnings (Abarbanell and Bernard 1992).

These findings would be of mild interest in their own right even if capital markets fully adjusted for this behavior. However, they take on added significance, to the extent that capital markets do not appear to unravel these biases and processing inefficiencies. Capital markets appear to reflect naively analysts' forecasts in prices. This finding appears to explain (at least partially) the abnormal returns associated with market-to-book and market-to-value strategies (Dechow and Sloan 1997; Frankel and Lee 1998). Analysts' forecasts appear to be a parsimonious way to capture "other information" (at least in part) in the Ohlson sense of the term (Dechow et al. 1999). Analyst coverage is greater for firms with more institutional investors (O'Brien and Bhushan 1990) and more intangible assets (Barth, Kasznik, and McNichols 2001).

Unresolved Issues

Researchers need a better understanding of the incentives of analysts with respect to forecasting. In particular, why do analysts form biased forecasts? Even in the face of evidence that the bias is associated with underwriter affiliation, there are multiple explanations for the bias. Is it intentional, or is it a manifestation of self-selection (McNichols and O'Brien 1997)? Why do analysts misestimate the persistence of earnings? Why do forecasts not fully reflect the available information?

Do analysts learn over time? Are they more accurate with experience (Clement 1999)? Does the capital market learn over time in its processing of analysts' forecasts? How do analysts make decisions regarding the allocation of their efforts across the firms covered? How does analysts' behavior vary with the financial-reporting environment? For example, Barth, Kasznik, and McNichols (2001) find that analyst coverage increases with the presence of unrecorded intangible assets. What other financial-reporting features are important? Furthermore, what are the mechanisms by which analysts' forecasts are incorporated into price? Why do errors in analysts' forecasts appear to result in the mispricing of securities? Why does the market price appear not to adjust fully for these documented regularities in analysts' forecasts?

Another major issue is to identify the other information besides accounting data that influences analysts' forecasts. Frankel and Lee (1998) and Dechow et al. (1999) have used analysts' forecasts as a proxy for other information. However, from the context of a broader system, analysts' forecasts are endogenous and are a function of underlying exogenous variables. The dimensionality of such other information is quite large. However, it is important to identify at least some of the major exogenous variables that explain analysts' forecasts. Amir and Lev (1996), Deng et al. (1999), Ittner and Larcker (1998), Lev and Sougiannis (1996), and Joos (2000) explore the ability of nonfinancial measures, such as population within licensed areas, penetration ratios, patents, FDA approvals, concentration ratios, and market share to aid in predicting future earnings and in explaining prices. Is this information reflected in analysts' forecasts as well?

VI. RESEARCH ON DISCRETIONARY ACCRUALS

Management can improve or impair the quality of financial statements through the exercise of discretion over accounting numbers.[4] Discretionary behavior includes voluntary earnings forecasting, voluntary disclosure, choice of accounting methods, and estimation of accruals. While research exists in all these areas, I will focus on the management of accruals (also known as earnings management). Accrual accounting is the heart of our financial-reporting system. I will discuss several aspects of earnings management: motives for earnings management, major findings, estimation of discretionary and nondiscretionary components, and unresolved issues.

Motives for Accrual Management

Motives fall into two broad categories: opportunistic or signaling. We tend to perceive the latter as benign, but not the former. Motives for managing accruals relate to compensation contracts, debt covenants, capital market pricing, taxes, litigation, and regulatory behavior (Watts and Zimmerman 1986; Beaver and Engel 1996). Each motive constitutes a broad category that encompasses a variety of specific behaviors. For example, capital market effects include management's attempts to influence the offering price in equity offerings, the terms or the value of stock options, and prices at which management-held securities are sold.

These motives can operate in either opposing or reinforcing ways, often making it difficult to isolate the primary motive (Healy and Wahlen 1999). For example, both capital market and compensation contracts can lead to incentives to overstate earnings. As a result, many researchers have not specified the precise nature of the underlying motivation, seeking instead to determine whether an empirical estimate of the discretionary accrual is related to some firm characteristic (e.g., financial difficulty, loss avoidance, income smoothing, big baths).

What Have We Learned?

Managers exercise discretion in response to a rich set of forces. Researchers use three major approaches to identify earnings management: generic models of discretionary accruals (e.g., Healy 1985; Jones 1991), tests based on discontinuities in the reported earnings distribution (e.g., Burgstahler and Dichev 1997), account-specific models of discretionary behavior (McNichols and Wilson 1988; Petroni 1992; Beatty et al. 1995), and combinations of these approaches (Beaver, McNichols et al. 2000).

[4] McNichols (2000) reviews recent research in earnings management and discretion with respect to accounting data. Schipper (1989) provides an early perspective on earnings management.

Management appears to manage earnings to avoid a loss, to avoid an earnings decline (Burgstahler and Dichev 1997), and to avoid falling below analysts' forecasts (Burgstahler and Eames 1998). Firms that issue earnings forecasts tend to manage earnings toward meeting those forecasts (Kasznik 1999; Matsunaga and Park 2001). Earnings management appears to be widespread and relatively easy to detect, at least as estimated by extant techniques. Loan loss reserves in the banking sector and policy loss reserves in the insurance sector appear to be two major accounts subject to management. Accrual management is only one form of earnings management. Others include hedging activities (Barton 2001) and altering research and development expenditures (Bushee 1998). In the banking sector, management appears to manage the loan loss reserves jointly with other forms of earnings management (Beatty et al. 1995).

Capital markets appear to price differently the nondiscretionary and discretionary components of an accrual. In the banking sector, capital markets treat additional loan loss reserves as good news, not bad news, consistent with signaling interpretations of discretionary reporting of estimated loan losses. In particular, financially stronger banks signal they can afford to take the hit to earnings (Beaver et al. 1989; Wahlen 1994). Capital markets price discretionary components of loan loss reserves differently than nondiscretionary portions (Beaver and Engel 1996).

In the property and casualty sector, the development of policy loss reserves is consistent with earnings management (Beaver and McNichols 1998). The stock prices of property and casualty firms appear to reflect fully the predictability in the policy loss development (Beaver and McNichols 1998, 2001). However, the evidence from the generic accrual studies suggests a different picture with respect to market efficiency and the pricing of accruals. Accruals, considered to be more subject to discretion, are less persistent than stock prices of existing securities imply, whereas cash flow from operations is more persistent than stock prices imply (Sloan 1996; Xie 2001). Unusual accruals occur at initial public offering dates and reverse themselves subsequently. These unusual accruals appear to be correlated with the negative abnormal returns observed in the initial public offering literature (Teoh et al. 1998a, 1998b; Teoh, Wong et al. 1998).

Estimation of Discretionary and Nondiscretionary Accruals

A major issue with respect to the power of this research is the ability to identify proxies or conditioning variables that reflect the discretionary and nondiscretionary components of the accrual. In the Jones (1991) model, sales is the key nondiscretionary variable driving current accruals, and capital expenditures is the key variable driving noncurrent accruals. Needless to say, this is a parsimonious model. Research investigating sector-specific accruals, such as the loan loss provision, typically uses sector-specific variables, such as nonperforming loans, to increase the precision with which one can measure the nondiscretionary component.

Identifying proxies for discretionary accruals can be a challenge. Often, studies regress total accruals on only the nondiscretionary variables and assume the residual is discretionary (e.g., applications of the Jones model). Of course, failure to identify fully the nondiscretionary component implies the regression residual contains both discretionary and nondiscretionary components, and the researcher has measured the estimated discretionary and nondiscretionary components with error. Typically, the explicit conditioning variables for discretionary accruals, such as earnings or leverage, are generic. These generic variables can be proxies for many firm characteristics, which make the interpretation of coefficients of the discretionary accruals in valuation equations challenging.

The development of policy loss reserves in the property-casualty sector provides a unique opportunity to identify the discretionary component of an accrual (Petroni 1992).

Property-casualty firms must report *ex post* estimation error for reserves reported in earlier years, where the amount of this error is called development. Researchers can estimate the discretionary component without a specification of either discretionary or nondiscretionary variables. Development includes *ex post* surprises of a nondiscretionary nature. However, if development is not subject to discretion, then it has an expected value of zero, and, by implication, zero serial correlation. As discussed earlier, empirically, development has a positive expected value for financially weaker firms, implying an understatement of the loss reserve (Petroni 1992), and development is highly positively serially correlated over time, consistent with management recognizing information slowly over several years (Beaver and McNichols 1998). Petroni et al. (2000) further decompose the development into discretionary and nondiscretionary components and find they have different implications for future profitability, risk, and market value.

Unresolved Issues

Much of this discussion implies that extant methods for the identification of discretionary accruals are of potentially low power. Using an empirical simulation, Dechow et al. (1995) provide evidence that extant models are not very powerful. Yet, empirically, the majority of studies observe earnings management. Moreover, many forms of earnings management appear to be identifiable not only by researchers, but also by the capital markets.

Why is it relatively easy to detect earnings management empirically if the models are of low power? One might conjecture that effective earnings management (at least of the opportunistic type) would not be easy to unravel. Why is it relatively easy for the researchers to detect earnings management, typically using contemporaneous (not future) data? Is management naïve? Does earnings management achieve its goals (often unstated) even if it is invertible? What incentives for earnings management are consistent with the capital market's ability to invert the discretionary portion and price it differently? Is discretionary behavior a natural manifestation of contracting in incomplete markets (Demski and Frimor 1999)? The nature of the discretion may be known but not contractible. Incentives and costs to eliminate discretionary behavior are unclear, and discretionary behavior may be an equilibrium outcome, albeit not a "first best" solution.

These questions, of course, raise the possibility that what looks like earnings management may not be. Perhaps what researchers observe is not discretion or management at all, but is a proxy for some other factor. If so, then what might those factors be? McNichols (2000) offers evidence that discretionary accruals are correlated with growth and that the mispricing of accruals may in fact be the "glamour stock" phenomenon (i.e., the mispricing of high-expected-growth stocks) in disguise. In particular, she shows that aggregate accruals models that do not incorporate long-term earnings growth are potentially misspecified and can result in misleading inferences regarding earnings management. The implication is differential behavior observed in prior studies may relate to the performance characteristics of the firms (e.g., correlated with growth) rather than to differential incentives to manage earnings.

VII. CONCLUDING REMARKS

Market efficiency, Feltham-Ohlson modeling, value relevance, analysts' behavior, and discretionary behavior not only have had the greatest impact on capital market research over the last ten years, but they also have the greatest potential to contribute significantly to our knowledge over the next five to ten years. These areas address important questions. They are linked together and build upon one another's knowledge and research designs.

They raise major issues that remain unresolved. Three recurring themes are markets (efficiency, valuation), individual behavior (investors, analysts, managers), and accounting structure or context. Accounting research is distinct and important only insofar as it confronts the first two themes with the third—an observation similar in spirit to the point made by my predecessor (Kinney 2001).

Each of these research areas is controversial in terms of either findings or research method. Is important research by nature controversial? I believe controversy is a natural consequence of conducting important research, especially in the early stages of the research. Innovative research is likely to be the most controversial of all. Thirty-five years ago, many questioned whether capital market research with respect to accounting numbers was legitimate accounting research.

Accounting and capital markets: a survey of the European evidence

Pascal Dumontier
Pierre Mendès-France University, Grenoble

Bernard Raffournier
University of Geneva

ABSTRACT

The relationship between accounting information and capital markets has been the subject of numerous studies, especially in the US. The purpose of this article is to examine the corresponding evidence in Europe. This review classifies the European literature into three groups: studies of the market reaction to newly released accounting information; studies of the long-term association between stock returns and accounting numbers; studies devoted to the use of accounting data by investors and to the impact of market pressure on accounting choices. The paper reviews and summarizes the main results related to each of these topics. It also addresses some methodological issues and provides suggestions for future research.

1. INTRODUCTION

Since the pioneering work of Ball and Brown (1968), the relationship between accounting information and capital markets has attracted considerable attention, to the point that it is probably one of the most popular issues in the accounting literature. The interest for this subject is legitimate, given the generally accepted statement that accounting figures are aimed at providing investors with relevant information for their investment decisions. Even if accounting data are used in various contexts such as the contracting process within the firm or between the firm and its creditors and suppliers, regarding capital markets they are supposed to facilitate the prediction of firms' future cash flows and help investors assess future securities' risk and returns. This is certainly why innumerable studies have been conducted in the US during the last three decades with the aim of determining to what extent this objective was achieved. This article examines

the corresponding European evidence. Three types of research are successively considered. (1) Studies of the market reaction to the release of new accounting information that analyse the stock price impact of accounting disclosures in order to determine whether these are useful to market participants. (2) Studies of the long-term association between stock returns and accounting numbers, which examine the extent to which the information conveyed by accounting figures is consistent with that reflected in stock prices. (3) Complementary studies devoted to the use of accounting data by investors and to the influence of market considerations on accounting choices. For practical reasons, this review focuses on the most recent studies and is limited to articles published in English.

2. THE MARKET RESPONSE TO ACCOUNTING DISCLOSURES

The primary objective of capital market research has been to assess whether accounting data provide value-relevant information to investors, incremental to all other sources of publicly available information. The information content of accounting numbers is inferred from changes in the level or in the variability of stock prices and from changes in the volume of security trades over a short time period during which these data are publicly released. After a short description of methodological issues related to market reaction studies, this section summarizes the European evidence on the impact of accounting disclosures on stock returns or trading volumes. It is shown that clear market reactions to accounting announcements have been detected in all European countries where such studies have been conducted. Since these reactions exhibit significant differences between firms, this section also reviews studies that have analysed the determinants of these differences. Finally, it examines the empirical evidence related to the post-announcement drift anomaly and offers conclusions and suggestions for future research on the market response to accounting disclosures.

Empirical design of market reaction studies

If capital markets are efficient, stock prices must reflect quickly and fully any newly released information. Consequently, a change in the level or in the variability of stock prices or a change in the quantity of security trades is expected during the announcement period if the disclosed numbers convey new information to market participants about the timing, the amount or the uncertainty of anticipated future cash flows. In fact, most of these studies focus on the informational characteristics of the bottom-line earnings only. The information content of earnings is inferred from the mean abnormal returns, from the volatility of returns or from changes in the volume of trading over a short period around the announcement date.

The mean abnormal return methodology makes the assumption that earnings should cause a stock price increase if they convey good news, and a price decrease if they communicate bad news. Since the amount of earnings is *per se* meaningless, this number must be contrasted to the market's expectations about earnings. The first step is therefore to disentangle the expected and unexpected components of reported earnings. Expected earnings are generally estimated in two different ways. Assuming that earnings follow a random process, some studies take earnings of a given year as the following year's expected earnings. Other studies use the analysts' consensus forecast as the best available measure of expected earnings. Under the information-content hypothesis, positive unexpected earnings should on average lead to positive abnormal returns, and negative unexpected earnings to negative abnormal returns. Earnings are supposed to convey relevant information if abnormal stock returns are statistically positive for firms with positive unexpected earnings, and statistically negative for companies with negative unanticipated earnings. Abnormal returns are defined as the difference between actual and market-adjusted predicted returns.

The methodology based on the volatility of returns assumes that any announcement that does convey information should cause a price change. The variability of returns is therefore expected to be higher at the announcement date than on any other day. Hence, observing whether there is an increase in the volatility of returns on announcement days can test the hypothesis that earnings convey information to investors. In the same way, if earnings are a relevant source of information for investors, they should lead to portfolio rearrangements and therefore their release should cause significant increases in the number of security trades. The methodologies used to detect these increases are very similar to those adopted to measure mean abnormal returns: the trading volume metric is either the number or the market value of traded shares, and abnormal volumes are defined as the difference between actual and expected volumes at the announcement dates. The methodology based on trades, just like the one based on the volatility of returns, has the advantage of circumventing the problem of specifying an earnings expectation model.

The market reaction to annual and interim accounting disclosures

European studies which have investigated the stock price reaction to earnings announcements confirm the seminal findings of Beaver (1968) in the US: earnings disclosures lead to significant stock price changes or trading volume increases. In the UK, Firth (1981) reported both abnormal absolute stock returns and significant trading volume increases at annual earnings announcement dates under the period 1976–78, for a sample of 120 companies. Similarly, Pope and Inyangete (1992) observed a strong increase in the volatility of security returns around announcement dates for a sample of 3,541 UK annual earnings announcements between 1985 and 1987. With a different approach, Hew *et al.* (1996) confirm that UK annual earnings have information content for investors, since positive (negative) unexpected annual earnings were found to cause significant positive (negative) returns. Results in Finland, Spain or France are consistent with those obtained in the UK. Using data from the Finnish stock market, Kallunki (1996) showed that positive (negative) unexpected annual earnings announcements are associated with positive (negative) abnormal returns at the announcement dates. In the same vein, Gajewski and Quéré (2001) analysed the French market response to annual earnings announcements by comparing actual earnings with those expected by financial analysts. Their data indicate that positive unexpected earnings lead to positive abnormal returns, while negative unexpected ones cause negative returns. This result is consistent with a study by Gajewski (1999) which found that trades on the Paris Stock Exchange increase significantly around earnings announcements. In Spain, Pellicer and Rees (1999) examined the volatility of security returns around 223 annual earnings announcements. By ranking the absolute abnormal returns across a 51-day window centred on the disclosure date, they observed that the volatility of returns was the highest during the two days surrounding earnings announcements. Stating that the information content of earnings announcements should cause a reaction that should be more pronounced on option prices than on stock prices because of the leverage effect of options, Donders *et al.* (2000) studied the impact of earnings releases on the volatility and the trading volume of call options on Dutch stocks at the annual earnings announcement dates. As expected, they found that the volatility of option prices and trading volumes increase around the announcement days and drop afterwards.

Firms regularly release information through quarterly and half-year disclosures that may help investors anticipate the level of annual earnings. Following Kiger (1972) or Foster (1977) in the US, several European studies have been devoted to the usefulness of these interim disclosures. In France, listed companies must disclose their quarterly turnovers and release half-year reports containing a six-month income statement and relevant information on their operations. Since interim disclosures are at once not audited and less abundant than semi-annual releases, Gajewski and Quéré (2001) hypothesized that the market reaction to quarterly disclosures should be lower than the one of half-year reports. Their results for the 1994–96 period indicate that turnover data disclosed by French quoted companies at the end of each quarter do not cause significant market reactions. This leads the authors to question the usefulness of these mandatory disclosures. In contrast, stock price reactions to half-year and annual releases are both statistically significant but, as expected, the information content of half-year disclosures appears to be less than the one of annual reports. With regard to interim accounting information, Spanish firms are subject to more demanding requirements than French ones. They must disclose earnings quarterly and publish a half-year report containing a profit and loss account and a balance sheet. This is certainly why, unlike the French evidence, Pellicer and Rees (1999) did not notice any significant difference in the volatility of returns accompanying annual and interim releases in Spain. In contrast with the French and Spanish evidence, the information content hypothesis of interim reports appears to be rejected in Belgium. In this country, a law implemented in 1990 obliges listed firms to disclose semi-annual earnings. Van Huffel *et al.* (1996) have thus analysed the stock price reaction to half-year report releases just after the establishment of this new legal requirement. Although the sign of unexpected earnings was positively associated with the sign of abnormal returns at the disclosure dates, the authors did not detect any clear announcement effect. Interim disclosures under study were not associated with statistically significant abnormal returns.

Since accounting figures are reported continuously throughout the year, Firth (1981) proposed to examine the incremental information content of four accounting events in order to better understand how investors process accounting data. These events are the release of interim reports, the announcement of preliminary earnings, the release of annual reports and the annual meeting of shareholders. The study covered the 1976–78 period and the sample consisted of 120 randomly selected UK companies listed on the London Stock Exchange. The information content of each event was determined by ranking by size the cross-sectional average of the absolute values of weekly abnormal returns around each announcement. Firth's results indicate that preliminary and interim announcements possess the highest information content. The release of annual reports also exhibits a significant information content. In contrast, the price impact of annual general meetings seems insignificant. Correlation tests showed that abnormal returns associated with preliminary earnings announcements were positively related to abnormal returns at both interim disclosure and annual report dates. This suggests that firms that exhibit highly informative preliminary announcements also have highly informative annual reports and interim disclosures. Rippington and Taffler (1995) replicated Firth's study using daily instead of weekly share returns. Unlike Firth, they noted that stock price reactions to annual reports are frequently low, suggesting that such disclosures do not convey relevant information to investors. However, since some of their sampled firms exhibited outstandingly high abnormal returns at the time of their annual report release, the authors analysed financial press comments on these firms' reports. They ascertained that the observed high returns were due to unexpected specific information in the audit report, the funds statement, the chairman's statement, geographical or activity breakdowns, or in the notes to the accounts. This led Rippington and Taffler to express the view that, although they do not generally induce significant price reactions because they mainly confirm data that are correctly anticipated by investors, annual reports play a significant role in the valuation process due to the extremely relevant information they disclose in a relatively small but nonetheless important number of specific cases.

The information content of specific accounting data

Several European studies have focused on the price effect of specific accounting data. Peasnell *et al.* (1987), for example, have investigated the information content of current cost information disclosed by about 200 companies listed on the London Stock Exchange between 1980 and 1984. Their results showed that this information has a small but real impact on stock returns in days surrounding the earnings announcement. Given that Finnish accounting rules allow firms to manage their reported earnings in a variety of ways and assuming that Finnish companies pay great attention to tax considerations when preparing their financial reports, Booth *et al.* (1996) expressed the view that accounting earnings should be strongly manipulated in Finland, which should restrict their information content. To examine this hypothesis, they measured the price impact of five different income levels that are systematically adjusted for earnings management by Finnish financial analysts, in addition to the traditional net earnings usually reported by firms. Their results suggest that investors react to negative but not to positive unexpected earnings. Moreover, and perhaps more interestingly, the authors noted that the magnitude of unexpected stock returns around announcement days is related to two specific income components which proxy for the intensity of earnings management. This suggests that, contrary to what was expected, investors are more interested in the information potentially conveyed by manipulated earnings than by the tax impact of such manipulations.

Given that Swiss firms can comply either with EU directives, IAS or Swiss GAAP on a voluntary basis, Switzerland offers the opportunity to determine whether different GAAP regimes possess different information content to investors. Using a sample of 247 earnings announcements made by Swiss listed companies which changed their accounting standards to switch from Swiss GAAP to either IAS or EU directives during the period 1985–93, Auer (1996) compared the stock price reactions to earnings announcements before and after the adoption of the new standards. He observed that the switch from Swiss GAAP to IAS or EU directives was accompanied by an increase of stock price volatility at the earnings announcement date. This suggests that earnings based on IAS or EU directives have an information content higher than those based on Swiss GAAP. The results also showed that there is no significant difference in the information content between EU directives earnings and IAS-based earnings. In the same line, Caramanolis-Çötelli *et al.* (1999) have examined the influence of disclosure quality on the Swiss market reaction to annual report releases. Using a rating measure computed by the Swiss Financial Analyst Federation as a proxy for disclosure quality, they observed a positive relationship between this variable and absolute abnormal stock returns. Given that this influence was significant for positive abnormal returns only, the authors suggest that 'good' firms might adopt a policy of high quality disclosure to signal their type to the market.

The determinants of the market reaction to accounting disclosures

Since the market reaction to accounting disclosures differs among firms, several studies have analysed the possible determinants of these differences. Following Beaver *et al.* (1979) in the US, European studies have investigated the magnitude of unexpected earnings, considering that the greater the surprise, the larger the investors' reaction. The results of studies by Firth (1981) in the UK, Pellicer and Rees (1999) in Spain or Gajewski and Quéré (2002) in France confirmed the US evidence: trading volumes, volatility of returns or mean abnormal returns are positively related to the size of unexpected annual or interim earnings.

Following Grant (1980), who found that the information content of earnings announcements was greater for small OTC firms than that for large companies listed on the New York Stock Exchange, several European studies investigated whether the market reactions induced by accounting disclosures are more pronounced for small firms. Results by Firth (1981) or by Rippington and Taffler (1995) in the UK and by Gajewski and Quéré (2001) in France confirm this intuition: the larger the market value of the firm, the smaller its abnormal returns at the preliminary or the interim announcement dates. The hypothesis put forward to explain this relation suggests that small firms tend to disclose less information and to receive less attention from professional investment analysts and fund managers than large firms. Consequently, their accounting figures should convey higher amounts of information than those of large firms because they have not been pre-empted by non-accounting information disclosed and extensively analysed during the reporting period. To determine whether the information content of accounting disclosures is negatively related to the amount of information that was available to market participants prior to these disclosures, Pope and Inyangete (1992) have tested whether cross-sectional differences in returns around announcement dates are statistically related to firm size, but also to the number of market makers, which is expected to increase with the amount of available information, and to the frequency of press comments. All these variables were highly significant, suggesting that the amount of information available before accounting announcements explains the information content of these announcements.

Elsharkawyand and Garrod (1996) tried to determine whether the positive association between price changes and the sign and magnitude of unexpected earnings was caused by sophisticated investors who are aware of the relevance of the disclosed numbers for valuation purposes, or whether the market reaction emanates from unsophisticated investors who react mechanically to reported earnings. The authors used two proxies proposed by Hand (1990) for measuring the level of investor sophistication: the percentage of each firm's stock held by non-institutional investors and the market value of the firm scaled by the difference between the market values of the largest and smallest firms in the sample. They used regression techniques to determine whether abnormal returns surrounding earnings announcements were related to the two proxies for investor sophistication, but also to the magnitude of unexpected earnings and to firm size. Using a sample of 511 UK companies listed on the London Stock Exchange between 1988 and 1991, they observed a positive investor sophistication effect that was significant even after having controlled for firm size. Their results showed that less sophisticated investors react to good news but tend to under-react to negative unexpected earnings in comparison with their sophisticated counterparts.

The post-announcement drift anomaly

The efficient market hypothesis states that stock prices should react instantaneously and completely to any value-relevant information and that subsequent price changes should not be related to these reactions. In contradiction with this hypothesis, several empirical studies have shown that stock price reactions at earnings announcement dates are incomplete, because prices adjust only gradually to the new information. Therefore, significant abnormal returns can be achieved in the days following these announcements. Since these abnormal returns have the same sign as unexpected earnings, investors seem to underreact to the information contained in earnings. First documented by Ball and Brown (1968), this phenomenon, referred in the literature as the 'post-earnings-announcement drift', has been extensively analysed by Bernard and Thomas (1990) in the US.

Hew *et al.* (1996) investigated the post-earnings announcement drift in the UK. Using data from 206 companies listed on the London Stock Exchange, they found evidence of such a drift for both interim and final announcements. However, this drift was statistically insignificant for large companies. This led the authors to suggest that transaction costs, trading volumes or the amount of information available to investors before the announcement date may explain this post-earnings announcement anomaly. Isakov and Pérignon (2001) have studied the post-announcement drift on the implied volatility of Swiss call options over the 1989–98 period. They observed a persistent increase of implied volatility after the announcement day. Dividing their sample into a good news subsample and a bad news one using the abnormal return on the event date and the analysts' forecast errors, they found that the market reaction depends on whether the announcement can be regarded as conveying good or bad news.

In a study of the Finnish stock market reaction to earnings announcements, Kallunki (1996) observed that unexpected returns disappear after the announcement day in case of good news (i.e. positive unexpected earnings) but persist during the period that follows the announcement of bad news. Kallunki proposes a very simple and convincing explanation of this drift with regard to Finland. Since short-selling is forbidden in the Finnish stock market, he considers that the lag in stock price reactions in case of bad news is due to the fact that sophisticated traders can immediately take an advantage of good news in their investment decisions, which they cannot do in case of bad news because of the short-selling restrictions. Contrary to Kallunki's findings, Booth *et al.* (1996) report that the post-announcement drift of Finnish companies is higher in case of good news (i.e. positive earnings surprises). More interestingly, after splitting their sampled firms into earnings smoothers and non-smoothers, they show that the larger part of the drift comes from the market reaction to announcements of firms that do not smooth earnings. This suggests that the assimilation of the information conveyed by earnings is complicated when these are not smoothed, which can be a motivation for the income-smoothing practices largely documented in the literature.

The market response to accounting disclosures: synthesis and suggestions

Studies summarized in this section provide several interesting results that shed light on the way investors process accounting information. These results indicate first that annual and interim announcements by European companies cause significant stock price changes and trading volume increases. If European capital markets are efficient in the sense that quoted prices do not significantly deviate from fundamental values, this evidence is consistent with the hypothesis that released accounting figures are useful to market participants. Moreover, the magnitude of stock price reactions is positively related to the level of surprise in the disclosed numbers and negatively related to the market value of firms. If market value is a good proxy for the amount of information available to market participants prior to accounting disclosures, the negative link between firm size and market reaction validates the hypothesis that numerous events related to earnings are publicly observed prior to accounting announcements. Therefore, at least for large firms, a substantial proportion of abnormal stock returns arises prior to the actual release of earnings. Finally, in contradiction with the efficient capital market hypothesis, several studies have shown that in Europe just like in the US, profitable strategies can be designed to benefit from abnormal returns that persist during the period following earnings announcements, particularly for small or medium-sized firms.

European studies reviewed in this section tend to concentrate on mandatory disclosures. However, in addition to mandatory reports, firms release more and more frequently voluntary information. Empirical evidence related to investors' reaction to voluntary disclosures by European firms might help understand the usefulness of such disclosures for anticipating firms' future prospects. Similarly, the Internet gives managers the opportunity to have a direct access to all investors and to disclose frequent updates of important information. Since the use of the Internet by firms and investors is likely to increase, future research aimed at analysing the information content of mandatory accounting disclosures in an environment where alternative continuously updated information is rapidly and easily available is of crucial importance.

Several recent US studies have reported a decline in the value relevance of accounting figures. Lev and Zarowin (1999) put forward the hypothesis that this decline may be due to the inability of financial statements to reflect in a timely manner the phenomenal technological innovations that occurred during the last twenty years. Studies of market reactions to accounting disclosures by firms strongly involved in technological innovations might help support or invalidate this argument. This could be done for instance by comparing security returns of firms that expend huge R&D outlays with those of firms not involved in R&D activities.

The growing literature devoted to earnings management offers another opportunity for future research on the information content of accounting figures. Several researchers such as Healy and Palepu (1993) or Subramanyam (1996) hypothesize that firms choose accounting policies or include discretionary accruals in earnings to reveal management's private information about the firm's future prospects. If discretionary accruals are really informative, then abnormal stock returns around financial statement releases should be related to the sign and the proportion of earnings that result from manipulations. Comprehensive analyses of the link between abnormal returns, earnings surprise and manipulated accruals, as in Wilson's (1986) study, may shed more light on the motivations and stock price impacts of earnings management.

With regard to the post-announcement drift, it might be interesting to investigate the persistence of this anomaly in Europe since the profits resulting from trading strategies based on this anomaly should dissipate once they become apparent to investors. A recent study by Johnson and Schwartz (2000) shows that the post-announcement drift persists in the US among small firms and among firms with little or no analyst coverage. However, profit opportunities do not seem large enough to compensate the substantial costs related to the trading strategies simulated in this study.

3. THE RELATIONSHIP BETWEEN STOCK RETURNS AND ACCOUNTING NUMBERS

Unlike event studies that concentrate on the market reaction to accounting disclosures over a short time interval, association studies analyse the relationship between stock returns and accounting data over a long period. While the former studies examine the role of accounting data in providing incremental information that may affect investors' perception of the firm's future prospects, the latter provide evidence of the role of these data as a summary of the events that have affected the firm during the reporting period. Contrary to market reaction studies, association studies do not infer any causal connection between accounting figures and stock prices. They do not even presume that market participants use accounting data in their valuation process. They only posit that if accounting data are good summary measures of the events incorporated in security prices, they are value-relevant because their use might provide a value of the firm that is close to its market value.

After a description of the theoretical and empirical foundations of association studies, this section summarizes the European evidence on the relationship between earnings and security returns. Research devoted to the value relevance of competing accounting practices, to the value relevance of various GAAP regimes and to the value relevance of accounting numbers other than earnings is successively reviewed. General comments and suggestions conclude the section.

Empirical and theoretical foundations of association studies

Association studies regress accounting figures on market data in order to test for any significant relationship. Ball and Brown (1968) in the US were the first to document an empirical relationship between earnings and stock returns. A study by Martikainen *et al.* (1993) that duplicates the Ball and Brown study, provides a good illustration of such research. The authors analysed the daily abnormal stock returns of thirty firms listed on the Helsinki Stock Exchange, 300 days before and 300 days after their shareholders' annual meeting for the 1977–86 period. Each year, firms were split into two portfolios on the basis of the sign of their unexpected earnings. These were estimated in two different ways. First, assuming that earnings follow a random walk process, unexpected earnings were defined as the difference between two successive earnings. Second, considering that all reported earnings are influenced by the same economic factors, the change in earnings for each firm in the sample was regressed with the change for all other firms. The estimated regression coefficients were used to forecast the change in each firm's earnings. For the ten years under study, abnormal returns were calculated over the year ending with the earnings release. The results indicated that stock prices move in the same direction as the sign of unexpected earnings. At the dates of earnings releases, the positive unexpected earnings portfolio exhibited positive abnormal returns, and conversely. The fact that unexpected earnings, which are supposed to convey new accounting information, are positively related to abnormal returns, suggests that earnings capture a portion of the information used to value stocks. This suggests also that a large part of the information conveyed by earnings is already incorporated in stock prices when these are disclosed, probably because investors have access to various sources of information about firms' future prospects which are likely to be more timely than reported earnings.

Following Ball and Brown, numerous empirical studies have measured the intensity of the relation between earnings changes and security returns to determine how earnings changes summarize the information incorporated in stock prices. Most association studies do not refer explicitly to a valuation model to specify how or which accounting data should be related to security prices. However, Ohlson's (1995) model, which offers a formal linkage between valuation and accounting numbers, is more and more frequently cited as the theoretical foundation of such research. This model extends the residual income model proposed by Preinreich (1938). Defining stock prices as the present value of expected future dividends and assuming the clean surplus relation, the residual income model views the market value of security j at time t, $p_{j,t}$ as the sum of two components: the book value of its equity at time t ($b_{j,t}$) and the present value of its expected future abnormal earnings $[E(x^a_{j,t+\tau})]$:

$$p_{j,t} = b_{j,t} + \sum_{\tau=1}^{\infty}\left[\frac{E(x^a_{j,t+\tau})}{(1+\rho)^{\tau}}\right] \tag{1}$$

where abnormal earnings are defined as the difference between reported earnings $[x_{j,t+\tau}]$ and a capital charge obtained by applying the discount rate $[\rho]$ to the book value of equity:

$$x^a_{j,t+\tau} = x_{j,t+\tau} - \rho b_{j,t+\tau}$$

Ohlson extends the residual income relation by imposing the following autoregressive behaviour on abnormal earnings:

$$x^a_{j,t+1} = \omega_j x^a_{j,t} + v_{j,t} + \varepsilon_{j,t+1} \tag{2}$$

$$v_{j,t+1} = \gamma_j v_{j,t} + \varsigma_{j,t+1} \tag{3}$$

where v denotes information not incorporated in abnormal earnings, ω is the persistence parameter of abnormal earnings, γ is the persistence parameter of the information not yet captured in earnings, and ε_t and ζ_t are error terms. Equation (2) states that abnormal earnings follow a one-period lagged autoregressive process. Equation (3) implies that value-relevant information not incorporated in accounting figures will be gradually integrated into earnings following another one-period lagged autoregressive process. Combining the residual income model given by (1) with the information dynamics given by (2) and (3) yields the following valuation function:

$$p_{j,t} = b_{j,t} + \alpha_{1j} x^a_{j,t} + \alpha_{2j} v_{j,t} \tag{4}$$

where $\alpha_{1j} = \omega_j/(1 + \rho - \omega_j)$ and $\alpha_{2j} = (1 + \rho)/(1 + \rho - \omega_j)(1 + \rho - \gamma_j)$. The empirical form of this model is given by the following relation:

$$p_{j,t} = a_0 + a_1 b_{j,t} + a_2 x_{j,t} + \mu^1_{j,t} \tag{5}$$

where a_1 and a_2 are regression coefficients, a_0 is the intercept and $\mu^1_{j,t}$ is an error term.

Although this relation provides strong motivation for regressing raw accounting data on stock prices, it can be rewritten to provide a theoretical basis for regressions of changes in accounting figures on returns. Replacing $x^a_{j,t}$ with $[x_{j,t} - \rho b_{j,t}]$, invoking the clean surplus relation, taking first differences and dividing both sides of the equation by the beginning-of-period price $p_{j,t-1}$, equation (4) can be restated as

$$\begin{aligned}\frac{p_{j,t} - p_{j,t-1} + d_{j,t}}{p_{j,t-1}} &= (1 - \rho\alpha_1)\frac{x_{j,t}}{p_{j,t-1}} + (1 + \rho)\alpha_1 \frac{x_{j,t} - x_{j,t-1}}{p_{j,t-1}} \\ &\quad + (1 + \rho)\alpha_1 \frac{d_{j,t-1}}{p_{j,t-1}} + \alpha_2 \frac{v_{j,t} - v_{j,t-1}}{p_{j,t-1}}\end{aligned} \tag{6}$$

The empirical form of this relation is given by

$$R_{j,t} = \beta_0 + \beta_1 \frac{x_{j,t}}{p_{j,t-1}} + \beta_2 \frac{\Delta x_{j,t}}{p_{j,t-1}} + \mu^2_{j,t} \tag{7}$$

where $R_{j,t}$ is the rate of return of security j for the period t, $\Delta x_{j,t}$ denotes earnings changes between period t and period $t-1$, β_1 and β_2 are regression coefficients, β_0 is the intercept and $\mu_{j,t}^2$ is an error term.

Equations (5) and (7) suggest regressions of accounting figures on market data. The strength of the association, as given by the regression R-squares, is often taken as a measure of the value relevance of the accounting numbers under study. A low association (R-square ≈ 0) suggests that these are useless to estimate prices or returns. Conversely, a strong association (R-square ≈ 1) means that any investor who would have to value a company from its accounting figures only, would obtain a price close to the market value. While equation (5) suggests regressions of the levels of book value and earnings per share on stock prices (price regressions), equation (7) leads to regress earnings and changes in earnings deflated by beginning-of-period stock prices on returns (return regressions). As a matter of fact, price regressions and return regressions are both commonly used to analyse the relation between market and accounting data. However, as shown by Brown *et al.* (1999), statistical associations inferred from price regressions suffer from a spurious effect of scale because large security prices tend to be mechanically related to large book value and large earnings per share, and conversely. Consequently, the value relevance measured by R-squares of price regressions are unwisely overstated, and comparisons of R-squares to infer changes or differences in value relevance are invalid if there is no explicit control for this scale effect. In contrast, return regressions are not affected by potentially serious scale problems because stock data and accounting figures per share are all scaled by beginning-of-period stock prices. Therefore, empirical studies should preferably rely on returns specifications. This is why the following review of European association studies concentrates mainly on results inferred from return regressions.

The association between earnings and security returns: the accumulated evidence

The relation between earnings and contemporaneous security returns has been analysed with data from most European stock exchanges. Results show that, in Europe like in the US,[1] this relation is weak, suggesting that reported earnings do not provide good summary measures of the value-relevant events that have been incorporated in stock prices during the reporting period. Even if coefficients obtained by regressing earnings and earnings changes scaled by beginning-of-period stock prices on stock returns are generally statistically significant, R-squares are relatively low. In the UK, Strong (1993) found an average R-square of about 10%, suggesting that only 10% of the cross-sectional variance of returns is explained by the cross-sectional variance of earnings. With regard to Germany, Harris *et al.* (1994) obtained R-squares that range from 7% to 17%. In Denmark, Plenborg (1998) reported yearly R-squares varying from 1% to 29% between 1985 and 1991. From a sample of French firms over the 1981–90 period, Dumontier and Labelle (1998) obtained *R*-squares ranging from 1% to 49% depending on the year under consideration. Vafeas *et al.* (1998) obtained similar results on a sample of firms listed on the Cyprus Stock Exchange.

The relatively low association observed between earnings and stock returns suggests that earnings capture only a weak proportion of the information incorporated in security prices. It is often argued that information included in stock prices is richer than the one reflected by earnings because investors focus on all events that affect expected future cash flows, while earnings incorporate only those that have met the conditions for accounting recognition. Since relevant events that are not captured in contemporaneous earnings should normally be captured in subsequent periods, there should be a lag in the inclusion of new information into earnings, and stock prices should be more prompt than earnings in reflecting new information. This recognition lag causes both an errors-in-variable problem and an omitted variable problem because earnings do not reflect some information captured in current returns, whereas they reflect some information that was captured in prior returns. Since this lag is potentially negatively correlated with earnings, *R*-squares of regressions of current returns with contemporaneous earnings are biased toward zero.

To correct for this lag effect, Dumontier and Labelle (1998), following Easton *et al.* (1992) in the US, have expanded both the returns and earnings windows by regressing multiple-year returns on multiple-year earnings. They showed that the correlation between earnings and returns improves with increases in the time interval under consideration. They obtained average *R*-squares ranging from 15% for a one-year interval to 28% for a two-year interval and to 39% for a five-year interval. In the same vein, Cormier *et al.* (2000) regressed the market returns of a sample of Swiss firms not only on contemporaneous earnings, but also on the previous and following year earnings. Their results indicate that lead, lag and contemporaneous earnings are all significantly related to returns. Moreover, when lead and lag earnings are added to contemporaneous earnings as explanatory variables for returns, *R*-squares strongly increase from 37% to 52%. This procedure is, however, not free of bias because of the well-documented positive serial correlation in earnings. Instead of using previous and subsequent earnings as additional explanatory variables for returns, Beaver *et al.* (1980) suggest to regress earnings on both current and past returns. Such 'reverse regressions' are less likely to suffer from multicollinearity since stock returns are supposed to be uncorrelated through time if capital markets are efficient.

Pope and Walker (1999) investigated extensively the magnitude of the recognition lag by analysing the effect of conservatism in accounting on the timeliness of earnings. They proposed a formal analysis of the different speeds of recognition of good and bad news in order to capture two distinct consequences of conservative accounting: delay in reporting good news and early recognition of bad news. Following Basu (1997), they took security returns as an indicator of the bad or good news that have affected the firm during the reporting period. Because stock prices are not likely to anticipate events incorporated in future earnings more than three years ahead, they used the following reverse regression to determine how quickly accounting data reflect information incorporated in stock prices:

$$\frac{x_t}{p_{t-4}} = \gamma_0 + \gamma_1 D_t + \sum_{t=0}^{3} \lambda_t R_{t-\tau} + \sum_{t=0}^{3} \theta_\tau R_{t-\tau} D_{t-\tau} + \mu_t$$

where x_t and p_t denote respectively reported earnings of period t and security price at the end of period t; $R_{t-\tau}$ is equal to $(p_{t-\tau} - p_{t-(\tau-1)})/p_{t-4}$; $D_{t-\tau}$ is a dummy variable for year $t - \tau$ which takes the value one in case of bad news (i.e. if $R_{t-\tau}$ is less than zero) and zero otherwise; γ_0, γ_1, λ_τ and θ_τ are regression coefficients. The λ_τ and θ_τ coefficients are associated respectively to good and bad news, μ_t is an error term.

Developing a formal analysis, Pope and Walker demonstrated that λ_τ coefficients should increase and θ_τ should decrease as the lag increases. Based on a sample of UK and US listed firms over the period 1976–96, their results showed that λ_τ coefficients are statistically significant and increase from lag zero to lag one, suggesting that most good news is delayed in earnings with a lag of one year. With regard to θ_τ coefficients, they are significant and they decrease until lag two, suggesting that bad news is anticipated in earnings by up to two years.

Lubberink and Huijgen (2002) hypothesized that earnings conservatism reflects not only financial reporting standards, but also managers' preferences. They stated that risk-averse managers, who are more concerned about their reputation among outside parties, report earnings more conservative than less risk-averse managers in order to lower the likelihood of conflict about the distribution of the firms' cash flows. To assess whether earnings reported by risk-averse managers are more conservative than those reported by non-risk-averse ones, Lubberink and Huijgen used a regression model similar to the one developed by Pope and Walker. Assuming that the coefficient of a regression of time-series levels of compensation on time-series variance of compensations provides a good proxy for managers' risk aversion, they partitioned their data into two distinct groups. In accordance with their intuition, their results obtained on a sample of listed Dutch companies, show that firms employing the most risk-averse managers report earnings significantly more conservative than firms with the less risk-averse managers. More precisely, differences in earnings conservatism between the two groups are mainly related to the fact that more risk-averse managers tend to anticipate the recognition of bad news: whereas the good news coefficients are significant for the two groups, the bad news ones are significant for the risk-averse group only.

Another explanation for the low association between earnings and returns is that negative earnings are not value-relevant because losses are not expected to perpetuate indefinitely. Consequently, sampled firms that report losses tend to weaken the strength of the association between earnings and returns. To validate this assumption already tested by Hayn (1995) in the US, Martikainen *et al.* (1997) split a sample of 498 earnings reported by Finnish companies into a sub-sample of positive earnings and a sub-sample of losses. While positive earnings were positively related to returns, losses were statistically insignificant in explaining returns. Consequently, the exclusion of loss observations strengthens the estimated relation between earnings and returns, probably because losses do not provide information about the firm's ability to generate future cash flows.

The value relevance of competing accounting practices

As explained above, the strength of the association between earnings and returns (i.e. *R*-squares obtained in regressing returns with earnings) can be taken as a measure of the value relevance of accounting data. Postulating that the higher the value relevance, the better the accounting numbers, several empirical studies used this simple criterion to determine the 'best' accounting practice among several competing alternatives.

Since German companies financing is based primarily on self-financing and private borrowings rather than on equity issues or public debts, German GAAP tend to focus more on the protection of lenders than on the information needs of investors. To remedy this situation, the German Financial Analysts' Association (*DVFA – Deutscher Vereinigung für Finanzanalyse und Anlageberatung*) developed an earnings metric aimed at reflecting the profitability of companies' ongoing operations without being contaminated by non-recurring events or by the exercise of accounting options related to tax purposes. Using the association methodology, Harris *et al.* (1994) and Booth *et al.* (1997) examined whether DVFA earnings provide information in addition to that included in earnings reported under German GAAP. Since regressions of returns on DVFA earnings exhibit the highest *R*-squares, both studies conclude that DVFA earnings are more value-relevant than German GAAP profits. In the same vein, Martikainen *et al.* (1997) tested the value relevance of earnings adjusted on the basis of the Finnish Committee for Corporate Analysis Recommendations. These statements stipulate to remove certain items from reported earnings in order to increase their relevance. Contrary to the German evidence, the results of this study indicate that adjusted earnings do not contain incremental information with respect to all-inclusive earnings.

In an attempt to test the usefulness of IAS, Niskanen *et al.* (1994) estimated IAS-based earnings of a sample of Finnish firms by adjusting reported earnings for six important differences between IAS and Finnish GAAP. Both reported and adjusted earnings were then entered in a regression with stock returns. Results indicated that adjusted earnings exhibit statistically significant coefficients, which gives support to the hypothesis that IAS-based earnings convey incremental information over those based on Finnish GAAP. IAS (or US GAAP) disclosure requirements exceed those of most European countries. The adoption of these standards may thus contribute to reduce information asymmetry, especially for firms from low-regulated countries. This hypothesis is validated by Leuz and Verrecchia (2000) who, after controlling for various firm characteristics, found that German companies which switched to IAS or US GAAP exhibit lower bid-ask spreads and higher share turnover than firms using German GAAP only.

Nevertheless, the assumption can be made that IAS-based earnings are more useful to foreign than to local investors. A characteristic of the Finnish market gave Kinnunen *et al.* (2000) the opportunity to test this hypothesis. From 1984 to 1992, the Finnish stock market was segmented into two categories of shares: one restricted to domestic investors, the other available to anybody, irrespective of its nationality. In order to isolate the respective information content of IAS and local earnings for each category of investors, Kinnunen *et al.* conducted separate regressions with returns of restricted and unrestricted shares. Their results showed that both IAS-based and local earnings are informative to foreign investors but that Finnish investors find information content in local earnings only. This led the authors to the conclusion that restating local GAAP earnings to conform to the IAS helps to meet foreign investors' information needs, but is of limited use to domestic investors.

Most European corporate annual reports include consolidated statements and parent company statements. Both consolidated and parent company earnings are potentially informative since parent earnings provide information about the ability of the company to pay dividends while consolidated earnings reflect the performance of the entire economic entity. This raises the question of whether consolidated earnings provide additional value-relevant information with regard to parent company earnings. Harris *et al.* (1994) hypothesized that the strength of the association between earnings and returns is positively related to the degree of consolidation. Apportioning their sample of German firms among parent-only, domestic-only and full consolidation, they showed that the explanatory power of earnings for returns increases with the level of consolidation. Using a sample of Finnish companies, Niskanen *et al.* (1998) found evidence that consolidated earnings have an incremental information content beyond that of parent companies, but the reverse was not true. These findings indicate that consolidation improves the value relevance of earnings. They suggest that parent earnings have no interest in terms of value relevance when consolidated earnings are disclosed. In Spain, as in most European countries, consolidated financial statements must report separately the minority interest component of earnings and equity. Using a sample of Spanish companies listed in the Madrid Stock Exchange between 1991 and 1997, Abad *et al.* (2000) investigated the value relevance of these requirements. Their results support those obtained in Finland and in Germany since they show that consolidated earnings are more strongly associated with security data than parent company earnings. However, they found no support for the value relevance of the minority interest portion of earnings and equity. This leads them to question the usefulness of requirements related to minority interest reporting.

The value relevance of different GAAP regimes

Several studies have focused on international differences in the propensity of earnings to reflect value-relevant information. Using a sample of seventeen countries to obtain evidence from a variety of accounting standards and information environments, Alford *et al.* (1993) provided a country-by-country comparison of the value relevance of earnings between US and non-US firms. They observed considerable variation in the explanatory power of earnings for contemporaneous returns across the countries under study. Regarding Europe, by comparing the *R*-squares of country regressions, they observed that earnings from France, the Netherlands and the United Kingdom were more value-relevant and more timely than US earnings. In contrast, those from Denmark, Germany, Italy and Sweden were less timely and reflected less value-relevant information than US earnings. Results from Belgium, Ireland, Norway and Switzerland were inconclusive.

Focusing on accounting practices in France, Germany and the United Kingdom, Joos and Lang (1994) found evidence of significant differences in the stock market valuation of accounting data. These three countries were selected to permit a comparison of the effects of two extreme and one intermediate example of alternative approaches to earnings measurement. While the UK accounting model traditionally focuses on equity holders, allows discretion in the preparation of financial statements and dissociates tax and financial reporting, the German model concentrates on debt holders, codifies reporting requirements and imposes a strong link between financial and tax reporting. Although the French model is basically close to the German one, it tends to draw near to the UK model in a number of respects. However, in so far as the Fourth and the Seventh Directives of the European Union have, to some extent, harmonized accounting practices throughout Europe, differences in the degree of association between stock returns and earnings were expected to be lower after these directives have been implemented. Surprisingly, while UK accounting practices are significantly more investor-oriented than French or German ones, *R*-squares for the pre-directives period were higher in France and Germany than in the UK, which invalidates the assumption that earnings reported in the UK were more value-relevant than those of French and German companies. Moreover, results for the post-directives period do not show that these differences have been reduced following the implementation of the directives. Regarding Germany, Harris *et al.* (1994) confirmed these results. They did not report a significant change in the explanatory power of earnings after the adoption of the new Accounting Law that changed the German reporting system by incorporating the Fourth and Seventh European Directives.

Using data from sixteen countries, Ali and Hwang (2000) regressed market returns with scaled earnings to explore the impact of several country-specific factors on the value-relevance of accounting data. Their results show that the degree of association between security returns and earnings is lower in countries with bank-oriented (as opposed to market-oriented) financial systems, in countries where private-sector bodies are not involved in the standard-setting process and, more generally in countries which belong to the continental model, as defined by Mueller *et al.* (1994). More precisely, earnings in bank-oriented countries seem more conservative and consequently less timely than those in market-oriented ones.

Focusing on differences between US and UK GAAP, Pope and Walker (1999) provided evidence that apparent differences in conservatism between these two regimes are sensitive to the inclusion or exclusion of extraordinary items. They showed that US earnings measured before and after extraordinary items have similar timeliness properties. In contrast, UK earnings are significantly less timely when measured before extraordinary items. Consequently, US earnings before extraordinary items are more timely than UK ones. However, UK earnings after extraordinary items are more timely than US ones, especially with respect to bad news. These results suggest that inferences regarding the relative timeliness of earnings under different regimes are highly sensitive to the earnings measure analysed. Therefore, the conclusions of international studies reported above should be regarded cautiously.

The value relevance of non-earnings data

Several studies have investigated the information provided by non-earnings data. A first set of these studies focused on the components of earnings commonly reported by firms in order to determine whether the decomposition of earnings provides incremental value-relevant information beyond the bottom-line earnings. With regard to Europe, the evidence is somewhat conflicting. On the one hand, Strong and Walker (1993) support the view that the decomposition of earnings is useful in the UK since earnings components tend to be significantly related to security returns. Their results show that partitioning earnings into pre-exceptional, exceptional and extraordinary components improves the association between earnings and stock returns. On the other hand, Giner and Reverte (1999) provide evidence that corporate taxes are the only earnings component that is related to security prices in Spain. They find that extraordinary items do not exhibit real information content. However, a contextual analysis of their results suggests that the decomposition of earnings may be particularly useful for small and for risky companies.

One specific feature of financial accounting is accrual adjustments that are added to or subtracted from cash flows from operations to obtain earnings. In order to determine the respective value relevance of cash flows and earnings, several researchers have studied which of the former or of the latter is the most highly correlated with stock prices. In the UK, Board and Day (1989) and Ali and Pope (1995) have provided evidence that earnings dominate cash flows in the sense that cash flows do not have incremental information content beyond earnings. Using a sample of UK companies, Clubb (1995) showed that cash flows from operations, accruals and accounting earnings are all positively related to stock returns, but accrual adjustments appear to possess information content beyond that reflected by cash flows and earnings. Following Dechow (1994), Charitou (1997) hypothesizes that the value-relevance of cash flows with respect to that of earnings depends on (a) the magnitude of accrual adjustments, since timing and matching problems in cash flows are minimized when accrual adjustments are small; (b) the length of the firm's operating cycle, since the shorter the operating cycle, the smaller the working capital requirements and consequently the smaller the volatility of accruals; and (c) the measurement interval under consideration, since the longer the measurement interval, the smaller the timing and matching problems in cash flows. Charitou's results are in conformity with these hypotheses. Using a sample of listed UK companies, he observed that earnings are more highly correlated with stock returns than cash flows for short measurement intervals, but earnings and cash flows tend to exhibit the same level of correlation with returns when measurement intervals increase, when accruals are relatively small or when firms have short operating cycles. In the same vein, Green (1999) showed that the value-relevance of UK cash flows was unsurprisingly related to the correlation between accounting earnings and cash flows from operations.

Considering that accruals may be affected by arbitrary estimations due to management's discretion over their recognition, a new stream of research uses association studies to determine whether discretionary accruals are aimed at manipulating earnings opportunistically or whether these accruals convey managers' private information about the firm's prospects. If earnings are manipulated through the use of discretionary accruals, they should not reflect accurately the firm's ability to generate future cash flows and their correlation with returns should be low. Conversely, if accruals are manipulated in order to report more value-relevant earnings, then discretionary component should be positively related to stock returns. With regard to Switzerland, results reported by Cormier *et al.* (2000) suggest that discretionary accruals are informative, not opportunistic. By splitting earnings into cash flow from operations, non-discretionary and discretionary accruals, the authors showed that these three components of earnings are all significantly related to stock returns. The statistically positive relationship between returns and discretionary accruals confirms the value relevance and the information content of the discretionary component of accruals.

Earnings obviously are not the only potential relevant accounting data. Other accounting variables are likely to reflect events that have affected the firm value during the reporting period. Using a sample of twenty-eight Finnish companies over the period 1975–86, Martikainen (1993) investigated the relationship between stock returns and various accounting data that served as proxies for four characteristics that determine the conditions under which firms generate future cash flows. These characteristics are profitability, financial leverage, operating leverage and growth. They resulted from a principal component analysis aimed at reducing original data into a smaller set of common factors. Results based on purely industrial firms indicate that profitability and financial leverage are the two characteristics the most strongly related to returns. Other characteristics do not affect returns. This led Martikainen to conclude that the calculation of a large number of accounting raw data or ratios is of little interest and that analysts should concentrate on a relatively low number of key data.

Using a sample of UK industrial companies that did not change their financial year-end between 1983 and 1992, Al-Debie and Walker (1999) examined the incremental value relevance of various fundamentals beyond that of accounting earnings. Following Lev and Thiagarajan (1993), they selected seven non-earnings data which signal abnormal changes in stocks of finished goods, debtors, capital expenditures, research and development expenses, gross margin, distribution and administration expenses or labour force. Moreover, since the value of these data depends both on the firm's industry and the state of the economy, Al-Debie and Walker adopted a conditional approach by using regression techniques that allow regression parameters to vary with each firm's industry and with the state of the economy. They considered fifteen industries and three states of the UK economy defined on the basis of the inflation rate, the real GNP growth and the unemployment rate. While their basic model with a constant intercept and a constant earnings variable provided an R-square of only 15%, they obtained R-squares of 36%, 40% and 43% when they allowed regression parameters to vary with the state of the economy, the industry, or with both variables. These results show that the inclusion of non-earnings variables increases strongly the correlation between returns and accounting data. They also indicate that allowing the regression parameters associated with accounting data to vary with various firms' characteristics improves significantly the performance of regression models. This confirms the need to adopt a conditional approach in association studies.

Association studies: synthesis and suggestions

Studies described in this section have investigated the ability of accounting data to summarize the relevant events that have affected the firm during the reporting period. They provide at least four interesting results. First, they show that the relation between security returns and contemporaneous earnings is low. Second, they validate the relevance of accrual accounting. Third, they find that consolidated accounting data are more value-relevant than non-consolidated ones. Fourth, they suggest that non-earnings data reported in financial statements help better perceive the events incorporated in security prices.

The most important result of association studies is certainly the low level of association between security returns and contemporaneous earnings. The lack of timeliness of earnings due to financial reporting conservatism is likely to explain a large part of this weak value relevance. If the conclusions of international studies are not significantly biased by differences in earnings measurement, it is clear that reported earnings in Anglo-Saxon countries exhibit greater timeliness than reported earnings in countries which belong to the continental accounting model. Moreover, in spite of the low association between earnings and returns, European association studies provide evidence on the usefulness of accrual adjustments. All studies devoted to the relative usefulness of cash flows and earnings show that earnings dominate cash flows in the sense that earnings and accrual adjustments possess information beyond that reflected in cash flows. In the same way, it is clear that consolidated accounting data have more value relevance than parent-company ones. Lastly, even if a large majority of association studies have focused on the bottom-line earnings only, studies that take various non-earnings accounting numbers into consideration show that these are incrementally associated with contemporaneous security returns.

The foundations of association studies, and consequently inferences drawn from their results, are however subject to several limitations. The most obvious is the validity of the efficient capital market hypothesis and consequently the validity of stock data as a proxy for value-relevant events that affect firms. If stock prices are assumed to represent fundamental values, then there is no doubt that a low relation between accounting figures and market data is a proof of the weak value relevance of accounting data. However, several recent studies, especially in the emerging field of behavioural finance, suggest that stock prices reflect mostly investors' myopic behaviour, so that stock prices might not be a reliable benchmark to analyse the value relevance of accounting data. Future research should address this limitation and investigate the value relevance of accounting figures with other benchmarks than market data.

Another limitation of association studies is that they concentrate mainly on bottom-line earnings without analysing the value relevance of other accounting data. Yet, several accounting numbers other than earnings can help investors perceive the value-relevant events that have affected the firm. Those numbers should be more extensively explored. Since their value relevance is likely to be related to the firm environment, future research should concentrate on the value relevance of specific accounting data under various contexts that characterize firms.

4. THE USE OF ACCOUNTING DATA BY INVESTORS AND THE INFLUENCE OF CAPITAL MARKETS ON ACCOUNTING DECISIONS

Studies described above provide indirect tests of the usefulness of accounting information for valuation purposes in so far as they do not analyse directly how investors process accounting data. They only focus on stock price reactions induced by accounting disclosures and on the association between accounting and market data. However, the usefulness of accounting numbers for market participants can also be assessed directly by questioning investors themselves. Several

European studies have adopted this latter approach. These are reviewed in the first part of this section. Moreover, even if market-based accounting research concentrates mainly on the usefulness of accounting data for firm valuation, a few studies have examined whether capital markets exercise pressures on accounting decisions of listed companies. Their main findings are explored in the last part of this section.

Direct tests of the usefulness of accounting information

Studies devoted to the use of accounting data by market participants have three main purposes. First, they analyse the importance of accounting figures with respect to other sources of information. Second, they examine the valuation techniques effectively used by investment professionals in order to assess whether they are based on accounting numbers or not. And last, they try to determine whether firms favour decisions which maximize accounting measures of profit rather than cash flows, because of the importance of earnings for market participants.

Day (1986) reports a laboratory experiment on the use of financial statements by UK investment analysts. Two sets of accounts were submitted to fifteen professionals who had to perform their initial review as if they were studying them for the first time. The participants were asked to think aloud so that a tape-recording could be made. The results tend to confirm that financial statements are seen by investment analysts as only one source of information, which does not generally contain price-sensitive information but which is nevertheless useful as a reference document. Barker (1998) expanded this analysis to finance directors and fund managers. On the basis of questionnaires and semi-structured interviews, he obtained evidence on how investment professionals perceive the role of accounting information. Annual reports and financial statements appear to be only a secondary source of information for market participants, after direct contacts or meetings with senior company management. This observation contrasts with a previous study by Arnold and Moizer (1984) which concluded that financial statements are the primary source of information for analysts. It is also in contradiction with a questionnaire study by Vergoossen (1993) which showed that accounting data are considered as the most important source of information by Dutch investment analysts.

As pointed out by Breton and Taffler (2001: 92), 'asking analysts or investors directly about the relative importance of different types of information may provide little real insight into what they use in practice'. Rather than considering financial statements globally, it may thus be more judicious to focus on data that are supposed to be the most relevant for security valuation. This was done by Barker (2000) who interviewed thirty-two British analysts on their use of reported earnings. He observed that analysts attach great importance to earnings announcements and particularly to deviations with forecasts, but their use and interpretation of accounting information is rather superficial. In particular, analysts seem to have a limited understanding of underlying issues of recognition and measurement, and more curiously of the interactions between earnings and the balance sheet items. This observation suggests that analysts, and more generally most market participants, may be fixated on accounting earnings and unable to detect earnings management. This issue was addressed by Vergoossen (1997) who examined the reports written by Dutch investment analysts about companies that made changes in their accounting policies. Two levels of fixation were defined: fixation at a strong level when analysts did not mention accounting changes in their reports, and fixation at a weak level when they noted these changes but did not discuss their quantitative effects on accounting figures. A fixation index was computed for each accounting change, ranging from 0 (no analyst was fixated) to 1 (all analysts were fixated at the strong level). The results showed an extreme diversity of fixation, values of the index varying from 0 to 0.867. These studies suggest that although annual reports are seen as a primary source of information by investors, numerous market participants are likely not able to correctly analyse the accounting information. This could incite some firms to manipulate accounting figures opportunistically.

Indications on the usefulness of accounting data may also be drawn from the examination of valuation techniques used by investment professionals. If analysts base their recommendations primarily on methods involving accounting data; i.e. fundamental analysis, accounting information can be considered as useful to the market participants. Adversely, if they use mainly non-accounting methods, as for example technical analysis or beta analysis, this will be an indication that accounting data are not particularly useful to investors. A questionnaire study by Arnold and Moizer (1984) clearly shows that fundamental analysis is the technique most frequently used by UK investment analysts. The study reports that 90% of respondents view fundamental analysis as 'extremely useful' or 'very useful', while the corresponding percentages are 16% for technical analysis and 5% for beta analysis. Moreover, the results also show that analysts base their recommendations essentially on price–earnings (PE) ratios, which emphasizes the role of earnings in stock valuation. This latter observation is consistent with a more recent study by Barker (1998) which reveals that British analysts and fund managers view the PE ratio and the dividend yield as the most important valuation methods. Olbert (1994) repeated Arnold and Moizer's analysis in Sweden. He also found that fundamental analysis was the most frequently used technique in stock valuation and noted an extensive use of PE ratios. A similar study conducted by Pike *et al.* (1993) in the UK and Germany confirms these findings: although German analysts place significantly more emphasis on technical analysis, fundamental analysis using PE ratios remains the dominant method in both countries. This result is consistent with Vergoossen's study (1993) that emphasizes the importance of fundamental analysis in The Netherlands. All these studies confirm the major role played by accounting data, and particularly earnings, in the way analysts appraise investments. They also clearly show that approaches recommended in the academic literature, such as discounted future cash flows, are still largely less popular than traditional techniques, even among investment professionals.

The importance of earnings for market participants may incite companies to favour decisions that maximize accounting measures of profit rather than cash flows. Although there is limited evidence on this matter, several European studies give some support to this conjecture. Using data from forty UK companies which made recent debt or equity issues, Davidson and Mallin (1998) compared the actual earnings-per-share (EPS) to the corresponding amount which would have been obtained if the company had chosen the other type of financing. As expected, results show that the type of the selected capital issue was that which gave the highest EPS, after controlling for other factors such as leverage and industry classification. The authors interpret this as an evidence of functional fixation on EPS. Collison *et al.* (1996) adopted a quite different methodology to assess how managers' decisions may be affected by their perceptions of investors' reasoning. They sent finance directors of the largest UK companies a questionnaire with several statements such as 'Top management will not accept proposals for increasing expenditure in the following separate categories if it results in a significant fall in profits from the previous year: (a) Research and development, (b) Advertising, (c) Training'. Respondents were asked to mention their relative agreement with each statement on a Likert scale. An analysis of the responses led the authors to conclude that managers consider that investors place heavy emphasis on earnings, which could lead them to favour the short-run, to the detriment of longer-term progress of their business. This corroborates the assumption of short-termism frequently expressed against market participants. In an attempt to test the validity of this assumption, Goodacre and McGrath (1997) conducted an experimental study in which a sample of UK investment analysts were asked to forecast earnings and market values of two companies, based on simulated financial statements. These firms were identical in all respects except for the method used to account for R&D expenditures. The mean market value estimates for the companies were almost identical, a result which is inconsistent with the hypothesis of functional fixation. In another experiment, the only difference between the two companies was that one invested in tangible fixed assets rather than in R&D. In that case, analysts attributed a higher value to the R&D spender, which is inconsistent with the short-termism hypothesis. The authors conclude that the managers' preoccupation with short-run earnings is not as obvious as is often ascertained.

Research on the influence of accounting considerations on managerial decisions is scarce, probably because decisions that would have resulted from other accounting treatments are not observable. This problem could be circumvented with the use of other methodological approaches, in particular interviews with managers. Such research should be encouraged because of its high value for standard setters who, before adopting a new accounting regulation, must anticipate its potential effects on firms' decisions.

The influence of market pressure on accounting decisions

Several empirical studies have examined the influence of market pressures on accounting choices and the disclosure policy of firms. These pressures come from investors as well as market authorities. On the one hand, listed companies must meet the information needs of market participants, and thus disclose more information than non-listed ones. For example, it is generally assumed that an extensive disclosure policy may contribute to lower the company's cost of capital. On the other hand, listed firms must adapt their disclosure policy to comply with the requirements of market authorities. The pressure for larger and specific disclosures is even stronger for firms that are listed on several markets since these firms have to comply with different market regulations and meet the needs of a larger set of investors.

Although accounting decisions may be influenced by many variables such as ownership diffusion or analyst following, listing status is probably the best proxy for market pressures since it is the only variable that captures both the influence of investors and market authorities. Empirically, its relationship with voluntary disclosure is clearly established. Firth (1979) in the UK, Cooke (1989) in Sweden, Wallace *et al.* (1994) in Spain, Patton and Zelenka (1997) in the Czech Republic, all found that the extent of disclosure of listed firms does exceed that of unlisted companies. With regard to international listing, Meek *et al.* (1995) studied voluntary annual report disclosures by a sample of multinational companies from the US, the UK and continental Europe. They also found evidence of larger disclosure by firms listed on several markets. Herrmann and Thomas (1996) for their part, focused on segment reporting. Their study based on annual reports of 223 companies from ten EU countries shows that the quality of segment reporting (as measured by the number of items disclosed per geographical segment) is better for firms listed on multiple stock exchanges than for those listed on their domestic market only. Moreover, Dumontier and Raffournier (1998) and Murphy (1999) have demonstrated that Swiss firms listed on foreign markets are more likely to voluntarily adopt IAS than those listed in Switzerland only. To the extent that IASB disclosure requirements exceed largely those of the Swiss Stock Exchange, this result can be considered as an evidence of the influence of market pressure on voluntary disclosures.

For a few years, there has been a growing interest for studying whether the disclosure requirements of stock exchange authorities affect the management decisions of companies. Muller (1999) provides a good example of such research in the accounting field. UK firms are used to write-off goodwill to equity in the year of acquisition rather than capitalize it on the balance sheet. The problem is that the London Stock Exchange (LSE) uses financial ratios with reported net assets as the denominator to determine whether acquisitions and disposals require shareholder approval. Firms with active merger or disposal plans should thus be reluctant to write-off goodwill against reserves, unless they can limit the impact of this treatment on equity. A solution was to separate the value of brand names from goodwill and capitalize this amount. Muller formulated thus the hypothesis that the recognition of brand names was positively correlated with the number of future transactions that could avoid LSE-mandated shareholder approval through brand name recognition. The empirical findings support this hypothesis, suggesting that capital markets may have a significant impact on the accounting choices made by listed firms.

5. CONCLUDING REMARKS

This short survey highlights the variety of issues addressed by European studies devoted to the relationship between financial accounting and capital markets. Like in the US, the empirical evidence relates mainly on the informational perspective of accounting figures that holds that accounting data are relevant for valuation purposes if they reflect information that influences stock prices or if they provide incremental information that affects investors' perception of the firm. Overall, this type of research is aimed at explaining how accounting numbers and stock returns are related. As suggested by Healy and Palepu (1993), however, these studies provide little evidence useful to standard-setting bodies for the assessment of accounting standards or to managers in forming disclosure strategies to communicate effectively with investors. Future research should address this limitation and respond to questions such as: What types of disclosures should firms provide? Which are useful and credible, which are not? Moreover, instead of focusing on large samples of heterogeneous firms without taking specific contexts into consideration such as the industry, the economic environment or the life-cycle stage of firms, future empirical studies should concentrate on contextual research. Such analyses, based on a judicious partitioning of firms, should improve our understanding of the value relevance of individual financial statement items under specific circumstances. In the same way, market-based research generally focuses on accounting data even though investors also use non-accounting information for valuing companies. The relation between non-accounting data and stock prices represents thus a potentially fruitful area for future research that deserves a more extensive exploration.

Although European capital markets have theoretically been unified, important differences remain across countries. This provides numerous research opportunities. A low association between market returns and accounting numbers is generally considered as an evidence that accounting information is not relevant for security pricing, but it may also be possible that prices do not reflect the true value of firms because stock markets are not as efficient as generally assumed. Comparative studies involving several markets would thus be useful inasmuch as they would make it possible to measure the influence of different levels of market efficiency on the value relevance of accounting information. It would also be interesting to more deeply explore the consequences of various financing traditions within Europe, opposing countries where capital is provided mainly by the banking sector (Germany and France) to others which make a larger use of stock markets (UK). Mixing country-specific factors with individual characteristics of firms would also permit to determine the influence of each type of variables on the attitude of companies with regard to capital markets.

Inasmuch as most European studies are based on British data, this survey confirms the dominance of UK over European accounting research. Our choice to restrict the review to studies published in English may partially explain this observation already suggested by Carmona *et al.* (1999). This language effect should not, however, be overestimated. There are, for example, only a few studies in the French accounting literature that could have been included in this survey. As far as it is possible to generalize from the French example, the inclusion of research published in other languages would probably not have substantially altered the UK dominance. More fundamentally, the preponderance of British studies may be a consequence of the Anglo-Saxon approach of accounting, which views investors as the primary users of financial statements. In continental Europe, the pre-eminence of investors over all users of accounting information is not as widely accepted as in the UK. This may explain that research on the relationship between accounting and financial markets is less developed in these countries. The overrepresentation of UK studies may also reflect differences in the way accounting research is viewed. While the positivist methodology is largely dominant in the Anglo-Saxon world, it is still contested in many countries of continental Europe where the normative or constructivist traditions are more popular.

A general limitation of European studies is that most of them have replicated research already conducted in the US, without questioning the applicability and relevance of the methodology and hypotheses in a different context. Accounting systems and financial markets are nevertheless the result of history and cultural traditions. Gray (1988) proposed several hypotheses relating the characteristics of accounting systems to cultural variables of countries but his work remained largely short-lived. A notable exception is Taylor Zarzeski (1996) who studied the influence of both cultural and market forces on the disclosure policy of companies from seven countries. Her results show that firms domiciled in cultures possessing more individualism, more masculinity and less uncertainty avoidance are more likely to disclose higher levels of information. Such research that takes into account the cultural dimensions of accounting and financial systems is highly desirable, especially when countries recently converted to a market economy are considered.

Generally speaking, Europe provides a unique and exciting field of investigation for accounting research, because of its economic, cultural and legal diversity. Significant contributions to the accounting literature could be made by multinational research teams that would systematically explore these differences.

ACKNOWLEDGEMENTS

We gratefully acknowledge Begoña Giner and Christian Leuz for their helpful comments on the first drafts of this paper. We would also like to thank the editors, Anne Loft and Kari Lukka, who gave us the opportunity to review an exciting field of research, as well as Barbara Pettit for her editing assistance.

NOTE

Abstract

The debate on the determinants of firm value is ongoing; and the increasing gap in the book-to-market ratio (Lev & Sougiannis 1999) has yet to be explained in the financial literature. This article contributes to the debate by examining whether intellectual capital measured using the value added intellectual coefficient (VAIC™) (Pulic 1998) contributes to the explanation of the book-to-market ratio. This study used Ohlson's 1995 valuation model and JSE Securities Exchange (SA) (JSE) data in an attempt to identify whether the book value of assets, accounting (accrual) earnings and VAIC™ explain the behaviour of South African share prices. The panel data least squares model results indicate a significant relationship between share prices three months after year end, and abnormal earnings, abnormal cash dividends, book value of assets, the capital employed coefficient, and the human capital coefficient.

1 Introduction

The increasing gap in the book-to-market ratio creates a problem which confronts businesses, users of accounting information, standard setters and regulators: it has highlighted the insufficiency of financial statement information to explain the market value of a firm (Lev & Sougiannis 1999). Furthermore, the efficient market hypothesis has discredited many of the objectives that were ascribed to financial statements. This study aims to explore whether intellectual capital, together with information from the financial statements, can explain a firm's market value.

Barth, Beaver and Landsman (2001) have identified three main arguments used to explain the widening book-to-market ratio. First, Fama and French (1993, 1995) suggest that higher returns are demanded to hedge against the possibility of financial distress than in the past. Second, Lakonishok, Schleifer and Vishny (1994) associate the gap with a mispricing of 'glamour companies'. Finally, Frankel and Lee (1998) attribute the difference to errors in the market's expectation of future earnings. Although these explanations do provide interesting insights into the book-to-market ratio gap, they do not yield a satisfactory explanation (Lev & Sougiannis 1999).

A number of recent studies have attempted to test whether elements of financial statements are 'value relevant'. Three competing explanations for the role played by the book value of assets in valuing companies are explored by Collins, Pincus and Xie (1999): the first relates to the use of the book value as a control for scale differences (Barth & Kallapur 1996); the second relates to the use of the book value as a proxy for expected normal earnings (Ohlson 1995; Penman 1992); and the final explanation relates to the use of the book value as a proxy for an abandonment option, or liquidation value (Berger, Ofek & Swary 1996). According to Collins *et al.* (1999), their results support the second and third explanations, namely that book value serves as a value relevant proxy for expected normal earnings, and as a proxy for an abandonment value.

In a series of papers, Ohlson (1995, 2001) and Feltham and Ohlson (1995, 1996) developed a valuation model that identifies the distinct roles played by accrual earnings, book value and dividends in equity valuation. The papers devise a cohesive theory of company value by relying on the concept of 'clean surplus': a concept that can easily be traced to residual income theory and Modigiliani and Miller's (1958) 'MM' valuation models. However, unlike other present value models, the Ohlson (1995) model uses data obtained from annual financial statements only. The valuation model incorporates both the bottom line items of the two traditional financial statements (accrual earnings from the income statement and net total assets from the balance sheet). The model does however include an 'other information' variable that is difficult to specify. Most recent empirical studies which use the Ohlson (1995) model, for example, Garrod and Rees (1998), Amir (1993), Louder, Khurana and Boatsman (1996) and Swartz (2005), use dividends as a surrogate for the 'other' information variable. However, these studies conclude that additional work is required to specify this variable fully.

One possible specification that is omitted by the book values used in the Ohlson (1995) model is intellectual capital. The results and findings from previous studies investigating the relationship between company performance and intellectual capital predict that intellectual capital will increasingly become the 'pivotal factor in corporate growth and development', and is 'becoming the preeminent resource for creating economic wealth' (Luthy 1998: 2). The role of intellectual capital in creating value has become crucial in achieving a competitive advantage in the market (Usoff, 2002). This role is also highlighted by Drucker (1993:54), who states that 'knowledge has become the key economic resource and the dominant and perhaps even the only source of competitive advantage. In this light, this article includes an intellectual capital variable as part of the 'other' information specification, and aims to test whether accrual accounting information and intellectual capital contribute to the explanation of share prices. The value added intellectual co-efficient (VAIC ™) (Pulic 1998) is used to measure intellectual capital performance.

This study is important in the South African context because of the significance of emerging economies for the overall well-being and balance of the global economy – it is important to achieve greater understanding of the development of intellectual capital in different socio-political and economic settings (Firer & Mitchell Williams 2003).

A panel data least squares approach was used in this study to test the original Ohlson (1995) model directly, adjusted for an intellectual capital variable (VAIC^{TM}), and for characteristics peculiar to emerging markets. The data used in the analysis was obtained from the Bureau of Financial Analysis (the BFA McGregor database for JSE-listed firms). The testing sample included 154 firms and the data covered a period of eight years. Only firms reporting the required information were included in the final sample. The results indicated that book value (net asset value per ordinary share), earnings (abnormal earnings per share), abnormal dividends and intellectual capital (the value added intellectual co-efficient (VAIC^{TM})) were significantly related to share price.

The remainder of the article is organised as follows: Section 2 provides a review of the relevant literature. Section 3 depicts the research environment, specifies the model and discusses the methodology and data selection process. The results of the empirical work are presented in Section 4. Finally, the conclusion, implications, limitations and possible directions for future research are set out in Section 5.

2 Literature review

Most recent empirical studies which use the Ohlson (1995) model, for example, Garrod and Rees (1998), Louder *et al.*, (1996), Woldegabir (2004) and Swartz (2005), conclude that, although the model provides a useful foundation for value relevance research, additional work is required to fully specify the additional information variable. This is evidenced by the low coefficients of determination, which range from 0.15 to 0.46. Stober (1999) and Ohlson (2001) in reviewing the empirical applications of the model emphasise the omission of difficult to measure, knowledge intensive intangible assets, or intellectual capital, from the Ohlson (1995) model specification.

The link between systems of high performance work practices and company performance was investigated by Huselid (1995), who concluded that these practices have a significant impact on company performance. Youndt, Snell, James and David (1996) examined the relationship between human resource management, manufacturing strategy and company performance. They concluded that human resource systems are directly related to a company’s performance. Van Buren (1999) examined the relationship between a core set of intellectual capital indicators and a company’s performance. The study concluded that intellectual capital is associated with a company’s performance. Low (2000) identified the importance of non-financial intangibles, examining their role in a company’s performance, concluding that improvements in critical intangible resources result in increased market value.

Firer and Stainbank (2003) investigated whether the performance of a company’s intellectual capital can explain organisational performance. The study concluded that the performance of a company’s intellectual capital can explain profitability and productivity, but not market valuation.

The above review of literature on empirical studies in this field clearly indicates the usefulness of intellectual capital. Hence, it was deemed essential to undertake an empirical investigation into intellectual capital in the context of the South African economy.

3 Research environment and model specification

3.1 *Ohlson's (1995) model*

The determinants of firm value in value relevance research remain an enigma. The usefulness of annual financial statements in determining a company's share price in particular has been increasingly questioned due to the increasing gap between book values (as reflected in the annual financial statements) and the market prices of equity (obtained from the stock markets). A large body of finance and accounting research has emerged attempting to test whether firms' book values are related to the market values of those firms. This article focuses on Ohlson's (1995) model.

Ohlson's (1995) model is a balanced model, relying on the 'clean surplus' relation ($X_t - d_t$) as the retained earnings of a given period:

$$bv_t = bv_{t-1} + x_t - d_t \tag{1}$$

where:

bv_t = company book value at Time t,

x_t = earnings for Period t,

d_t = dividends for Period t.

The clean surplus relation can be analysed further by ruling out infinite growth in book value, implying an accrual accounting-based expression for equity value, namely:

$$P_t = bv_t + \sum_{\tau=1}^{\infty} R_f E_t[\overset{\sim a}{x}_{t+\tau}] \tag{2}$$

where abnormal earnings (~a denotes abnormal) are defined as follows:

$$\overset{\sim a}{x_t} \equiv x_t - (R_f - 1)bv_{t-1} \tag{3}$$

Abnormal earnings are therefore equal to earnings less a capital charge (the risk free rate), based on the concept that the inclusion of book value in the model represents normal earnings on capital invested. Any earnings in excess of normal earnings are therefore abnormal.

The third specification made by Ohlson's (1995) model concerns the time variant behaviour of normal earnings. Hence, the role of other information is recognized. The information dynamic is formulated by adding another information variable, v_t, to include information other than abnormal earnings, which is yet to have an impact on the information available.

$$\overset{\sim a}{x}_{\tau+1} = \omega \overset{a}{x}_\tau + v_t + έ1\ t{+}1 \tag{4a}$$

$$vt{+}1 = \gamma vt + έ2\ t{+}1 \tag{4b}$$

where the disturbance terms $έ_{1\,t+1}$ and $έ_{2\,t+1}$ are with zero means and constant variances. The parameters of the process ω and γ are fixed and known. The superscript 'a' on coefficient x_τ denotes abnormal earnings.

Combining equation (2) with equations (4a) and (4b) yields a linear function for P_t:

$$P_t = bv_t + \alpha_1 x^{a}_{\tau} + \alpha_2 v_t \qquad (5)$$

Hence, Equation 5 implies that the market value is equal to the book value of the firm's assets, adjusted for abnormal earnings and other information that modifies the prediction of future profitability. The model therefore elegantly incorporates accrual accounting variables, distinguishing it clearly from other valuation models such as Modigliani and Miller's (1958) earnings (cash flows) capitalization model, or Gordon's dividend growth model.

3.2 *Cost of capital*

Thus far the model has not included any measure of risk, as the discount rate used has been the risk free rate, R_f (see Equations 2 and 3), based on risk neutrality. The model can be modified to introduce risk in the anticipated dividend sequence. One possible approach suggested is replacing R_f with some factor ρ, which adjusts R_f for risk by introducing a risk premium, determined by the company's cost of capital or the expected market return determined from models such as the capital asset pricing model (CAPM), which implies that $\rho = R_f + \beta$. However, this approach has been criticised as being empirically inadequate – so, for example, Fama and French (1996) argue that betas do not explain average return or size. Similarly, Bowie and Bradfield (1998) investigated beta stability on the JSE and found that thin trading conditions caused distortions. Van Rensburg and Robertson (2003), in a similar study on the JSE, found an unambiguous empirical contradiction of the CAPM.

Fama and French (1992) suggest using variables such as the price earnings (PE) ratio and the cash flow to price ratio as a surrogate for the discount rate. The use of the PE ratio is further supported by Cheng and McNamara (2000), who argue that the PE ratio captures the risk and growth of companies. This study adopted a similar approach to that used by Cheng and McNamara (2000) in using the PE ratio as a surrogate for the cost of capital.

3.3 *Specification of the 'other' information variable*

The empirical application of Ohlson's (1995) and Feltham and Ohlson's (1995, 1996) valuation models was reviewed by Stober (1999), who concluded that the collective models provide a rigorous foundation for value relevance studies, and emphasized the need to pay close attention to specification issues, in particular of the 'other' information variable.

Ohlson (1998) himself has discussed the specification issues in greater detail, and he emphasizes the crucial role of the 'other' information variable in predicting the expectations of future earnings. Ohlson (2001) stresses the need for the correct measure of the 'other' information variable, arguing that current residual income is unlikely to explain goodwill adequately.

Hand and Landsman (1998) take a different view on the specification of the 'other' information variable: they set v_t at zero, and then split net dividends into cash dividends and other capital flows (share repurchases and issuances). They conclude that including cash dividends is consistent with information theories of dividends, where dividends signal future profitability, and therefore act as a surrogate for v_t.

3.4 *Intellectual capital*

Stober (1999) and Ohlson (2001) emphasize the omission from Ohlson's (1995) model specification of assets that are difficult to measure, knowledge intensive and intangible, or intellectual capital. The creation, management, and maintenance of intellectual capital fall within a field that is broadly known as knowledge management, according to Firer and Mitchell Williams (2003), whose paper investigates intellectual capital valuation models, attempting to place a value on three intangible factors of an organisation identified as its knowledge and know-how, created by and stored in its people (human capital), its relationships (social capital), and its organisational information technology systems and processes (organisational capital).

Previous studies have illustrated the increasing importance of a company's intellectual capital to its overall value. For example, the Brookings Research Institute found that in 1962, 62% of a company's value was represented by its physical capital, but that this percentage had declined to 38% in 1992. Luthy (1998) described the growing significance of intellectual capital by stating that intellectual capital was becoming the pre-eminent resource for creating wealth and that the relative importance of tangible assets had decreased over time, due to the increasing importance of intangible, knowledge-based assets.

Resource-dependence theories have resulted in a number of intellectual capital valuation models which indicate that all facets of human resources need to be fully incorporated into valuation models (see, for example, Barney 1991; Grant 1991; Pulic 1998; Sveiby 2000, 2001). These theories argue that human resource assets enable a firm to increase its performance and wealth-creation potential.

Thus far, intellectual capital has been described as a broad term that is considered to be synonymous with a firm's intangible assets. However, to date, there is no precise agreement on the definition of intellectual capital. Stewart (1997:67) defines intellectual capital as 'packaged useful knowledge'. Brookings (1996:12) offers a more comprehensive definition, stating that intellectual capital refers to the 'combined intangible assets which enable a company to function'. It is beyond the scope of this article to assess the respective merits of the various definitions of intellectual capital. Hence, for the purposes of this study, intellectual capital is simply defined as the enhanced value of a firm attributable to assets, generally of an intangible nature, resulting from the company's organisational function, processes and information technology networks, the competency and efficiency of its employees and its relationship with its customers (Mitchell Williams 2000c).

As yet there is no fully accepted measure of intellectual capital and the success of its application by a business. Generally speaking, the methods used to measure intellectual capital can be classified into two main groups (Firer & Mitchell Williams 2003).

The first group adopts an approach where the value of intellectual capital is expressed in financial terms at an organisational level, with a specified benchmark of a perceived value, such as shareholders' equity. Common measures of intellectual capital at the organisational level are the calculated intangible value, Tobin's q, and the market-to-book ratio (Stewart 1997). The primary premise of these measures is the relationship of intellectual capital to shareholder value.

The second group of measures uses a component-by-component analysis of the intellectual capital held by a firm. So, for example, intellectual capital may be considered to consist of three main components, namely human capital, customer capital and infrastructure capital. If the component-by-component approach is used, each component is valued separately using a measure appropriate for that component. Difficulties in aligning various component measures have led to criticism of the component-by-component approach to measuring intellectual capital (Firer & Mitchell Williams 2003). Another limitation of the component-by-component approach is that such measures have usually been designed to fit the characteristics of one single company or industry. The generalisability of such measures is therefore questionable (Firer & Mitchell Williams 2003).

Mindful of the respective criticisms of the various measures of intellectual capital, two screening criteria were adopted in selecting the measure for intellectual capital performance for this article. These criteria were, first, that the basic underlying feature of the measure should be based on a key component of intellectual capital rather than a measure of physical capital; and, second, that the measure should be simple enough to enhance understanding and to allow relative ease in collecting data. The use of an uncomplicated intellectual capital measurement model can be supported for various reasons, including behavioural, cognitive and cost/benefit reasons (Firer & Mitchell Williams 2003). With increased complexity, there is an increased risk of ambiguity and thus there is the potential that the measure may reduce the understandability and applicability of the intellectual capital model. It is also suggested that the value of an intellectual capital measurement model comprising log checklists and complicated simulations between indicators may be compromised by the inability of stakeholders to comprehend all the indicators at once (Mitchell Williams 2000a). Finally, from a pragmatic perspective, it can be argued that if the cost of designing, implementing, administering and updating the intellectual capital measurement model outweighs the benefits derived from it by company management and its stakeholders, there is little incentive to use it.

In view of the two screening criteria outlined above, the value added intellectual coefficient (VAIC^{TM}) (Pulic 1998) was selected to underpin the measurement of intellectual capital performance in this study. This measure is considered to be a 'universal indicator showing [the] abilities of a company in value creation and representing a measure for business efficiency in a knowledge based economy' (Pulic 1998:9). VAIC^{TM} is an analytical procedure designed to enable the management of a company, its shareholders and other stakeholders to effectively monitor and evaluate the efficiency of value added (VA) by a company's total resources and by each key resource component. VAIC^{TM} is the sum of three separate indicators: first, capital employed efficiency (CEE) – an indicator of the value added (VA) efficiency of the capital employed; second, human capital efficiency (HCE) – an indicator of the value added (VA) efficiency of human capital; and third, structured capital efficiency (SCE) – an indicator of the value added (VA) efficiency of structured capital. The following formula can be employed:

$$VAIC^{TM}_i = CEE_i + HCE_i + SCE_i \quad (9)$$

Where VAICTMi	=	VA intellectual coefficient for Firm i;
CEEi	=	VAi /CEi ; VA capital employed coefficient for Firm i;
HCEi	=	VAi /HCi ; human capital coefficient for Firm i; and
SCEi	=	SCi / VAi ; structured capital coefficient for Firm i;

VAi	=	Ii+ DPi + Di +Ti + Mi + Ri ; VA for Firm i computed as the sum of interest expenses (Ii); depreciation expenses (DPi); dividends (Di); corporate taxes (Ti); equity of minority shareholders in the net income of subsidiaries (Mi); profits retained for the year (Ri);
CEi	=	book value of the net assets for Firm i;
HCi	=	total investment in salaries and wages for Firm i;
SCi	=	VAi - HCi ; structured capital for Firm i

Human capital is measured through the total investment in salaries and wages (staff costs) for the financial year (Pulic 1998). The book value of net assets of a company is measured by the physical capital employed by a company (Mitchell Williams 2000b, 2001; Pulic 1998). Human capital and structural capital are reverse proportional; the less human capital participates in value creation, the more structural capital is involved (Pulic 1999).

The main reasons to support the use of the above measure are described as follows (Firer & Mitchell Williams 2003):

- the measure is unique in its flexibility for application to both the macro and the micro economic levels. The methodology can therefore be applied in developing an understanding of the intellectual capital performance of a single company, a group of companies, specific business sectors or an entire capital market;
- the methodology provides a standardised and consistent basis of measurement, thereby enabling national and international comparison; and
- all data used in the equation are based on audited information; calculations can therefore be considered to be objective and verifiable.

The documented evidence therefore illustrates that Ohlson's (1995) valuation model has been revised and re-specified for specific purposes and environments, and empirically tested. Furthermore, the inclusion of Pulic's (1998) measure of intellectual capital as an additional specification of the 'other' information variable appears to be appropriate. The remaining sections of this article depict the research environment and specify the v_t variable.

3.5 *Research environment*

A central feature of this study is its focus on South Africa. There were a number of reasons for this focus: South Africa is an emerging economy seeking to attract foreign capital and investment and it is not always easy to distinguish South Africa from the common perception of the entire southern African region, as illustrated by the Rand's volatility and the events in Zimbabwe (PricewaterhouseCoopers 2003). Valuation problems in emerging markets include thin trading, illiquidity, pyramid structures and information asymmetry (Bruner *et al.* 2002).

3.6 *Model specification*

The following model was used to test the value relevance of intellectual capital:

$$P^{*}_{it} = \overset{a}{\zeta}_t + \beta_1 x_{it} + \beta_2 bv_{it} + \beta_3 d_{it} + \beta_4 CEE_{it} + \beta_5 HCE_{it} + \beta_6 SCE_{it} + \delta_{it} + u_{it} \qquad (10)$$

where:

P_{it}^{*} = the value of Firm i's equity at Year t + 3 months (per share)

ς_t = an intercept

x_{it} = abnormal accrual earnings per share for Firm i at Time t

bv_{it}^{a} = book value of Firm i's assets at Time t (per share)

d_{it} = a proxy for 'other' information, abnormal dividends of Firm i at Time t (per share) $DPS_t - DPS_{t-1}$

CEE_{it} = VA_{it}/CE_{it} ; VA capital employed coefficient for Firm i at Time t;

HCE_{it} = VA_{it}/HC_{it} ; human capital coefficient for Firm i at Time t; and

SCE_{it} = SC_{it}/VA_{it} ; structured capital coefficient for Firm i at Time t;

VA_{it} = $I_{it} + DP_{it} + D_{it} + T_{it} + M_{it} + R_{it}$; VA for Firm i at Time t is computed as the sum of interest expenses (I_{it}); depreciation expenses (DP_{it}); dividends (D_{it}); corporate taxes (T_{it}); equity of minority shareholders in the net income of subsidiaries (M_{it}); profits retained for the year (R_{it});

CE_{it} = book value of the net assets for Firm i at Time t;

HC_{it} = total investment in salaries and wages for Firm i at Time t;

SC_{it} = $VA_{it} - HC_{it}$; structured capital for Firm i at Time t;

Δ_i = an unobservable individual (fixed) specific effect;

u_{it} = an error term (remainder disturbance).

Note that δ_i is time-invariant and accounts for any firm-specific effect, while the disturbance u_{it} varies from firm to firm and across time.

Abnormal earnings are calculated using normal earnings less a charge for capital. In line with Cheng and McNamara (2000), the weighted average cost of capital is estimated using the PE ratio as a base, charged on the net book value of the company's assets. Hence abnormal earnings are defined as follows:

$$X_{it}^{a} = X_{it} - WACC.TA^{*}$$

where:

X_{it}^{a} = Operating earnings after taxation and finance charges

WACC = Weighted average cost of capital

TA^{*} = Total assets – total debt

Total debt is subtracted from total assets because operating earnings X_{it}^{a} are after finance charges. Thus, to avoid double counting the cost of debt, this is removed as a form of finance by subtracting the value thereof from total assets.

The other information variable, v_{it}, can either be other financial statement information or any other publicly available information. 'Other' information v_{it} is estimated using dividends (d_t) and intellectual capital ($VAIC_{it}$) as proxies. The use of dividends is in line with the results of Cheng and McNamara (2000) and Garrod and Rees (1998). As noted earlier, dividends as a form of information are particularly important on the JSE, as in other emerging markets, where liquidity is important (Bhana 1991). Changes in dividends are used to avoid conflict with the abnormal earnings variable. Hence, for the purposes of this study, 'other' information is defined as follows:

$d_t \quad = \quad DPS_t - DPS_{t-1}$

Colinearity between abnormal earnings and abnormal dividends should not be a problem as earnings are accrual earnings, and dividends per share refers to the movement in dividends and therefore only represents the informational effect.

Intellectual capital is estimated using Pulic's (1998) model, as discussed earlier, with specifications included for the capital employed coefficient (CEE_{it}), the human capital coefficient (HCE_{it}), and the structural capital coefficient (SCE_{it}).

As the model is essentially predictive using historical information, a problem of leads and lags is present for the dependent variable P_{it}. Even though there are a number of studies that confirm the JSE's semi-strong stage of market efficiency, share prices three months after each company's year-end were used to allow time for the publication and analysis of financial statements.

4 Results and discussion

The results of the panel data least square regression are presented in Table 1 below. The results of the basic T-statistic indicate that the Ohlson (1995) regressors of book value of assets (bv_{it}), abnormal earnings (x_{it}), and abnormal dividends (d_{it}) all have a statistically significant and robust effect on the dependent variable. Furthermore, the Pulic (1998) regressors for the capital employed coefficient (CEE_{it}), and the human capital coefficient (HCE_{it}) have a statistically significant and robust effect on the dependent variable. However, the structural capital coefficient (SCE_{it}) displays a weak relationship with the dependent variable, and therefore is not considered to be value relevant. Structural capital has been defined as value added minus human capital. Human capital and structural capital are reverse proportional; the less human capital participates in value creation the more structural capital is involved (Pulic 1999). The lack in significance of the SCE_{it} coefficient is therefore not unexpected, as the same structural information is contained in the book value assets, measured at T0, and therefore the information includes the value added in the current year; and in the abnormal earnings coefficient.

The regression statistics indicate that the panel equation fits the data relatively well; an R^2 of 0.9114 and adjusted R^2 of 0.9110 indicate that the equation explains around 91% of the variation in share prices during the sample period. In addition, all coefficient estimates, with the exception of SCE_{it}, are significantly different from zero at 95% confidence levels.

Table 1 Panel data results

Model:

$$P^{*}_{it} = \zeta_t + \beta_1 x^{a}_{it} + \beta_2 bv_{it} + \beta_3 d_{it} + \beta_4 CEE_{it} + \beta_5 HCE_{it} + \beta_6 SCE_{it} + \delta_{it} + u_{it} \quad (10)$$

Dependent variable: P^{*}_{it}

Method: Panel least squares

Sample: 1997 2004

Cross-sections included: 154

Variable	Coefficient	Std. error	t-Statistic	Prob.
β_1	8.493600	0.111578	76.12258	0.0000
β_2	45.44563	7.814148	5.815814	0.0000
β_3	-1.999493	0.230031	-8.692285	0.0000
β_4	-1289.808	477.4625	-2.701381	0.0070
β_5	289.0229	72.75019	3.972813	0.0001
β_6	-3.28E-06	1.92E-05	-0.170351	0.8648

R-squared	0.911409	Mean dependent variable	4156.530
Adjusted R-squared	0.910872	S.D. dependent variable	5262.436
S.E. of regression	1571.067		
Sum squared residuals	2.03E+09		

The lack of a significant relationship reflected in the structural capital coefficient (SCE_{it}) was further investigated by performing a panel data analysis using the Pulic (1998) coefficients only, as reflected in Table 2 below. The results indicate that all three of the Pulic (1998) coefficients have a statistically significant and robust effect on the dependent variable, and therefore that the SCE_{it} coefficient is indeed value relevant. The contradictory results in the two panel data models indicates that although the SCE_{it} coefficient is value relevant, such information is already incorporated in the Ohlson (1995) model coefficients as discussed above, and supports the conclusion that the inclusion of the structural capital coefficient as part of the other information variable is inappropriate.

The results therefore indicate that abnormal earnings, abnormal dividends, book value of assets, the capital employed coefficient and the human capital coefficient all have a significantly positive and robust effect on the share price three months after the year-end for South African listed firms.

Table 2 Panel data results

Model:

$$P^*_{it} = \zeta_t + \beta_1 CEE_{it} + \beta_2 HCE_{it} + \beta_3 SCE_{it} + \delta_{it} + u_{it} \quad (11)$$

5 Concluding remarks and suggestions for future research

This study investigated the relevance of accrual accounting data and intellectual capital measured using VAIC™ to determine share prices. The results indicate that abnormal earnings, the net book value of assets, abnormal dividends and intellectual capital all provide information relevant to the establishment of market prices in an emerging market environment.

The annual financial statements not only report earnings and the book value of assets, but also report other accounting information such as various revenues, expenses, assets, liabilities and cash flow information, each of which have different measurement attributes and thus different characteristics in respect of any particular valuation model. Disaggregation of the summary measures used in this study provide a rich field for future research.

The focus of this study was on one single measure of intellectual capital performance. Future studies could explore a different standardised measure for intellectual capital performance.

Is fair value accounting information relevant and reliable? Evidence from capital market research

Wayne R. Landsman*

Abstract—In financial reporting, US and international accounting standard-setters have issued several disclosure and measurement and recognition standards for financial instruments. The purpose of this paper is to review the extant capital market literature that examines the usefulness of fair value accounting information to investors. In conducting my review, I highlight findings that are of interest not just to academic researchers, but also to practitioners and standard setters as they assess how current fair value standards require modification, and issues future standards need to address. Taken together, evidence from the research suggests that disclosed and recognised fair values are informative to investors, but that the level of informativeness is affected by the amount of measurement error and source of the estimates – management or external appraisers. I also provide a discussion of implementation issues of determining asset and liability fair values.

1. Introduction

Accounting standards setters in many jurisdictions around the world, including the United States, the United Kingdom, Australia, and the European Union, have issued standards requiring recognition of balance sheet amounts at fair value, and changes in their fair values in income. For example, in the US, the Financial Accounting Standards Board (FASB) requires recognition of some investment securities and derivatives at fair value. In addition, as their accounting rules have evolved, many other balance sheet amounts have been made subject to partial application of fair value rules that depend on various ad hoc circumstances, including impairment (e.g., goodwill and loans) and whether a derivative is used to hedge changes in fair value (e.g., inventories, loans, and fixed lease payments). The FASB and the International Accounting Standards Board (IASB) are working jointly on projects examining the feasibility of mandating recognition of essentially all financial assets and liabilities at fair value in the financial statements.

In the US, fair value recognition of financial assets and liabilities appears to enjoy the support of the Securities and Exchange Commission (SEC). In a recent report prepared for a Congressional committee (SEC, 2005), the Office of the Chief Accountant of the SEC states two primary benefits of requiring fair value accounting for financial instruments. First, it would mitigate the use of accounting-motivated transaction structures designed to exploit opportunities for earnings management created by the current 'mixed-attribute' – part historical cost, part fair values – accounting model. For example, it would eliminate the incentive to use asset securitisation as a means to recognise gains on sale of receivables or loans. Second, fair value accounting for all financial instruments would reduce the complexity of financial reporting arising from the mixed attributed model. For example, with all financial instruments measured at fair value, the hedge accounting model employed by the FASB's derivatives standard would be all but eliminated, making it unnecessary for investors to study the choices made by management to determine what basis of accounting is used for particular instruments, as well as the need for management to keep extensive records of hedging relationships.

But, as noted in the SEC report, there are costs as well associated with the application of fair value accounting. One key issue is whether fair values of financial statement items can be measured reliably, especially for those financial instruments for which active markets do not readily exist (e.g., specialised receivables or privately placed loans). Both the FASB and IASB state in their Concepts statements that they consider the cost/benefit tradeoff between relevance and reliability when assessing how best to measure specific accounting amounts, and whether measurement is sufficiently reliable for financial statement recognition. A cost to investors of fair value measurement is that some or even many recognised financial instruments might not be measured with sufficient precision to

He thanks Mary Barth, Stephen Lin, Richard Macve, Ken Peasnell, Brian Singleton-Green, Steve Stubben, Pauline Weetman (editor), Shu Yeh, and an anonymous reviewer for helpful comments and suggestions.

help them assess adequately the firm's financial position and earnings potential. This reliability cost is compounded by the problem that in the absence of active markets for a particular financial instrument, management must estimate its fair value, which can be subject to discretion or manipulation.

The purpose of this paper is to review the extant capital market literature that examines the usefulness of fair value accounting information to investors. In conducting my review, I highlight findings that are of interest not just to academic researchers, but also to practitioners and standard-setters as they assess how current fair value standards require modification, and issues future standards need to address. Taken together, evidence from the research suggests that disclosed and recognised fair values are informative to investors, but that the level of informativeness is affected by the amount of measurement error and source of the estimates – management or external appraisers. I also provide a discussion of implementation issues of determining asset and liability fair values. In doing so, I also look to evidence from the academic literature.

As a prelude to my literature review, I begin by discussing the definition of fair value used in standard setting, and reviewing the accounting standards issued by the FASB and IASB that relate to fair value accounting and have been the subject of study by academic research.

2. Background of fair value accounting in standard setting

2.1. Definition of fair value

The FASB defines 'fair value' as the price that would be received to sell an asset or paid to transfer a liability in an orderly transaction between market participants at the measurement date' (FASB, 2006a).[1] As the FASB notes, 'The objective of a fair value measurement is to determine the price that would be received to sell the asset or paid to transfer the liability at the measurement date (an exit price).' Implicit in this objective is the notion that fair value is well defined so that an asset or liability's exchange price fully captures its value. However, in practice, fair value may not be well defined. This occurs when no active market exists for the asset or liability. In this situation, it becomes difficult to disentangle an asset or liability's fair value from its value-in-use to the entity. For example, the estimate of fair value of a non-market traded swap derivative to a bank is likely to depend on the existing assets and liabilities on the bank's balance sheet. I will return to the implications of this problem when discussing fair value estimate implementation issues below.

2.2. Applications to standard setting

In the US, the FASB has issued several standards that mandate disclosure or recognition of accounting amounts using fair values. Among the most significant are those standards that explicitly relate to financial instruments. Two important disclosure standards are Statement of Financial Accounting Standards (SFAS) No. 107, *Disclosures about Fair Value of Financial Instruments* (FASB, 1991) and SFAS No. 119, *Disclosure about Derivative Financial Instruments and Fair Value of Financial Instruments* (FASB, 1994). SFAS No. 107 requires disclosure of fair value estimates of all recognised assets and liabilities, and as such, was the first standard that provided financial statement disclosures of estimates of the primary balance sheet accounts, including securities, loans, deposits, and long-term debt. In addition, it was the first standard to provide a definition of fair value reflecting the FASB's objective of obtaining quoted market prices wherever possible. SFAS No. 119 requires disclosure of fair value estimates of derivative financial instruments, including futures, forward, swap, and option contracts. It also requires disclosure of estimates of holding gains and losses for instruments that are held for trading purposes.

Among the most significant fair value recognition standards the FASB has issued are SFAS No. 115, *Accounting for Certain Investments in Debt and Equity Securities* (FASB, 1993), SFAS No. 123 (Revised), *Share-based Payments* (FASB, 2004), and SFAS No. 133, *Accounting for Derivative Instruments and Hedging Activities* (FASB, 1998). SFAS No. 115 requires recognition at fair value of investments in equity and debt securities classified as held for trading or available-for-sale. Fair value changes for the former appear in income, and fair value changes for the latter are included as a component of accumulated other comprehensive income, i.e., are excluded from income. Those debt securities classified as held to maturity are recognised at amortised cost. SFAS No. 123 (Revised) requires the cost of employee stock options grants be recognised in income using grant date fair value by amortising the cost during the employee vesting or service period.[2] This

[1] The IASB recently issued a discussion paper, *Fair Value Measurements Part 1: Invitation to Comment* (IASB, 2006), that explicitly asks the question of whether the FASB's focus on exit value for fair value measurement is appropriate and under what circumstances exit value or other approaches (i.e., entry value and value-in-use) are more appropriate.

[2] Although SFAS No. 123 (Revised) requires the cost of option grants be recognised at fair value, it is not strictly a fair value standard. First, amortisation of the cost of option grants is based on the grant date fair value – i.e., the historical cost of the grants. Second, the standard requires vesting features be reflected in the grant date fair value estimate by adjusting the number of options rather than their price. As discussed below, Landsman et al. (2006) advocate also recognising in income changes in fair value of option grants.

requirement removed election of fair value or intrinsic value cost measurement permitted under the original recognition standard, SFAS No. 123, *Accounting for Stock-based Compensation* (FASB, 1995). Until recently, most firms elected to measure the cost of employee stock options using intrinsic value. However, for such firms, SFAS No. 123 required they disclose a *pro forma* income number computed using a fair value cost for employee stock option grants, as well as key model inputs they use to estimate fair values.

SFAS No. 133 requires all freestanding derivatives be recognised at fair value. However, SFAS No. 133 retains elements of the existing hedge accounting model. In particular, fair value changes in those derivatives employed for purposes of hedging fair value risks (e.g., interest rate risk and commodity price risk) are shown as a component of income, as are the changes in fair value of the hedged balance sheet item (e.g., fixed rate loans and inventories) or firm-commitments (i.e., forward contracts). If the so-called fair value hedge is perfect, the effect on income of the hedging relationship is zero. In contrast, fair value changes in those derivatives employed for purposes of hedging cash flow risks (e.g., cash flows volatility resulting from interest rate risk and commodity price risk) are shown as a component of accumulated other comprehensive income because there is no recognised off-setting change in fair value of an implicitly hedged balance sheet item or anticipated transaction.[3]

Outside the US, standards issued by the IASB are accepted or required as generally accepted accounting principles (GAAP) in many countries. For example, since 2005, the EU generally requires listed companies in member states to issue financial statements prepared in accordance with IASB GAAP. IASB GAAP comprises International Accounting Standards (IAS) issued by its predecessor body, the International Accounting Standards Committee (IASC), as well as those International Financial Reporting Standards (IFRS) that it has issued since its inception in 2001. The IASC issued two key fair value standards, both of which have been adopted by the IASB, IAS 32: *Financial Instruments: Disclosure and Presentation* (IASB, 2003a), IAS 39, *Financial Instruments: Recognition and Measurement* (IASB, 2003b). The former standard is primarily a disclosure standard, and is similar to its US GAAP counterparts, SFAS Nos. 107 and 119. IAS 39, which has been amended several times since its initial issuance, describes how particular financial assets and liabilities are measured (i.e., amortised cost or fair value), and how changes in their values are recognised in the financial statements. The scope of IAS 39 roughly encompasses accounting for investment securities and derivatives, which are covered under SFAS Nos. 115 and 133, although there are some minor differences between IAS and US GAAP.

The IASB has also issued *IFRS* 2, *Accounting for Share-based Payments* (IASB, 2004). *IFRS 2* is similar to SFAS No. 123 (Revised) (FASB, 2004) in requiring firms to recognise the cost of employee stock option grants using grant date fair value.[4]

As part of their efforts to harmonise US and international accounting standards, the IASB issued in November 2006 a two-part discussion paper on Fair Value Measurement (IASB, 2006). Part 1 of the discussion paper describes issues and concerns with the FASB's approach to fair value measurement; part 2 reproduces SFAS No. 157. Regarding disclosure, the IASB issued *International Financial Reporting Standard 7, Financial Instruments: Disclosures* (IASB, 2005a). *IFRS 7* requires disclosure of detailed information for recognised financial instruments, both those measured at fair value and those that are not. *IFRS 7* builds on IAS 32 by requiring disclosure of fair value amounts at the end of each accounting period (year, quarter), how the fair values are determined, and the effect on income arising from each particular class of assets or liabilities (i.e., separate disclosure of recognised and unrecognised gains and losses). In addition, *IFRS 7* mandates disclosure of qualitative information relating to financial instruments' liquidity, credit, and market risks.

Regarding recognition, in 2005 the IASB amended IAS 39 by describing conditions under which firms can elect fair value measurement for financial instruments.[5] Under this so-called fair value option, entities can designate, at the time of acquisition or issuance, a financial asset or financial liability be measured at fair value, with value changes recognised in income. This option is available even if the financial asset or financial liability would ordinarily be measured at amortised cost, but only if fair value can be reliably measured. Once an instrument is designated as a fair

[3] The FASB has issued several other standards with elements of fair value recognition or disclosure. For example, SFAS No. 87, *Employers' Accounting for Pensions* (FASB, 1985) requires footnote disclosure of the fair value of pension plan assets and the pension obligation associated with defined benefit plans. However, the standard requires balance sheet recognition of only the net of the unrecognised asset, liability, and equity amounts. The SEC report (SEC, 2005) recommends that pension assets and liabilities be recognised at fair value in the body of the financial statements. Recently, the FASB issued SFAS 158 (FASB, 2006c), partially implementing the SEC's recommendation. Evidence in Landsman (1986) and Barth (1991) is consistent with equity prices reflecting pension asset and liability fair values. See the literature review on pricing effects of financial instruments' fair values in the next section.

[4] The comment in footnote 2 relating to SFAS No. 123 (Revised) applies also to *IFRS 2*.

[5] IASB (2005b).

value instrument, it cannot be reclassified. A goal of the fair value option is to mitigate the effects of income volatility arising from the mixed attribute model without having to apply hedge accounting. In 2006, the FASB issued an Exposure Draft, *Proposed Statement of Financial Accounting Standards, The Fair Value Option for Financial Assets and Financial Liabilities* (FASB, 2006b), which largely mirrors the IAS 39 fair value option standard. Critics of the fair value option raise the concern that permitting two different entities to classify the same financial instrument differently will reduce cross-firm financial statement comparability.

As noted earlier, the FASB issued *Statement of Financial Accounting Standards No. 157, Fair Value Measurements* (FASB, 2006a), which provides a definition of fair value.[6] However, SFAS 157 also establishes a framework for measuring fair value and expands disclosures about fair value measurements. The FASB recognises that active markets may not always exist for a specific asset or liability, and therefore develops a hierarchy of preferences for measurement of fair value. The preferred *Level 1* fair value estimates are those based on quoted prices for identical assets and liabilities, and are most applicable to those assets or liabilities that are actively traded (e.g., trading investment securities). *Level 2* estimates are those based on quoted market prices of similar or related assets and liabilities. *Level 3* estimates, the least preferred, are those based on company estimates, and should only be used if Level 1 or 2 estimates are not available. With its emphasis on market prices, the FASB requires that firms should base their Level 3 estimates on market prices as model inputs wherever possible (e.g., use of equity market volatility estimates when employing the Black-Scholes valuation model to estimate the fair value of employee stock options). Fair value estimates can be constructed using entity-supplied inputs (e.g., discounted cash flow estimates) if other models employing market inputs are not available.

Critics of SFAS 157 express both conceptual and practical concerns.[7] The key conceptual concern is that exit value may not appropriately capture the value of an asset (or liability) to a firm's shareholders even if an active market exists for the asset. This can occur if there is a significant divergence between an asset's value-in-use and its exit value. An asset's value-in-use reflects management skill as well as how the asset is used in conjunction with other assets with which it is combined to generate income. The key practical issue is that because active markets may not exist for an asset or liability, much of the time fair value will have to be measured based on Levels 2 and 3 estimates. Level 2 or 3 estimates are subjective, subject to manipulation, and potentially difficult to verify (audit).[8]

3. Are fair values useful to investors? Evidence from research

3.1. US-based research

When assessing the quality of fair value information, a natural question to ask is whether fair value information is useful to investors. For example, when it was deliberating SFAS No. 107, the FASB was concerned with policy questions relating to the relevance and reliability of disclosed amounts. Regarding relevance, the FASB was interested in whether SFAS No. 107 disclosures would be incrementally useful to financial statement users relative to items already in financial statements, including recognised book values and disclosed amounts. Regarding reliability, the FASB was concerned with whether fair values estimates, especially those relating to loans, would be too noisy to disclose.[9]

As Barth et al. (2001) note, policy-based accounting research cannot directly address these questions, but can provide evidence that helps standard-setters assess relevance and reliability questions. A common way to assess the so-called value relevance of a recognised or disclosed accounting amount is to assess its incremental association with share prices or share returns after controlling for other accounting or market information.

Much of the value relevance research assessing the relevance and reliability of fair value information focuses on banks, since banks are largely comprised of financial assets and liabilities.[10] Several studies address the value relevance of banks' disclosed investment securities fair values before issuance of SFAS No. 115 mandating recognition of investment securities' fair values and effects of their changes on the balance sheet and the income statement. For a sample of US banks with data from 1971–1990, Barth (1994)

[6] As noted above in footnote 1, the IASB has yet to settle on a definition of fair value.

[7] See, for example, Ernst & Young (2005) and AAA FASC (2005).

[8] Even though the goal is always, for all estimates, regardless of the level, exit value, Level 3 estimates will, almost by necessity, have a strong value-in-use flavour in that inputs may often be entity-supplied rather than those based on models employing market inputs. In addition, any adjustments that are made to model-based estimates to arrive at exit value are likely to be highly subjective.

[9] Bank regulators are also interested in these and related questions. See footnote 12 below.

[10] Note that prior to issuance of SFAS 157, 'fair value' was not clearly defined as exit value, nor was the procedure for estimating fair values in the absence of active markets clearly laid-out. Thus, studies examining the value relevance of fair value information are not necessarily based on exit value prices as defined in SFAS 157.

finds that investment securities' fair values are incrementally associated with bank share prices after controlling for investment securities' book values. When examined in an annual returns context, the study finds mixed results for whether unrecognised securities' gains and losses provide incremental explanatory power relative to other components of income. One leading candidate for the ambiguous finding for securities gains and losses is that the gains and losses estimates contain too much measurement error relative to the true underlying changes in their market values.[11] Using essentially the same database, Barth et al. (1995) confirm the Barth (1994) findings and lend support to the measurement error explanation by showing that fair value-based measures of net income are more volatile than historical cost-based measures, but the incremental volatility is not reflected in bank share prices.[12]

Barth et al. (1996), Eccher et al. (1996), and Nelson (1996) use similar approaches to assess the incremental value relevance of fair values of principal categories of banks assets and liabilities disclosed under SFAS No. 107 in 1992 and 1993, i.e., investment securities, loans, deposits, and long-term debt. Supporting the findings of Barth (1994) using pre-SFAS No. 107 data, all three studies find investment securities fair values are incrementally informative relative to their book values in explaining bank share prices. However, using a more powerful research design that controls for the effects of potential omitted variables, Barth et al. (1996) also find evidence that loans' fair values are also incrementally informative relative to their book values in explaining bank share prices. Barth et al. (1996) also provide additional evidence that the fair values of loans reflect information regarding the default and interest rate risk of those loans. In addition, the study's findings suggest that investors appear to discount loans' fair value estimates made by less financially healthy banks (i.e., those banks with below sample median regulatory capital), which is consistent with investors being able to see through attempts by managers of less healthy banks to make their banks appear more healthy by exercising discretion when estimating loans fair values.

Finally, Venkatachalam (1996) examines the value relevance of banks' derivatives disclosures provided under SFAS No. 119 for a sample of banks in 1993 and 1994. Findings from the study suggest that derivatives' fair value estimates explain cross-sectional variation in bank share prices incremental to fair values of the primary on-balance accounts (i.e., cash, investments, loans, deposits, and debt).

3.2. International research

Because Australian and UK GAAP permit upward asset revaluations but, as with US GAAP, require downward revaluations in the case of asset impairments, several studies examine the dimensions of value relevance of revaluations in these countries.[13] Most studies, including Easton et al. (1993), Barth and Clinch (1996), Barth and Clinch (1998), and Muller and Riedl (2002), focus on tangible fixed asset revaluations. These studies are potentially informative to standard-setters as they consider requiring disclosure or recognition of tangible fixed assets at fair value. Such assets, of course, are likely to fall into the Level 3 category in the fair value measurement hierarchy, and hence are likely to be subject to a greater amount of management discretion than is the case for financial assets.[14]

Using a sample of Australian firms with data from 1981–1990, Easton et al. (1993) estimate annual return regressions and find that asset revaluations of tangible long-lived assets have incremental explanatory power relative to earnings and change in earnings. Also using a sample of Australian firms but from a later period, 1991–1995, Barth and Clinch (1998) estimate annual stock price regressions to determine if financial, tangible, and intangible asset revaluations have incremental explanatory power relative to

[11] Another equally plausible explanation is that investment securities' fair value gains and losses are naturally hedged by fair value changes of other balance sheet amounts, which are not included in the estimating equations. Ahmed and Takeda (1995), who include other on-balance sheet net assets in the estimating equations, provide support for this explanation by providing evidence of incremental explanatory power for unrecognised securities gains and losses in explaining banks' stock returns.

[12] Of particular interest to bank regulators, Barth et al. (1995) also find that banks violate regulatory capital requirements more frequently under fair value than historical cost accounting, and fair value regulatory capital violations help predict future historical cost regulatory capital violations, but share prices fail to reflect this increased regulatory risk.

[13] See Black et al. (1998:1,289–1,291) for a brief discussion of accounting standards applicable to asset revaluations in the UK, Australia, and New Zealand.

[14] In response to concerns about the effects of inflation on balance sheets and income statements, the FASB issued SFAS 33, *Financial Reporting and Changing Prices* (FASB, 1979), which mandated disclosure of *current cost* information for tangible assets, principally inventories and plant and equipment. The current cost data are similar to revaluation data. The general conclusion reached by studies assessing the value relevance of the current cost data is the failure to detect, relative to historical cost earnings, incremental explanatory power for stock prices or returns for any of the alternative income measures based on the current cost information (see, e.g., Beaver and Landsman, 1983; Beaver and Ryan, 1985). Reasons for the lack of incremental explanatory power include unbiased estimation error and bias arising from exercise of managerial discretion. Factors contributing to the low data quality were that the data were unaudited and subject to a 'sunset' provision, whereby the disclosure requirement would expire after five years unless the FASB made the provision permanent (it did not). See Barth et al. (2001, section 2.2) for more discussion.

operating earnings and equity book value less the book value of revalued assets. Consistent with US-based research, Barth and Clinch (1998) find revalued investments are incrementally priced. Contrary to the view that intangible asset revaluations are likely to be noisy and uninformative, the study finds a positive association between such revaluations and share prices. However, with the exception of mining firms, they fail to find a significantly positive association between share prices and property, plant and equipment revaluations. Regarding managerial discretion in determination of revaluation amounts, the study also finds little evidence indicating independent appraiser-based revaluations are more relevant than director-based estimates. This finding is of potential importance to the FASB and IASB, as it bears directly on the issue of whether Level 3 fair value estimates will lack value relevance because investors will be concerned about managerial manipulation and measurement error. In particular, the study concludes that the findings suggest that the relevance of directors' private information about asset fair values has the potential to outweigh the effects of self-interest on the estimates.

In contrast to the findings in Barth and Clinch (1998), Muller and Riedl (2002) find evidence that the market finds asset revaluations estimates made by external appraisers are more informative than those made by internal appraisers. Using a sample of UK investment property firms for the period 1990–1999, the study shows that information asymmetry as measured by the adverse-selection component of the firms' average stock price bid-ask spread in the seven months subsequent to fiscal year-end is greater for firms employing internal appraisers. Muller and Riedl (2002) interpret this as evidence that the market finds asset revaluation estimates based on external appraisals to be more reliable. One potential explanation for the difference in findings between the two studies is that the Muller and Riedl (2002) research design is more powerful than the Barth and Clinch (1998) research design. However, this conclusion must be made with caution because the Muller and Riedl (2002) sample of firms is limited to a specialised industry, investment property firms, where external appraisals are an institutional feature. Moreover, the Muller and Riedl (2002) findings do not suggest that the market finds asset revaluations made by internal appraisers to be uninformative.

Cotter and Richardson (2002) also find that external appraisals are more reliable than those made by directors for a sample of Australian firms from 1981–1994. Their measure of reliability is the amount of subsequent years' reversals of upward asset revaluations. However, Cotter and Richardson (2002) also find that independent appraisers are more likely to be used for revaluations of land and buildings and directors are more likely for investments, plant and equipment and identifiable intangibles. The authors interpret this as evidence of firms relying on directors' superior knowledge of asset values for assets that are more specialised and difficult for outside appraisers to value.

Aboody et al. (1999) examine the performance prediction and pricing implications of fixed asset revaluations for a sample of UK firms from 1983–1995. The study finds that upward revaluations are significantly positively related to changes in future performance, measured by operating income and cash from operations. Regarding pricing, using annual regressions similar to those employed in Easton et al. (1993) and Barth and Clinch (1998), the study finds that current year revaluations are significantly positively related to annual stock returns, and current year asset revaluation balances are significantly positively related to annual stock prices. However, regarding the effects of managerial incentives to manipulate asset revaluation amounts, the study also finds that relations between revaluations and future performance and prices are weaker for higher debt-to-equity ratio firms. That is, managerial manipulation affects the usefulness of asset revaluations made by managers of firms facing the pressures of financial distress.[15]

One reason accounting standard setters state in support of fair value measurement is that it mitigates incentives for firms to time asset sales to manage earnings. If gains and losses are recognised in income when assets are revalued and gains on sale are based on fair value rather than historical cost, then the incentive to time asset sales for earnings management purposes evaporate. Black et al. (1998) find evidence in support of this reasoning. In particular, for a sample of UK, Australian, and New Zealand firms in 1985–1995, the study finds no difference in earnings management behaviour for asset revaluing and non-asset revaluing firms. The finding does not hold for UK firms in the pre-1993 period when asset-revaluing firms were permitted to include in income gains and losses based on historical cost, which is further evidence that mandating fair value measurement for gain/loss recognition for firms that elect to use fair value measurement reduces the practice

[15] In the discussion of Aboody et al. (1999), Sloan (1999) states that the study's findings are inconclusive because of the potential confounding effects of other variables unrelated to, but correlated with asset revaluations. Aboody et al. (1999) do include several controls for such omitted variables, although it is never possible to determine whether important controls are absent. This criticism applies, of course, not just to Aboody et al. (1999) but also to all similar pricing studies.

of timing asset sales for income management purposes.[16,17]

One interesting study of Danish banks, Bernard et al. (1995), focuses on the impact of fair value accounting on bank regulatory capital as opposed to the value relevance of fair values for investors. Denmark is an interesting research setting because Danish bank regulators have used mark-to-market accounting to measure regulatory capital for a long period of time. Bernard et al. (1995) find that although there is evidence of earnings management, there is no reliable evidence that 'mark-to-market' numbers are managed to avoid regulatory capital constraints.[18] In addition, when compared to US banks, Danish banks' mark-to-market net equity book values are more reliable estimates of their equity market values, thereby providing indirect evidence that fair value accounting could be beneficial to US investors and depositors.[19]

3.3. US-based stock option research

As noted above, estimates of employee stock options fair values have been required to be disclosed for several years under SFAS No. 123. Several studies examine the value relevance of such disclosures, including Bell et al. (2002), Aboody et al. (2004), and Landsman et al. (2006). Findings in Bell et al. (2002) differ somewhat from those in Aboody et al. (2004), although both studies provide evidence that employee option expense is value relevant to investors. Landsman et al. (2006) provide theoretical and empirical support for measuring the fair value of employee stock option grants beyond grant date, with changes in fair value recognised in income along with amortisation of grant date fair value.

Because quoted prices for employee stock options typically are not available because of non-tradability provisions, the fair value estimates are based on models that rely on inputs selected by reporting firms. Aboody et al. (2006) find evidence that firms select model inputs so as to manage the pro forma income number disclosed in the employee stock option footnote. This finding is potentially relevant to accounting standard-setters as well as bank regulators in that it is additional evidence that managers facing incentives to manage earnings are likely to do so when fair values must be estimated using entity-supplied estimates of values or model inputs if quoted prices for assets or liabilities are not readily available.[20] If managers have the incentive to use discretion when estimating fair values of on- and off-balance sheet asset and liability amounts when such values are not recognised in the financial statements, it is reasonable to assume the incentive will only increase if fair value accounting is used for recognition of amounts on the balance sheet and in the income statement.

4. Fair value implementation issues

Estimating fair value, i.e., exit value, for assets and liabilities is relatively easy if they are actively traded in liquid markets. The problem becomes more complicated if active markets do not exist, which is why the FASB offers Level 2 and Level 3 estimation categories in SFAS 157. Although absence of active markets is an obvious problem for non-financial assets, the problem is no less obvious for financial instruments, particularly if the financial instrument is a compound instrument comprising several embedded option-like features, values for which depend on inter-related default and price risk characteristics.

In this section, I discuss issues relating to implementation of fair value estimates when market prices for particular financial instruments are not readily available by focusing on findings from two related studies by Barth et al. (1998, 2000) on the use of binomial option pricing models to estimate fair values for corporate debt and its components. The issues I discuss should provide some insights to the FASB and IASB regarding the relevance and reliability of Level 3 fair value estimates.

4.1. Binomial option pricing of corporate debt

Barth et al. (1998) uses a binomial option pricing model to estimate the fair values of corporate debt and its components, i.e., conversion, call, put, and sinking fund features, to provide evidence on

[16] In another study using the same sample of firms as that used in Muller and Riedl (2002), Dietrich et al. (2001) find that UK investment property firms in the pre-1993 period appear to select the valuation approach – historical cost or fair value – that results in smoother earnings. Because post-1993 UK firms were required to disclose income from property sales separately on the income statement, the authors interpret this as evidence that changes in disclosure requirements altered manager's use of property sales to smooth earnings. Dietrich et al. (2001) also find evidence that property appraisal estimates of fair value better reflect asset selling prices than historical costs, and interpret this as evidence consistent with greater reliability of fair value estimates, at least with respect to assets that are ultimately disposed.

[17] See Lin and Peasnell (2000) for a discussion of managerial strategic considerations in the timing asset revaluations. The study provides evidence that firms appear to time asset revaluations to offset the effects of so-called equity depletion arising from immediate write-off of goodwill.

[18] The ability to mark-to-market an asset suggests the existence of a reasonably liquid market for the asset. From this perspective, mark-to-market values can be viewed as approximating Level 1 or Level 2 fair value estimates.

[19] Bernard et al. (1995) caution that drawing inferences from the Danish experience with fair value accounting for banks regarding the benefits of requiring fair value accounting for US banks is subject to many caveats. These include differences in the relative size of the US and Danish banking sectors, as well as relative differences in US and Danish banking regulatory systems.

[20] See also the discussion above of the Barth et al. (1996) findings relating to loans fair values estimates by banks with lower regulatory capital.

the relevance and reliability of estimated fair values. A companion study, Barth et al. (2000), describes details of how the binomial model is implemented. The 1998 empirical study is based on data from 1990 for a sample of 120 publicly traded US firms that have corporate debt with multiple embedded option features. The binomial model the study implements is based on the models of Cox et al. (1979) and Rendleman and Bartter (1979), and considers directly only default risk, but includes information in the interest rate yield curve.

Findings from Barth et al. (1998) reveal component value estimates are relevant in that they represent large fractions of estimated total bond fair value. In addition, implementing a fundamental components approach in which call options are classified as assets, conversion options as equity, and put options as debt, indicates there are material changes to recognised balance sheet accounts and debt-to-equity ratios for sample firms.[21] The study also finds that estimates of component fair values depend on whether a bond has multiple features. For example, the value of the conversion feature for a convertible, callable bond depends on the value of the call feature and vice versa. In addition, because components' values are interdependent, the order in which components are considered when estimating each bond's total fair value can materially affect each component's estimated fair value. This issue is particularly important if a fundamental components approach is used for separate recognition of bond components as assets, liabilities, and equity.

However, additional evidence in Barth et al. (1998) suggests model estimates of total bond value may lack reliability. In particular, when the authors re-estimate bond fair values excluding from the sample those bonds with available market prices (such bonds comprise approximately half of sample bonds), estimated bond values for those bonds that are not publicly traded differ significantly from value estimates when all bonds are included in the estimation procedure. This finding suggests that financial instruments' fair value estimates are sensitive to whether actual market price information from other instruments an entity has on its balance sheet is available for use as model inputs.

Barth et al. (1998) reach several conclusions regarding limitations to implementation of binomial option pricing models for estimating bond fair values that generalise to all financial instruments issued or held by an entity. First, the authors had to make several educated guesses for values of model inputs (e.g., conversion schedules and equity volatility). In principle, managers of the reporting entities likely have access to better information than financial statement users (including academic researchers), and the authors suggest that fair value estimates could improve if firms were required to disclose them.[22] Second, models quickly become too complex and difficult to implement if they are to incorporate all of the dimensions of risk and value that can affect an instrument's fair value. For example, presently, few models consider both interest rate and default risk. In addition, financial instruments' fair values are interdependent. For example, the fair value of one debt instrument issued by an entity is dependent upon actions that holders of another debt instrument issued by that entity can take. The model Barth et al. (1998) implement considers some sources of bond value interdependence (e.g., debt priority) but basically ignores the issue because of its complexity. The issue of financial instruments' value interdependence is another illustration of the issue raised by Barth and Landsman (1995) that a financial instrument's fair value – i.e., its exit value – may not adequately capture the value of the instrument to the entity that owns it. When an asset's value-in-use departs significantly from its exit value because of value interdependence, fair value will be less informative to investors who are using the information to value the entity's equity.

4.2. *Manipulation of model inputs*

Having to rely on managers' estimates of asset and liability fair values introduces the general problem of informational asymmetry.[23] That is, in the case of Level 3 fair value estimates, managers have private information regarding appropriate values to select for model inputs as well the true

[21] See FASB (1990, 2000) for a description of the fundamental components approach to accounting for complex financial instruments. In addition to the FASB, several other standard-setters have considered or require separating compound financial instruments into components, including the CICA (Section 3860 of the *CICA Handbook*, 'Financial Instruments – Disclosure and Presentation') and the AASB (AASB Accounting Standard 1033, *Presentation and Disclosure of Financial Instruments*). Under the revised version of IAS 32 (IASB, 2003a), firms that issue compound financial instruments with debt and equity components must account for, and present separately, the components according to their substance based on the definitions of liability and equity.

[22] Relatedly, as noted above, Cotter and Richardson (2002) also suggest managers have superior information about non-investment property values and therefore rely on director estimates of fair value rather than appraisals for these assets. However, this does not preclude requiring managers to disclose assumptions they make as inputs to the valuation process.

[23] This is not to suggest that informational asymmetry is peculiar to fair value estimation by managers. Informational asymmetry arises in accounting whenever managers have discretion regarding the timing or amount of non-market adjustments to amounts arising from past transactions, e.g., allowances bad debt, allowances for loan losses, and impairment charges.

underlying economic value of an asset (or liability) to the firm.[24] Informational asymmetry creates two somewhat different problems, adverse selection and moral hazard.

An important implication of adverse selection is that the market will tend to value apparently similar, but different, assets held by two firms similarly when assessing their fair values and the values of the firms' equities. Thus, for example, in the absence of credible and verifiable information, two property investment firms that are otherwise equivalent except one has a higher quality portfolio of investments than the other will have their stocks valued similarly by the securities market. How can the firm with the higher quality portfolio of investments signal its fair value estimates are a more reliable indicator of economic value? One solution is for the firm to sell a portion of its portfolio to establish that the selling price is close to the fair value estimate of the property sold. Another solution is to permit the firm to disclose its valuation assumptions, the quality of which can be verified by others. For example, the firm can select a high cost external appraiser to value its properties. Both of these solutions illustrate the same point: for the signal to be credible, it must be costly, but less costly for the property investment firm with the higher quality investment portfolio. The investment firm with the lower quality portfolio could mimic the actions of the higher quality firm, but doing so would be more costly as the market would learn its portfolio of investments was of lower quality.[25]

The problem of moral hazard is that managers will tend to use their private information to their personal advantage by manipulating the information that they disclose to the securities markets and regulators. For example, under a fair value measurement regime, managers have the incentive to value assets upward to increase income and their bonus-based compensation, and to time any impairments or upward revaluation reversals to minimise the effect on their compensation, e.g., in a period when the firm's income is otherwise depressed and the manager will not get any bonus regardless. This is the so-called 'big bath' problem.

As noted above, the findings in Aboody et al. (2006), which indicate that managers select model parameters to manage estimates of disclosed employee stock option fair values, raise the broader question of whether managers will behave similarly when selecting model parameters for fair value estimates of other financial instruments, including those whose values are recognised in the body of the financial statements. The Barth et al. (1998) conclusion that managers can provide better estimates of bond fair values because they have access to private information, presumes implicitly that managers apply their private information in a neutral fashion – i.e., they do not succumb to the temptation to manipulate bond fair value estimates for private gain.

If fair value accounting for financial instruments or non-financial assets is generally applied for financial statement recognition, accounting standard-setters and securities regulators face the challenge of determining how much latitude to give managers when they estimate fair values, balancing the benefit of permitting managers to reveal private information, thereby mitigating the adverse selection problem, and the moral hazard cost of their exercising discretion to manipulate earnings and balance sheet ratios that affect contracting relationships with lenders and, in the case of financial institutions, financial statement-based regulatory capital used by bank regulators interested in stability of the banking system.

Although the securities market tends to act as a disciplinary force to keep firms and its managers honest, it does so with a lag. One solution advanced here to the problem of balancing the adverse selection and moral hazard problems is to require extensive disclosure of the underlying assumptions used when estimating fair values, whether the fair value estimates be Level 1, 2, or 3. For example, in the case of Level 2 estimates, investors should be provided with sufficient information to determine which assets or liabilities are used as a basis for comparison. In the case of Level 3 estimates, investors should have access to all relevant model inputs. The FASB appears to require ample disclosure in SFAS 157. For example, regarding Level 3 estimates the FASB (FASB, 2006a, p. 12, para. 32) requires that 'the reporting entity shall disclose information that enables users of its financial statements to assess the inputs used to develop those measurements and for recurring fair value measurements using significant unobservable inputs (Level 3).' Whether investors find SFAS 157 disclosures to be useful in assessing the relevance and reliability of the firms' fair value estimates is an empirical matter that will undoubtedly be the subject of much future study by accounting researchers.

[24] Managers also have private information regarding appropriate Level 1 or Level 2 fair value estimates (see discussion of Cotter and Richardson, 2002, in footnote 22).

[25] One can view the election of fair value or historical cost (with impairment) measurement that was permitted under UK GAAP as an opportunity for higher quality firms to signal their quality through the selection of fair value. For example, suppose both a high quality and low quality property investment firm selected fair value measurement and revalued their assets by the same amount. The firm with the lower quality property investment portfolio would be more likely to reverse the revaluation in future years, which would hurt the firm's credibility with the financial markets, thereby reducing its incentive to revalue its assets, and possibly avoid election of fair value measurement.

4.3. Fair values measurement error

One problem that remains even in the absence of managerial manipulation of fair value estimates is that fair value estimates of assets and liabilities are likely to contain measurement error. If the findings in Barth et al. (1995) relating to banks' investment securities generalises to other bank assets and liabilities, implementation of a full fair value model for recognition of financial instruments at fair value could yield unrecognised gains/losses that could cause earnings (and, in the case of banks, regulatory capital) to be more volatile than earnings based on the current historical cost model. This would be expected to occur particularly if measurement error in assets' fair values – which is likely to be positively correlated across assets – is not fully offset by measurement error in bank liabilities' fair values.

Of course, not all earnings volatility arising from the application of fair value accounting is the result of measurement error. Barth (2004) makes the observation that there are three primary sources of 'extra' volatility associated with fair value-based accounting amounts relative to those determined under historical cost. The first is true underlying economic volatility that is reflected by changes in the fair value of assets and liabilities. The second is volatility induced by measurement error in estimates of those fair value changes. The third, induced volatility arising from using a mixed-attribute model, would be less of a concern if all instruments are recognised at fair value, or if a firm elects the fair value option that is permitted under IAS 39.

Before leaving the discussion of measurement error, it is important to note that although fair value estimates of assets and liabilities likely contain measurement error relative to true economic values, so do historical cost-based book value estimates.[26] The key question for policy makers and academic researchers alike is whether fair value-based financial statements improve information investors receive relative to information provided by historical cost-based financial statements. The overall conclusion from the research I review is that investors do indeed benefit from having access to fair value information.

5. Concluding remarks

This paper reviews the extant capital market literature that examines the usefulness of fair value accounting information to investors. In doing so, I highlight findings that are of interest not just to academic researchers, but also to practitioners and standard-setters as they assess how current fair value standards require modification, and issues future standards need to address. Taken together, the research findings suggest that disclosed and recognised fair values are informative to investors, but that the level of informativeness is affected by the amount of measurement error and source of the estimates – management or external appraisers. I also provide a discussion of implementation issues of determining asset and liability fair values.

Fortunately for academic accounting researchers, the IASB and FASB continue to issue standards relating to fair value measurement, disclosure, and recognition, providing ample opportunity for future research. Findings from extant studies of firms in the US, UK, and Australian capital markets suggest that investors are provided with information that is somewhat reliable and relevant. Whether relevance and reliability of asset and liability fair values improves with the new measurement and disclosure standards and with fair value recognition extended to a broader set of assets and liabilities than has been the case to date remains to be seen. In addition, because standards issued by the IASB either are or will be required to be adopted by firms in a great number of countries around the world, researchers will have an opportunity to examine how the relevance and reliability of disclosed and recognised fair value amounts vary across the many countries, where depth of markets for assets and liabilities and other institutional features that can affect fair value estimates are likely to differ.

[26] As noted above (footnote 23), historical cost-based estimates are also subject to managerial discretion.

Accounting and capital market measures of banks' risk: evidence from an emerging market

Abstract

Depending on the purpose, both accounting and market information can be used as appropriate measures to assess bank's risk. According to Bliss and Flannery (2001), the market is likely to provide supervisors with signals that can be used to improve control quality through bank supervision. In this context, the prudential supervision reforms proposed by Basel Committee (BIS 2003) are based on three pillars including one calling for greater use of market discipline. However, market discipline can lead to a safe and efficient bank only when the market is sufficiently developed and its participants are competent and motivated to monitor banks.

Several authors have focused on the banking systems of developed countries and found that there are significant relations between accounting and market risk measures. Nevertheless, given the significant role of banking systems in emerging countries and the need to promote their stability, these countries are also preparing the adoption of prudential regulation. Therefore, it seems very interesting to examine the market ability to reflect the risk taking by banks in an emerging country. By applying a panel data analysis on 10 listed Tunisian commercial banks during the period of 1998-2007, the results show that neither the capital measure of total risk nor the systematic risk are linked to the accounting measures of total risk, leverage risk and credit risk of banks. Therefore, we can conclude that capital market is not able to reflect accounting information; therefore, prudential Tunisian authorities have to focus on accounting measures to assess the risk-taking by banks.

Keywords: risk accounting measures, risk capital market, total return risk, systematic risk, specific risk.
JEL Classification: G21, G30, G32, M41.

Introduction

According to the objective, in order to choose a suitable measurement to evaluate the banks' risk taking, one can use accounting information as well as capital market measures of risk. If a banking regulator seeks to evaluate the financial health of a bank, a CAMEL rating, made up of accounting variables would be preferred. However, according to Bliss and Flannery (2001), the market is likely to provide to the prudential authorities signals which they can exploit to improve control quality and the banking supervision. In this context, the prudential reforms proposed by the Basel Committee (BIS 2003) rest on three pillars including one recommending the improvement of market discipline. Nevertheless, there are many conditions that encourage the success of market discipline. First of all, the market has to be competitive and to function satisfactorily. If the capital market is not sufficiently active and the investors are not informed properly, nor sufficiently qualified and reasonably encouraged to control the banks, the information existing on the market can never reflect the risk undertaken by the banks and the signals can not be exploited by the regulator. So, it is of major interest to evaluate the aptitude of the market to reflect the risk taking by banks and their quality of the credit.

Since the work of Pettway (1976), several other authors[1] were interested in establishing the relation between risk accounting measures and those apprehended on the stock markets. These various studies made exclusively on the data of the developed countries' banks found that there are significant relations between the accounting and market measures of risk. Given the importance of the banking industries role within the emerging countries and the need for promoting their stability, the Official Authorities of these countries prepare, in their turn, the adoption of the Basel II prudential reforms.

For the reason of the recent reforms to stimulate and promote the market discipline and to improve the control quality of the Tunisian banks, we estimate that it is interesting to examine the aptitude of the Tunisian capital market to reflect the risk taking by the banks. In order to achieve this goal we will use the panel data analysis of the 10 listed commercial banks over the period of 1998-2007.

1. Relations between accounting and capital market measures of banks' risk: literature review

In a context of instability, such is the case of these last years, risk accounting measures can be differentially affected by economic environment and their relative importance can change over time (Agusman et al., 2008), so it becomes very important to use capital market measures. However, the data of the market can be exploited only if the

[1] Jahankhani & Lynge (1980), Lee & Brewer (1985), Brewer & Lee (1986), Mansur et al. (1993), Elysiani & Mansur (2005).

investors are properly informed and sufficiently qualified and incited to control the firms.

Several previous researches concerned with the problem of the relationship between the two various risk measures, namely accounting and capital market measures of risk. Treating this problem on the data of the American banks, Jahankhani and Lynge (1980), Lee and Brewer (1985), and Mansur et al. (1993) found significant relations between these two kinds of measures. Elyasiani and Mansur (2005) examined the Japanese banks using a GARCH model and also found a significant relation between accounting and capital market measures of risk.

In fact, the interest to this topic goes up for more than three decades. The pioneer was Pettway (1976) who explored the relation between these two kinds of risk measures. He studied the impact of the bank's capital level and other accounting variables on market beta and on the price to earning ratio. He noted that the amount of bank equity had an effect on market beta in 1974 and on the price to earning ratio in 1972 and 1974. Pettway and Sinkey (1980) developed an early warning system using, at the same time, the accounting and market information. Thereafter, Jahankhani and Lynge (1980) examined a sample of 95 commercial banks in the United States during the period of 1972-1976. They considered the market beta as a dependent variable, and noted that there were several factors which acted on the systematic risk such as the dividends yields and the coefficient of variation of the deposits. In the same way, they noted that accounting measures of risk explained 26% of systematic risk variability. Moreover, when the total risk is considered as a dependent variable, all the variables except for the ratio of loans/deposits prove statistically significant relations, and 43% of variability in the dependent variable are explained.

Also, Rosenberg and Perry (1981) examined 124 American banks between March 1969 and June 1977. The systematic and specific risks are used as dependent variables and a certain number of accounting ratios are used as independent variables. They noted that the most important predictive factors of beta are the size of the bank, the *dividend yield*, equity capitalization, and the asset to long-term liability ratio. In addition, the income variability, the leverage ratio and the accounting measure of beta are the most important predictive factors of the specific risk

In the same way, Karels et al. (1989) examined the relationship between the total risk, the systematic risk, and the specific risk and an accounting measure of risk, namely, the capital ratio. They examined these relations using a sample of 24 American banks for the period exceeding 30 quarters between 1977 and 1984. They noted that, as predicted, the coefficients of correlation between the capital ratio and the systematic risk were negative in each of the thirty quarters. They also explained that higher capital adequacy ratios provided a greater buffer against default and, therefore, implied less risk.

Mansur et al. (1993), using also a sample of American banks, examined the data of 59 institutions, chosen randomly, during the period of 1986-1990. Using the market beta as a dependent variable, they announced that only the loan loss reserve to total loans ratio and the coefficient of variation of deposits were statistically significant. They found that the independent variables explained 35% of the variability of the systematic risk. Moreover, using the total risk as a dependent variable, only the liquidity ratio was found statistically significant, and it explained 24% of the variability of this risk. In a general way, these studies indicate that accounting measures and the capital market measures of risk are interdependent in the case of the American banks.

Finally, in their recent work, Agusman et al. (2008) were interested in this topic and concentrated particularly on the banks' data of certain emerging countries, especially the banks of the Asian countries. The sample consisted of 46 institutions observed over the period 1998-2003. By applying the panel data analysis, their results show that the standard deviation of the return on assets (ROA) and loan-loss-reserves-to-gross-loans are significantly related to total risk. Also, gross loans to total assets and loan loss reserves to gross loans are significantly related to specific risk. Agusman et al. (2008) specified, consequently, that in these countries the specific risk of the banking firms is more important than the systematic risk.

The question which arises in this case, is such a result can be generalized to the other emerging countries, where the banking environment is instable and where the insolvency risk is omnipresent, such as for Tunisia? The answer to this question is of a major interest, because these countries are preparing to adopt the fundamental principles of the Basel II agreement which rests primarily on the market discipline.

2. Data and empirical methodology

The aim of this section is to examine the aptitude of the capital market to reflect the risk undertaken by Tunisian listed commercial banks. This topic was the subject of several previous researches that often use the prices of the subordinate obligations (Adrian Pop, 2005). Alternatively, there were few studies which treated this topic using the stock prices. The interest to use the stock prices rises from the weak liquidity of the other compartments of the financial markets or even from the inexistence of a market for the subordinate debts, such as the case of Tunisia. Among the studies which used the stock prices to evaluate the aptitude of market data to reflect the risk undertaken by banks is the study by Distinguin, Rous and Tarazi (2005) which relates to a sample of European banks for the period going from 1995 to 2002. The methodology used by these authors is in forecasting the deteriorations of the financial situation of banks which are identified using the rating deteriorations published by the three principal rating agencies (Fitch, Standard & Poors and Moody's). Gropp, Vesala and Vulpes (2005) also used the public information carried out by the agencies charged to evaluate the financial health of the borrowers. These authors justified the use of this kind of information by the insufficient number, in the case of Europe, of the officially declared banking bankruptcies, which does not make it possible to form a representative sample and also, by the difficulty of access to the internal notation systems of the banking supervision authorities used by the American studies (e.g., Curry, Elmer and Fissel, 2003; and Gunther, Levonian and Moore, 2001).

However, for the case of Tunisia, not all the listed commercial banks have a solicited notation, and if there are some banks which have it, this notation is available only for the few recent last years; therefore, it will not enable us to build a representative sample. So, to achieve our purpose, we are limited to check if there is a relation between the risk accounting measures and the capital market risk measures. Thus, we have chosen to use the stock prices to apprehend the total risk, the systematic risk and the specific risk of each bank. We will use these measures as dependent variables and we will examine the relation which can exist between these measures of risk and accounting measures of risk, namely, the total risk, the leverage risk, the credit risk and the liquidity risk.

2.1. Data and sample. In order to calculate the total risk, the systematic risk and the specific risk of the various banks, we obtained the data from the Web site of "La Bourse des Valeurs Mobilières de Tunis"[1]. The accounting data are collected from the financial statements and the annual reports for each bank. Data concerning the nonperforming loans and the loans loss reserves, which we will use as indicators of credit risk, are obtained from the services of the central bank of Tunisia. These data are rarely disclosed in the banks' annual reports. The collected data enabled us to have a sample composed by the ten listed commercial Tunisian banks over the period of 1998-2007. Because of the adoption of the new Tunisian accounting system in 1997 we could not take into account one longer period.

2.2. Specification of the empirical model. This study tests empirically the relations between capital market risk measures and accounting ratios using the following general model:

CMR= f (Total Risk, Leverage Risk, Credit Risk, Liquidity Risk, Control Variables) + error, (1)

where, *CMR* represents the capital market risk measures including the total risk, the systematic risk and the specific risk.

The Capital market Total risk (σ_i) is the annualized standard deviation of the banks' daily stock returns.

The systematic and specific (idiosyncratic) risk measures are calculated using the following market model. This model is estimated for each year for each bank:

$$R_{it} = \alpha_i + \beta_i R_{mt} + \varepsilon_{it}, \quad (2)$$

where i and t denote bank and time, respectively; R is the bank's equity return; Rm is the return on TUNINDEX market index; α is the intercept term; ε is the residuals. β_i is the systematic risk of bank i. Finally, the specific risk is calculated as the standard deviation of residuals of Eq (2) for each year and for each bank.

The three dependent variables, presented above, are regressed to several accounting measures of risk used to reflect the total risk (SDROA and Z-score), the leverage risk (EQTA and DEPEQ), the liquidity risk (LIQATA) and the credit risk (LLPGL, LLRGL and NPLGL).

The total risk accounting measure (SDROA) is the standard deviation of return on assets calculated estimated in a three-year moving window of annual observations. This variable is used by Brewer and Lee (1986), Shiers (1994) and Agusman et al. (2008). Moreover, we introduce in the regression function a second measure of bank's total risk, namely the Z-score[2]. This measurement was not used by the previous researches which seek to

[1] www.bvmt.com.tn

[2] The Z-score appreciates the total insolvency risk of a bank. This measure was proposed by Par Roy (1952), Blair and Heggestad (1978), Boyd and Graham (1986) and used by Goyeau and Tarazi (1992). Z-score = (ROA+K/A)/ SDROA, where ROA is the return on assets, SDROA is the standard deviation of ROA, and K/A is the capital on total assets ratio.

examine the relation between the risk calculated by the accounting ratios and capital market risk measures. The Z-score was introduced in the regression function as an inverse form, i.e. 1/Z, so as to make the interpretation of the signs of coefficients comparable. Otherwise, a high Z-score means less insolvency risk whereas a high total risk, the systematic risk or the specific risk indicate more risk. We also introduced the inverse form of Z-score to alleviate the muticollinearity problem with the indicator of credit risk (EQTA).

We expect to have a positive sign between these accounting measures (SDROA, Z-score) of total risk and the capital market measures of risk.

The leverage risk measure (EQTA) is the ratio of book value equity to total assets, which is the proxy for the Cooke ratio. This measure was used by Pettway (1976), Jahankhani and Lynge (1980), Brewer and Lee (1986) and Karels et al. (1989). We expect to have a negative sign between this accounting measure of leverage risk and the capital market risk measures. The second measure (DEPEQ) that we propose to introduce in the regression function to appreciate the leverage risk is the total deposits held by the bank to the book to value equity. This measurement was not used by the previous studies but we estimate that it is relevant to explain the leverage risk of the banks because the deposits are ensured by the organization of deposits insurance. Thus, the amount of the deposits is high; the incentive with moral hazard of the bank is high, contrary to the other uninsured loans. Consequently, a higher ratio of deposits on book value equity corresponds to a more important leverage risk. We expect that the correlation between this ratio and the capital risk measures is positive.

The liquidity risk (LIQTA) is apprehended by the ratio of liquid assets to gross loans. This measure was used by Jahankhani and Lynge (1980) and by Mansur et al. (1993). We expect to have a negative sign between this ratio and the capital market measures of risk of the market.

The accounting measure of credit risk (LLPGL) is the ratio of loan loss provisions to gross loans. This variable was used by Mansur et al. (1993) and by Hassan (1993). We expect to have a positive sign between this accounting measure of credit risk and the capital market risk measures. As alternative measures of credit risk we use the ratio of loan loss reserves to gross loans (LLRGL), used previously by Agusman et al. (2008) and the ratio of nonperforming loans to gross loans (NPLGL). This last ratio has not been already used in this context, but it represents a relevant measure of credit risk largely used as an indicator of the asset quality of the banking firm.

In order to better determine the impact of accounting measures of risk on those of the capital market, we controlled for the effects of banks' size, of banks' ownership (private or public) and of the quantity of information disseminated by the banks on their risk profile in their annual reports.

In fact, it is very important to control for the effect bank size because the banking regulation exerts a discipline on the behavior of the risk taking by the banks. But this discipline is imperfect for the case of big banks. Indeed, the bankruptcy of a big bank could result in very important costs, and consequently, these establishments generally anticipate a non intervention of the regulator. Their anticipations of the non interventionism of the regulator rise from the problem of *"too big to fail"*. Indeed, this behavior can generate incentives for the banks to engage in too risky activities. To apprehend the bank size we used the natural logarithm of total assets.

Moreover, the ownership of the bank can have a considerable effect on its level of the risk. In fact, the economic literature stipulates that the raison d'être of the public banks is due to the existence of insufficiencies on the financial and credit markets (Stiglitz and Weiss, 1981; Greenwald and Stiglitz, 1986). Indeed, the private banks which search, generally, to maximize their profits do not take into account the social returns in their projects financing decisions. Consequently, the aim of public banks is to enhance the economic development and to improve the social well-being (Stiglitz, 1993). According to this theory, the object of the public banks must be to direct the financial resources towards projects which are socially advantageous or to firms which do not have an access to other sources of financing, but have high risks. To take into account the bank ownership in the regression function we have created a dummy variable which equals 1 if the bank is private and 0 if the bank is public.

Finally, the interest to control the effect of the information quantity disseminated to the investors in the annual reports, is that the banks which reveal more information choose a lower level of risk (Cordella and Yeyati, 1998; Boot and Schmeits, 2000). The choice of a low level of risk by these banks is due to the fact that those are exposed to the market discipline, thus, they would be penalized by the investors if they choose a high level of risk. This effect is weak if the information given to the investors is limited and it is absent if the investors do not know the risk profile of the banks. To take into account the impact of information quantity on capital market measures of risk we introduce in the regression function an index drawn on a previous study of Nier and Baumann (2006). It synthesizes disclosure based on annual reports information. In Table 3 of the Appendix we present a summary of 17 categories used to construct the composite disclosure index (named Index). It is defined as: $Index = \frac{1}{17}\sum_{i+1}^{17} S_i$, where each sub-index S_i can be related to one or more sources of risk. For all subindices, we assign 0 if there is no information about the corresponding categories and 1 if there is at least one informed category. Then, the composite index will range between 0 and 1.

Finally, the general model (Eq1*)* presented above is detailed as follows:

$CMR = \alpha_0 + \alpha_1(SDROA) + \alpha_2(z\text{-}score) + \alpha_3(EQTA) + \alpha_4(DEPEQ) + \alpha_5(LIQTA) + \alpha_6(LLRGL) + \alpha_7(NPLGL) + \alpha_8(LLPGL) + \alpha_9(Index) + \alpha_{10}(Size) + \alpha_{10}(PRIV) + error.$

3. Empirical results

3.1. Descriptive analyses. Table 1 presents descriptive statistics of the various dependent and independent variables, and it shows that the data contain negative values. This table shows that the standard deviation is very high for the majority of the variables. Thus, we can conclude that the data are not homogeneous and they require additional tests so being able to choose the suitable estimator.

Table 1. Descriptive statistics of dependent and independent variables

Variables	Obs	Mean	Std. dev.	Min	Max
Total risk	100	1.453849	1.0603	.15194	10.66866

PRIV	100	.58	.496045	0	1

3.2. Regressions results. Baltagi (2001) and Hsiao (1986) indicate panel data methodology controls for individual heterogeneity, reduces problems associated with multicollinearity and estimation bias, and specifies the time-varying relation between dependent and independent variables. This study uses a panel data methodology and an F-test is used to determine whether the fixed-effects model outperforms the pooled OLS. The appropriateness of the random-effects model relative to the pooled OLS model is examined with the Breusche and Pagan Lagrange multiplier (LM) test. These tests indicate that there are no specific effects and the Ordinary Least Squares (OLS) estimator is more suitable. However, the post regression analysis shows that the residuals are not independent and not identically distributed because of the presence of serial correlation, the contemporaneous (spatial) correlation and the panel-level heteroscedasticity.

We used the Feasible Generalized Least Squares estimator to overcome these problems and to provide consistent standard deviations.

Thus, the results of the regressions by Feasible Generalized Least Squares estimator are presented in Table 2.

Breusch-Pagan LM test of independence: chi2 (45) = *Pr =*		53.642 (0.1768)	112.669 *** (0.0000)	59.453* (0.0730)
Modified Wald test for groupwise heteroskedasticity *chi2 (10) =* *Prob> chi2 =*		9860.33 *** (0.0000)	15.93 (0.1018)	4365.26 *** (0.0000)
Observations *Number of banks*		100 10	100 10	100 10

Notes: *, ** and *** indicate statistical significance at the 10%, 5% and 1% levels, respectively. Robust standard errors (to account for both heteroskedasticity and autocorrelation) are in parentheses.

Total return risk is the annualized standard deviation of the banks' daily stock returns. Systematic risk is the beta of the banks' stock returns. Specific risk is the annualized standard deviation of residual errors from the market model. SDROA is the standard deviation of return before taxes on assets estimated in a three-year moving window of annual observations. Z-score is the total insolvency risk. EQTA is the book value equity to total assets ratio. DEPEQ is the total deposits to the book to value equity ratio. LIQAT is the liquid assets to total assets ratio. GLTA is the gross loans to total assets ratio. LLRGL is the loan loss reserves to gross loans ratio. NPLGL is the non performing loans to gross loans ratio. LLPGL is the loan loss provisions to gross loans ratio. Index = $\frac{1}{17}\sum_{i+1}^{17} S_i$ as in Nier and Baumann (2006) and detailed in Table 3 in the appendix. Size is the natural logarithm of total assets. PRIV = 1 if the bank is private and 0 if the bank is public.

The results from the Feasible Generalized Least Squares specification indicate that when total return risk is used as the dependent variable, only LIQTA is significant but it has a negative relation with the total return risk, not as expected. When systematic risk is used as the dependent variable, only the LLPGL variable is significant but the sign is negative.

Finally, when the specific risk is used as the dependent variable, EQTA, DEPEQ and LIQTA show significant relations with the expected signs.

These results show that firm specific risk is more important in Tunisia than is systematic risk, like as for the listed Asian banks studied by Agusman et al. (2008).

However, the capital market neither reflects SDROA nor Z-score, witch are the measures of both total and insolvency risks that are so high for Tunisian banks. In addition, in spite of the importance of Tunisian banks' credit risk, with a high level of nonperforming loans that are not sufficiently provisioned, the relations between LLPGL, LLRGL and NPLGL and the capital market risk measures are not significant and do not have the expected signs. So, we can conclude that the market is not able to reflect the most important source of risk of Tunisian banks. We can explain this result by the fact that the investors on Tunisian capital market have no information about asset quality of Tunisian banks because the latter, generally, do not disclose the information about their nonperforming loans.

Consequently, prudential Tunisian authorities have to focus on accounting measures to assess the risk-taking by banks until the information disclosed to investors will be of better quality. As we can observe in Table 2, the *Index* variable made up to apprehend the quantity of information disclosed to investors is significant and negatively related to systematic and specific capital market risks. So, prudential authorities have to encourage banks to be more transparent in the aim to reduce risk taking and to ameliorate the functioning of the market.

Conclusion

The relations between accounting and capital market measures of risk are examined for a sample of 10 listed Tunisian banks for the period of 1998-2007. Using panel data analysis, the Feasible Generalized Least Squares model indicates that the capital market risk measures do not reflect accurately the risk taken by banks. In fact, almost all the coefficients are insignificant for the total and systematic risks. And for the systematic risk, only EQTA, DEPEQ and LIQTA are significant and have the expected signs; but the variables that apprehend the total risk and the credit risk are not significant and they don't have the expected signs. The results indicate that the bank specific risk is more important than the bank systematic risk and indicate also that the market is not able to reflect accurately the risk taken by banks. So, the prudential Tunisian authorities have to focus on accounting measures to better assess risk-taking of commercial banks.

Appendix

Table 3. Sub-indices used to make up a disclosure index based on annual reports information

Items	Sub-index	Categories
		Assets
Loans	S1: Loans by maturity	Loans and advances 〈3 months, loans and advances 3-12 months, Loans and advances〉 1 year
	S2: Loans by counterparty	Loans to group companies, loans to other corporate, loans to banks
	S3: Problem loans	Total problem banks
	S4: Problem loans by type S5: risk weighted assets	Overdue/ restructured/ Other non-performing loans, total of risk weighted assets
Other earning assets	S6: Securities by type	Treasury bills, other bills, bonds, CDs, equity investments, other investments
	S7: Securities by holding purpose	Investment, trading
Liabilities		
Deposits	S8: Deposits by maturity	Demand, savings, sub 3 months, 3-6 months, 6 months-1 year, 1-5 years, + 1 year
	S9: Deposits by type of customer	Banks/customers/ municipal, government
Other funding	S10: Money market funding	Total money market funding
	S11: Long-term funding	Convertible bonds, mortgage bonds, other bonds, subordinated debt, hybrid capital
		Income statement
	S12: Non-interest income	Net commission income, net fee income, net trading income
	S13: Loan loss provisions	Total loan loss provisions
		Memo lines
	S14: Reserves	Loan loss reserves (memo)
	S15: Capital	Total capital ratio, Tier 1 ratio, total capital
	S16: Off-balance sheet (OBS) items S17: Liquid assets	OBS items, total liquid assets

The usefulness of accounting information; evidence from the Egyptian market

School of Accounting & Finance, University of Dundee, Dundee, UK

Abstract

Purpose – The purpose of this paper is to ascertain financial analysts' views regarding the usefulness of a number of items of accounting information via a postal survey. This usefulness is explored in the context of the Egyptian capital market. In addition the usefulness of different types of information is researched, namely: historical vs forward-looking information; mandatory vs voluntary information; and quantitative vs non-quantitative information.

Design/methodology/approach – This paper uses descriptive analysis to investigate the views of a sample of 23 financial analysts regarding a number of items of accounting information. Analysts' ratings are obtained via a postal questionnaire, most of which are collected by hand. Fifteen out of 23 responses are collected in person, which offer the opportunity to ask follow-up questions about the information which the analysts see as valuable.

Findings – The findings indicate that different items of information are valued differently. In the context of the Egyptian market, financial analysts tend to value: mandatory disclosure more than voluntary disclosure; quantitative information more than non-quantitative information; and historic information more than forward-looking information. This type of preference reflects the information environment in Egypt, where mandatory disclosure is comprehensive and detailed based on International Accounting Standards but where compliance is an issue. Voluntary disclosure is limited and other sources of information are less common. Since mandatory information in Egypt tends to be historic and quantitative in nature, this may explain the preference for these types of disclosures.

Research limitations/implications – The findings suggest that the importance of different types of information may be affected by the degree of maturity of the market and how rich the information environment is.

Practical implications – The results should be useful in informing companies and market regulators about the types of information that financial analysts find useful for investment decision making and the areas of disclosure where financial analysts suggest that improvement is needed.

Originality/value – This paper contributes to the literature by investigating the views of a sample of financial analysts regarding the usefulness of accounting information and different types of disclosure in the context of an emerging capital market where a dearth of studies exist.

Keywords Accounting information, Capital markets, Financial analysis, Egypt

1. Introduction

This study contributes to the current literature by investigating financial analysts' ratings of accounting information and different types of disclosure in the context of an emerging capital market. The importance of this study arises from the key role played by the Egyptian market. The Egyptian equity market capitalization was $26.1 billion

Qualitative Research in Financial Markets
Vol. 1 No. 3, 2009
pp. 125-141

1755-4179
DOI 10.1108/17554170910997393

in 2002. It was the second largest market in the Middle East and North African region in terms of absolute size after the Saudi Arabia market (Report on the Observance of Standards and Codes (ROSC), 2004).

Egypt is an emerging capital market which applies International Accounting Standards (IAS), but where divergence from full compliance with mandatory disclosure is the norm and voluntary disclosure is limited (Hassan *et al.*, 2006). Potential explanations for this non-compliance are: unfamiliarity with IAS and language barriers (Abd-Elsalam and Weetman, 2003); the deep-rooted tendency towards secrecy in the Egyptian culture (Dahawy *et al.*, 2002); and the lack of an effective enforcement policy for non-compliant companies (ROSC, 2002). Dahawy and Conover (2007) argue that although mandatory disclosure requirements in the Egyptian market are comprehensive and detailed, they are based on IAS rather than the users' information needs. This might also explain the divergence from full compliance with mandatory disclosure in the Egyptian context. In addition, Ragab and Omran (2006) find that accounting information is value-relevant in the Egyptian market compared to more mature markets, which (in their opinion) might indicate that other sources of information are less common in the Egyptian context; such as earnings forecasts, firm research by financial analysts, and management conference calls.

The purpose of the current study is to investigate whether financial analysts in Egypt view accounting information (whether disclosed or not) in corporate annual reports as valuable for investment decision-making, and whether they value different types of information differently. Although this issue is examined via a questionnaire instrument, the analysis employs mainly descriptive statistics to form an impression of how the respondents rated different items of information; a detailed quantitative analysis of the responses was not conducted because the sample size did not permit such an examination and because the authors were more interested in a qualitative investigation of an issue which has not been studied within the Egyptian context previously. The findings suggest that the perceived importance of different types of information is subject to market development in terms of how rich the information environment is and how effective any disclosure policies are.

The remainder of this paper is organised as follows. A review of prior studies from both developed and emerging markets is provided in Section 2. The research method which involves a questionnaire is outlined in Section 3. Section 4 provides a discussion of the results from the questionnaire. Finally, the research conclusions and suggestions for future work are presented in Section 5.

2. Literature review

The current study examines financial analysts' preference for information in the context of an emerging capital market. Financial analysts' views and usage of information are of particular interest perhaps because other user groups such as individual investors and fund managers depend either directly or indirectly on their advice for investment decision making (Dhaliwal, 1980; Dimson and March, 1984). Traditionally, financial analysts have tended to attach a great level of importance to historical accounting data (Benjamin and Stanga, 1977; Buzby, 1974, 1975; Chandra, 1974; Firth, 1979; Chang and Most, 1985). Non-financial information on the other hand has typically only received limited attention from the financial analyst community (Previts *et al.*, 1994; Rogers and Grant, 1997). Over time, the use of non-financial information has increased (Nielsen, 2005; García-Meca and Martínez, 2007) in response to several changes in the business environment such as rapid developments in information technology, globalisation and the emergence of new businesses with a sizeable proportion of intangible assets.

Although conventional accounting information implicitly includes some forecasts about the future, for example, estimating the expected economic life of non-current assets when accounting for depreciation, research suggests that more explicit forecasts about firms' prospects are needed. Reports from the Association for Investment Management and Research (AIMR, 1993) and the American Institute of Certified Public Accountants (AICPA, 1994) have suggested that users need more information of a strategic, forward-looking and non-financial nature to aid their evaluations of company performance. In addition, prior studies conducted mainly in developed markets, where lots of information is published and disclosure policies are effective, emphasize the importance of strategic and forward-looking information (both financial and non-financial) for decision making (Beattie and Pratt, 2002; Hussainey *et al.*, 2003; Orens and Lybaert, 2007). They highlight limitations of information included in the financial statements; a lack of timeliness, (some) inaccuracy, and a limited ability to convey details about the prospects and risks facing the firm (García-Meca and Martínez, 2007). Forward-looking data as such does not replace the historical financial information provided in corporate annual reports but tends to be seen as complimentary when analysts attempt to predict share prices as it gives more insights about future corporate performance.

Whether or not financial analysts really use forward-looking strategic information in company valuations is an issue that has been investigated in the substantive literature. For example, García-Meca's (2005) and Orens and Lybaert (2007) studied corporate disclosure of voluntary non-financial information and financial analysts' use of this information. Results suggest that financial analysts use less non-financial information in their reports than that published by companies. In addition, whether or not forward-looking information is value relevant is still an issue. For example, Orens and Lybaert's (2007) examined the association between:

- financial analysts' forecast accuracy; and
- financial analysts' use of forward-looking information. Financial analysts' use of forward-looking information was measured via a content analysis of their reports and via a questionnaire.

The results showed a positive association between financial analysts' forecast accuracy and financial analysts' use of forward-looking information obtained from the survey. By contrast, the content analysis of analyst reports showed no significant relationship with analysts' forecast accuracy. In addition, prior studies (Botosan, 1997; Richardson and Welker, 2001) indicate that analysts tend to give more weight to quantitative information compared to non-quantitative information, because it is generally seen as more precise and more useful (Botosan, 1997).

For the purpose of the current study, accounting information (both provided and not currently included) in the corporate annual reports of Egyptian companies is examined to see if it is a useful input for investment decision making. This usage could be particularly important within the context of a developing capital market where secrecy is the norm (Dahawy *et al.*, 2002). For example, in Egypt, companies tend to view information as a private asset owned by the firm; hence, the voluntary disclosure of information is rare and compliance with mandatory disclosure is often problematic. In this context, market participants might value the mandatory information available; they might focus on historical quantitative financial information.

Prior studies on financial analysts' need for and use of information can be classified into two strands based on the research methodology employed. The first strand of research uses interviews and questionnaires (Bartlett and Chandler, 1997; Chang and Most, 1985; Chandra, 1974; Lee and Tweedie, 1975). The second strand of research performs a content analysis on the reports produced by analysts (Previts *et al.*, 1994; Rogers and Grant, 1997; Breton and Taffler, 2001; Garcıá-Meca, 2005) to uncover the frequency with which certain items of information are mentioned.

It is the first of these two strands that is relevant for the current study. Within this strand, studies employ interviews or questionnaires in order to investigate different issues: such as the views of a user group (or user groups) in relation to a set of information (Coleman and Eccles, 1997; Beattie and Pratt, 2002); the appraisal methods employed by financial analysts in valuing ordinary equities (Arnold and Moizer, 1984; Barker, 1998; Carsberg and Dey, 1984; Lee and Tweedie, 1975; Pike *et al.*, 1993) and corporate disclosure practice (Buzby, 1975; Firth, 1979; Choi, 1973; Chow and Wong-Boren, 1987; Naser and Nuseibeh, 2003). Studies examining the appraisal methods employed in share valuations have investigated how investors use financial statement information in developed markets such as the UK (Arnold and Moizer, 1984; Barker, 1998; Carsberg and Dey, 1984; Lee and Tweedie, 1975; Pike *et al.*, 1993) and the USA (Arnold *et al.*, 1984; Belkaoui *et al.*, 1977). One of the main conclusions of these studies is that financial analysts pay a great deal of attention to the income statement and balance sheet figures when valuing ordinary shares with priority given to income statement figures. This finding is not unique to developed capital markets, since studies on emerging capital markets in Saudi Arabia (Al-Abdulqadar *et al.*, 2007), China (Wang *et al.*, 2007), Nigeria (Tijjani *et al.*, 2009) and Central and Eastern Europe (Middleton *et al.*, 2007) have reached similar conclusions.

One of the survey studies which is relevant to the current research was conducted by Coleman and Eccles (1997). They investigated the views of a sample of 209 financial analysts and investors regarding the value of 21 different financial and non-financial performance measures. They conducted face-to face interviews with 102 investors and telephone interviews with 107 financial analysts. Participants' perceptions about whether British companies disclosed performance measures were also ascertained. The results indicated that financial analysts had a greater need for information than their investor counterparts. However, financial analysts and investors found some financial measures (e.g. earnings and cash flow) to be especially valuable when arriving at decisions. Both financial analysts and investors had little interest in certain non-financial measures such as employee satisfaction information and employee turnover rates. The results also highlighted some differences between financial analysts and investors in the perceived importance of various measures of corporate performance especially non-financial measures. Within the investor group, non-financial performance measures were not regarded as particularly useful.

Recently, Beattie and Pratt (2002) investigated the views of 538 different user groups in the UK; expert users, private shareholders, finance directors and audit partners were surveyed in relation to a set of 130 items of information categorised into eleven groups. The results showed similar views across the four user groups in terms of the ranking of items of information according to their usefulness for investment decision making. Their results also indicated that financial information was ranked first followed by objective and strategic management information. Employee value drivers and environmental, social, and community items were ranked very low.

Content analysis studies (Previts *et al.*, 1994; Rogers and Grant, 1997; Breton and Taffler, 2001; Garcıá-Meca, 2005) that investigate financial analysts' use of information generally argue that this approach compliments the findings of investigations that employ the interview/questionnaire method because it investigates financial analysts actual usage of information (Dhaliwal, 1980). However, the extent to which financial analysts use information in their reports could be driven by other factors. For example, Garcıá-Meca and Martínez (2007) found that financial analysts provided more information in their reports on profitable firms and firms with high growth opportunities. In addition, using the content analysis technique does not allow researchers to uncover details about the value or the sort of information that financial analysts use but do not report on. For example, Orens and Lybaert (2007) compared financial analysts' views about a set of voluntary non-financial information obtained via a survey with their actual use of the same set of information via a content analysis of their reports. Their findings indicated that financial analysts did employ some of this information, even though they did not discuss it in their report. Also a content analysis of financial analysts' reports does not allow us to find out about the sort of information that analysts need but which is not available (Previts *et al.*, 1994). Using an interview/questionnaire approach might provide us with more detailed views about the importance of different items of information for shares valuation process. For this reason, the questionnaire approach is adopted in the current study.

3. Methods

In order to investigate financial analysts' perceptions regarding accounting information, a list of items of information was constructed. This list of items of information was drawn from the Guidelines Manuals published in 2002 by the Capital Market Authority (CMA) in Egypt on its web site[1], it constitutes the mandatory disclosure that is required in Egypt. The reason for including mandatory disclosure in our list is to check whether financial analysts find the current information requirements useful, since these items are based on IAS rather than users' views. In addition, a careful review of the disclosure literature was undertaken to select items of information (not included in the checklist of the CMA) that Egyptian companies might disclose voluntarily. The checklist used by the Center for International Financial Analysis and Research (CIFAR, 1995) to evaluate corporate disclosure levels for leading non-financial companies in a number of emerging and developed countries was thought to be a reasonable starting point for the voluntary list. It included not only some fundamental information that sometimes overlapped with that mandated by the CMA but also other voluntary disclosure items.

This process led to the inclusion of 115 items of information in the initial list: 71 items from the CMA checklist and 44 items from the CIFAR checklist. This list of items was grouped under seven categories[2]: general information; income statement information; balance sheet information; cash flow statement information; details about accounting policies; shareholders' information and supplementary information.

The list of items was sent out to a sample of Egyptian analysts in order to ascertain their views regarding the usefulness of these items of information. Specially, they were asked to indicate their views about the usefulness of these items of information when making an investment in ordinary shares. An unbalanced five-point scale[3] was employed for this purpose, ranging from one (not useful) to five (very useful). In addition, the respondents were asked to order seven different categories of information[4] according to their relative importance; thus respondents had to rank these categories from one (the most important) to seven (the least important) allowing the relative usefulness of these items to be determined.

A postal questionnaire was used as the research instrument, despite of its limitations (e.g. its low response rate), because it was thought to be efficient in terms of time and cost when contacting a large number of professional investors in Egypt. The sample consisted of 200 brokers and investment analysts in banks and insurance companies within Egypt. This sample was drawn from the brokers' directory obtained from the CMA, the insurance sector directory and the banks directory.

The questionnaire contained three sections[5]. The first section included a covering note and a set of instructions. The second section dealt with the usefulness of financial statement information. The final section sought additional details about the user: the nature of their employment, their level of education and their years of experience. Closed-end questions were mainly employed because they were considered to be easier to answer, code and analyze, thereby saving time for both the researcher and the respondents (Gillham, 2000; Frazer and Lawley, 2000; Bourque and Fielder, 1995). Moreover, closed-end questions were thought to be more efficient and reliable than their open-ended counterparts when questionnaires are mailed to the respondents (Fink, 1995; Bourque and Fielder, 1995). However, as 15 of the questionnaires were collected by one of the authors in person, she was able to conduct follow-up interviews. Specially, she asked for any additional information that a financial analyst might find useful but which was not included in the questionnaire. The answer to the question was normally no. The only feedback regarding the items of information included in the questionnaire from one of the respondents was that the cash flow statement information was incomprehensible; hence he did not use it for stock valuation purposes.

The questionnaire was pilot tested on thirteen people and feedback was used to revise and improve the research instrument before it was posted. Reminders were sent after 21 days to those who did not return the original copy of the questionnaire. A second request together with another copy of the questionnaire was sent after a further 21 days in order to maximise the response rate.

4. Analysis and results

A total of 23 responses out of 200 were received (Table I), giving a response rate of 11.5 percent. This low response rate was disappointing but not atypical of questionnaires in the finance area (Collier and Wallace, 1992). The replies were tested for non-response bias to see if the results obtained from the questionnaire were representative of the whole sample. The results[6] indicate the absence of a material non-response bias; hence, chance alone was a reasonable explanation for any difference in the scoring of items of information between early and late responders.

The 23 responses were classified according to the respondent's level of education and experience in order to explore whether either of these characteristics affected their

Respondent	Employment business	Education	Experience (years)

Notes: This table provides background information about the respondents. Specifically, it shows the type of employment business, respondents’ level of education and experience

Table I.
Descriptive information about the respondents

rating of the relative usefulness of the items of information included in the questionnaire. According to the data obtained from the questionnaire, respondents were classified into two main groups: those with a University level (15 respondents) or a postgraduate level of education (seven respondents). The range of experience among respondents differed from 0 to 15 years. The respondents were therefore classified into two groups according to the median years of experience (5.5 years): less than or equal to 5.5 years of experience (13 respondents), and more than 5.5 years of experience (10 respondents). We then examined whether respondents attached different ratings to different items of information according to their level of education or experience. We found that there was no significant difference in the usefulness of items of information among respondents according to their level of education. In addition, we discovered that there was no significant difference in the rating attached to different items of information among respondents according to their level of experience. Therefore, we excluded these two variables as reasonable explanations of the differences between the groups’ scores.

The descriptive analysis of the data collected from the questionnaire shows that 46 out of 115 items of information included in the questionnaire were found to be useful or very useful (they were awarded a mean rating of at least four out of five). Table II shows items of information that have been awarded a mean of more than four sorted in a descending order. Table III shows items of information that have been awarded a mean of less than 3.5 sorted in an ascending order.

Items of information	M/V	Q/N	Mean	STD

Table III. Items of information that were found to be least useful with a maximum average rating of less than 3.50

From Tables II and III we can extract the top and bottom ten items of information in terms of mean scores awarded for their usefulness in investment decision-making. The top ten items (extracted from Table II) in terms of the highest mean awarded (4.5 or higher) for their usefulness are: operating income, dividends per share, net income, comparative financial statements, purpose of the company's activity, earnings per share, total dividends, sales revenue, number of issued shares and par value per share, and statement of earnings distribution, respectively. These results indicate that financial analysts rated historical financial statement information relating to earnings and dividends as the most useful items. This result is consistent with Coleman and Eccles' (1997) findings where they discovered that earnings data were of most interest to investors. This result is also consistent with a finding cited in Abd-Elsalam (1999, p. 37) where:

> [. . .] in one of the very few empirical studies on Egyptian investors, it was suggested that they (respondents) are more interested in the profit figure than any of the other ratios.

In addition, our results support Ragab and Omran's (2006) findings that earnings information in particular is value-relevant in the Egyptian market.

The ten least important items of information in terms of the lowest means (3.13 or lower) were: pension costs, outside manager of pension funds, reasons for extraordinary items, contingent liabilities, geographical segment data, acquisition method used, remuneration of directors and officers, number of employees, and cash flow representing increase in operating capacity disclosed separately from that representing maintenance of current operating capacity[7]. These results highlight the low levels of interest among the financial analyst community in information about pension details perhaps because this item was not disclosed in Egypt at the time of the survey. However, the low interest shown for other items which are currently included in the Egyptian financial statements might indicate that financial analysts are not interested in details such as geographical segment data and minority interest information. Alternatively, such information may have been available to financial analysts on an informal basis via contacts with the company, so that the analysts might have been less interested in seeing details about these items disclosed in the annual report.

By contrast, the lowest standard deviation values were awarded to the following items: operating income, purpose of the company's activity, and dividends per share, respectively, which might reflect consistency among financial analysts' perceptions regarding the usefulness of these items of information. These results suggest that investors in Egypt paid a great deal of attention to income and dividend figures when making investment decisions. This finding is supported by an analysis of the ranking of the categories of information according to their relative importance in decision-making (Table IV).

The income statement was ranked first (the lowest mean) followed by the balance sheet and the cash flow statement. These findings are consistent with results obtained in Arnold *et al.* (1984) where the income statement and balance sheet were found to be the most important sources of information for UK and USA analysts when valuing shares based on company fundamentals. The last four categories of information (in terms of highest mean) were: supplementary information, general information, accounting policies, and shareholders information, respectively.

The highest standard deviation reported for individual items of information (about 1.5) was for the list of board members. This result reflects inconsistency among

Groups of information	Mean	STD	Rank
Income statement	1.87	0.968	1.00
Balance sheet	1.96	1.261	2.00
Cash flow statement	3.70	1.460	3.00
Shareholders' information	4.35	1.799	4.00
Accounting policies	4.65	1.071	5.00
General information	4.87	1.890	6.00
Supplementary information	6.04	1.107	7.00

Table IV.
Descriptive analysis for categories of information

financial analysts regarding the importance of such information in Egypt. Further, inconsistency among financial analysts regarding the importance of another eight items of information was reported where the standard deviation was about 1.4; acquisition method; earnings per share numerator; a physical count and valuation of inventory; number of employees; business segment; outside manager of pension funds; events after the balance sheet date; the policy used for determination of cash and cash equivalents.

We also looked at the results in terms of the importance of different types of information: mandatory vs voluntary information; historical vs forward-looking information, and quantitative vs non-quantitative information. An analysis for the mean score awarded to each type of information and standard deviation information is reported in Table V. An inspection of this table reveals that financial analysts tended to value mandatory disclosure slightly more than voluntary disclosure in terms of mean score awarded to mandatory information. This could be due to the fact that voluntary disclosure in the Egyptian context is limited (Hassan *et al.*, 2006). Financial analysts also tended to value historical information slightly more than forward-looking information; the mean score for the former category was 3.84 while the average score for the latter category was 3.71. This small difference could be explained by the dearth of forward-looking information in Egypt. This result is consistent with prior studies; for example Firth (1979, p. 275) found that historical accounting information tended to receive fairly high scores when users were asked to rank information according to the importance that they attached to it. Firth (1979) also discovered that forecasts of the future (forward-looking information) received moderate to important scores, suggesting that financial analysts were in some doubt about the accuracy of such forecasts. In addition, consistent with prior studies (Botosan, 1997; Richardson and Welker, 2001) financial analysts in Egypt tended to give more weight to quantitative information (mean score 3.94) compared to non-quantitative information (average score 3.66), presumably because it is seen as less ambiguous.

The results were then analyzed in terms of the most and least useful items of information according to each type of disclosure individually. When the results are analyzed in terms of the most and least useful items of historical information, they show that information such as operating income, dividend per share and net income appeared to be important for analysts in the Egyptian context. By contrast, information about pensions, extraordinary items, and geographic segment detail seems to be viewed as less important perhaps because this information was not disclosed

Type of information	Mean	STD
Mandatory-voluntary split		
Mandatory information	3.85	0.39
Voluntary information	3.79	0.58
Historical – forward-looking split		
Historical information	3.84	0.47
Forward-looking information	3.71	0.47
Quantitative – non-quantitative split		
Quantitative information	3.94	0.43
Non-quantitative information	3.66	0.49

Table V. Descriptive analysis for average analysts' rating for different types of information by listed companies; they are not mandatory disclosure and might explain why financial analysts rated their usefulness as law for valuation purposes.

Table VI focuses on future orientated information. It shows that financial analysts in Egypt were also interested in forward-looking information as indicated by the high mean score awarded to items such as: future plans, qualitative, and quantitative forecasts of revenues, expenses, profits, and cash flows and assumptions underlying forecasts; these items were awarded an average score of 4.00 or more. Consistent with Meeks' (1998) views, Egyptian financial analysts attached a great deal of importance not only to forecasts but also to the underlying assumptions on which these forecasts were based. Other future oriented information was found to be less useful in a share valuation setting; such as contingent liabilities, long-term contracts, long-term leases, capital leases, sales on installments, and related interest. Although information about contingent liabilities is voluntary in Egypt, information about long-term contracts, long-term leases, capital leases, sales on installments, and related interest is mandatory. Given that full compliance with mandatory disclosure is an issue in the Egyptian market, the availability of this type of information might be responsible for the lower ratings awarded to it by financial analysts.

When the results are analyzed according to the usefulness of mandatory items of information a number of findings emerged. Information about net income, comparative financial statements, the nature of company activities, sales revenue, the number of shares issued, and their par value, were considered to be essential for stock valuation purposes with ratings of 4.5 or above out of five. Other mandatory information was found to be less useful for stock valuation purposes such as remuneration paid to directors and officers and cash flow details about operating capacity. Financial analysts in Egypt were found to be less concerned in general about the cash flow statement, given that all items of information included in this part of the annual report were awarded a rating of less than four out of five.

An inspection of the average scores awarded to voluntary information reveals that the analysts emphasized the importance of earnings and dividend information for stock valuation, i.e. operating income; dividends per share; earnings per share; total dividends; earnings distribution statement. This type of voluntary information was

	Mean	STD
Future plans	4.30	0.70
Qualitative and quantitative forecasts of revenues, expenses, profits, and cash flows	4.30	0.93
Assumptions underlying forecasts	4.09	1.00
Chairman's or chief executive officer's statement	4.00	0.95
Disclosure of subsequent events	3.78	1.00
Schedule of interest and principal due on long-term debt in future years	3.65	0.93
Amount of facilities available for the company but not used yet	3.52	1.08
Events after the balance sheet date	3.39	1.37
Long-term contracts, long-term leases, capital leases, sales on instalments, and related interest	3.22	1.24
Contingent liabilities	2.87	1.25

Table VI.
Descriptive analysis for forward-looking information

seen as essential for investment decision making since it was awarded a rating of 4.5 or more. This result could be of interest to market regulators who are seeking more transparency in the Egyptian market. They might regulate this type of information if it is seen as essential from market participants' points of views. It could be also of interest to companies who want to discover the voluntary information which is found most useful; it may guide them when they are contemplating the disclosure of detailed information for analysts.

When the results are analyzed in terms of the quantitative vs non-quantitative items of information, the importance of quantitative information about the profitability of the business is apparent: operating profits, net income, earnings per share, earnings distribution statement, dividends, sales revenue, information about past performance (comparative financial statements) and the number of shares in issue along with their and par value. This quantitative information seems essential for investment decision making in Egypt. However, some quantitative information seems to be less relevant for stock valuation such as geographic segmental data, remuneration details of directors and officers, the number of employees, cash flow information about the operating capacity disclosed separately from that representing maintenance of current operating capacity.

The analysis also revealed that non-quantitative information that seemed useful for investment decision making relates to general information about the business (e.g. purpose of company activities, its legal status, the period covered by the financial statements, its name, the currency used for the preparation of financial) and the auditors' report. The auditors' report seems to be useful (mean score is 4.30) but not essential (awarded score is less than 4.50) for stock valuation in the Egyptian context. The least useful non-quantitative information is related to information about pensions, reasons for extraordinary items, contingent liabilities acquisition method. All these non-quantitative items of information are voluntary; some of them have never been actually disclosed in Egyptian financial statements (e.g. pension's funds). The current lack of such information in the Egyptian market might lead financial analysts to underestimate their importance for stock valuation.

5. Concluding remarks

This study contributes to the current literature on the usefulness of accounting information in the context of emerging markets. It has investigated the views of a small sample of financial analysts in the Egyptian market with regard to the usefulness of a number of items of information for investment decision making. In addition, a comparison of the level of importance of different types of disclosure has been carried out; namely: historical vs forward-looking information; mandatory vs voluntary information; and quantitative vs non-quantitative information.

The results show the relative importance awarded to different items of information, with the highest scores being given to net income and dividends figures consistent with prior studies (Coleman and Eccles,1997; Ragab and Omran, 2006). In addition, the results highlight that investors in Egypt pay more attention to mandatory, historical, and quantitative information, with priority being given to the income statement data consistent with results from prior studies on the appraisal methods used by financial analysts in valuing ordinary shares. These perceptions reflect the type of information available to financial analysts in the context of the Egyptian market. However, the findings do also indicate that financial analysts view forward-looking information such as future corporate plans, qualitative and quantitative forecasts of revenues, expenses, profits, and cash flows and assumptions underpinning these forecasts as useful inputs for investment decision making. This result suggests that companies might provide more forward-looking information voluntarily.

Moreover, our analysis reveals the most and least useful items of information under each disclosure category, which should inform market regulators and companies in Egypt about useful information for stock valuation from a user perspective. Our findings could be of useful in informing companies and market regulators about the types of information that financial analysts find useful for investment decision making and the areas of disclosure where financial analysts suggest that improvement is needed. Moreover, the results show that there are no differences among the professional users in Egypt in evaluating this list of items of information with respect to their level of education or experience.

Although we have tested for non-response bias, the low response rate to this survey calls for more future research in order to be able to conduct a quantitative analysis and generalise the results. In addition, future research could increase the sample size by investigating the views of other users groups such as private shareholders, finance directors and auditors. Future research could also compare the importance of different types of disclosure such as historical and forward-looking information in different emerging markets with varying levels of maturity in order to draw a firm conclusion. Nonetheless, the current study provides a useful starting point for future investigators in this area.

Notes

1. It informs companies issuing financial securities and their auditors of the procedures followed by the CMA when ensuring that companies have complied with disclosure and transparency requirements according to Egyptian Accounting Standards (IAS).
2. This categorising is derived from the CIFAR with one exception where we replaced the funds statements by the cash flow statements.
3. Both words and numbers were used in this five-point scale to avoid the weakness of using one rather than the other of these approaches (Gillham, 2000). We decided to put the negative end (not useful) of the scale first for the content question in this questionnaire, although deciding which end of the scale should be placed first is considered to be less important for a postal questionnaire than for face-to-face interviews (Fink, 1995).
4. The seven categories of information are: general information, income statement, balance sheet, funds flow statement, accounting policies, shareholders' information, and supplementary information.
5. A copy of the questionnaire is available from the authors upon request.
6. Full results of this non-response bias test are available from the authors upon request.
7. It is worth noting that minority interest and the treatment of intangible assets have been awarded a mean of 3.13 as well.

Does corporate disclosure policy change financial analysts' behaviour? Evidence from France

Faten Lakhal
IRG, Université Paris Est, Paris, France and
ISG, Université de Sousse, Sousse, Tunisia

Abstract

Purpose – The purpose of this paper is to examine whether financial analysts are sensitive to voluntary earning disclosures.

Design/methodology/approach – The paper is based on a literature review of the relationship between analysts' behaviour and corporate disclosures. It is assumed first that analyst coverage both influences and is influenced by voluntary earning disclosures, and that second, French managers are expected to make voluntary disclosures in order to reduce market uncertainty. To test these hypotheses, a simultaneous equation model and an ordinary least square regression framework were estimated on a sample of 154 French-listed firms between 1998 and 2001.

Findings – The results show that voluntary earning disclosures positively influence analyst coverage decision. They also show that voluntary disclosures improve the accuracy of analyst forecasts and reduce market uncertainty.

Research limitations/implications – The paper does not cover all forms of corporate voluntary disclosures.

Practical implications – The findings suggest that corporate disclosure policy is likely to change financial analysts' behaviour. The results are useful to both managers, wishing to meet market expectations and, to investors wishing to invest in richer informational environment firms.

Originality/value – This paper provides original results about the role of analysts in France as information intermediaries. These analysts pay little attention to French firms with a poor information environment in which minority shareholders are less inclined to ask for costly analyst coverage.

Keywords Financial forecasting, Dispersions, Disclosure, Financial analysis, France

Paper type Research paper

1. Introduction

Most research over the last few years has focused on the determinants and consequences of voluntary disclosure practices (Ajinkya *et al.*, 2005; Leuz and Verrecchia, 2000). This study examines the relationship between financial analysts' behaviour and voluntary earning disclosures. Analysts provide valuable earnings forecasts and stock recommendations to market participants (Lys and Sohn, 1990; Womack, 1996; Roulstone, 2003). They play a major role as financial intermediaries and as information providers for stock recommendations (Schipper, 1991). Voluntary

This paper has benefited from comments by Edith Ginglinger, the anonymous referees, and participants at the European Accounting Association. The author is grateful to Florence Labégorre for her precious help in data processing and to Patricia Robinson and Brian Bloch for their valuable editing.

disclosures help analysts to make their earnings forecasts. These disclosures may also reduce the extent of information gathering by analysts. Thus, we can expect a relationship among voluntary disclosures, analyst coverage and the characteristics of analysts' forecasts. Lang and Lundholm (1996) on the US market and Hope (2003a, b), on a multi-country sample, examines the relationship between analyst behaviour and corporate-provided information. They show that analysts provide coverage to firms with liberal disclosure policies for which they issue accurate analyst earnings forecasts.

This paper provides evidence on the relationship between voluntary earning disclosures and analyst behaviour in France. The case of French-listed firms is of particular interest since they show a concentrated ownership structure with an agency problem between large shareholders and minority shareholders, rather than between managers and shareholders as in highly diffused ownership structures. Moreover, minority investor rights are not adequately protected in civil law countries as is the case in France (La Porta *et al.*, 1998). Because of weak legal protection for investors, large shareholders or families are able to retain information or to provide optimistic and unreliable forecasts to minority shareholders. The costs of following firms with large shareholders are high as these firms have a poor informational environment. Minority shareholders are then less likely to turn to analysts as primary information providers, because their services are too costly.

Management forecasts and quarterly earnings disclosures were selected to test the relationship between analyst behaviour and voluntary earning disclosure. This choice is advantageous for two main reasons. First, unlike other more regulated forms of disclosure, management has considerable discretion as to whether or not to make a forecast or a quarterly announcement. Second, even though existing research examines voluntary disclosures extensively, the relationship between analyst behaviour and these voluntary disclosure modes has not so far been fully examined.

The purpose of this study is to show that analysts are likely to follow those firms with highly informative earnings disclosures which can provide more accurate earnings forecasts. Voluntary earnings disclosures may allow analysts to revise their earnings forecasts and reduce the dispersion between analysts' forecasts. The second objective is to assess whether managers use voluntary earning disclosures to reduce information asymmetry between market participants.

The results show that financial analysts are attracted by a firm's disclosure reputation. There is a positive association between analyst coverage and voluntary earnings disclosures. Both, the decision to provide voluntary information and to follow a firm have been tested as two decisions that can be simultaneously determined. The results show that voluntary earning disclosures influence analyst coverage decisions, where analyst coverage does not affect these voluntary disclosure modes. The findings also show that voluntary earning disclosures improve forecast accuracy and reduce dispersion between analysts' forecasts. It should be noted that few studies have considered information asymmetry between market participants as a major reason why managers issue voluntary disclosures. Furthermore, this study differs from existing ones because it examines the effect of a specific component of voluntary disclosures, i.e. earnings disclosures (management forecasts and quarterly earnings announcements[1]). Such disclosures are extensively used by financial analysts and investors to assess firm value (Gajewski and Quéré, 2001).

The remainder of this paper is organized as follows. Section 2 presents a review of the literature that highlights the relationships between voluntary disclosures, analyst coverage and their forecast characteristics. Section 3 describes the sample, data collection and methodology. The empirical findings and discussions are presented in Section 4. The last section concludes the paper.

2. The relationship between voluntary earning disclosures and financial analyst behaviour

2.1 Analyst coverage and voluntary earning disclosures

Bhushan's (1989) model predicts that analyst coverage is determined by a firm's various characteristics including corporate disclosures. Jensen and Meckling (1976) suggest that analyst activity mitigates agency costs arising from conflicts of interests between managers and shareholders. Analysts act as a monitoring device for insiders because they are likely to enhance the corporate information environment. The authors also argue that voluntary disclosures are one means to control managers and to reduce information asymmetry between market participants. As two distinct control mechanisms, voluntary disclosures and analyst coverage could either complement or be substitutes for one another.

The existing literature shows that analyst coverage and corporate disclosures are complementary. The link between them was tested initially by Lang and Lundholm (1996) in the US market. The authors found that firms with poor disclosure policies are less likely to be followed by analysts. Analysts mainly follow firms with extensive disclosure practices, because the cost of information collection is relatively low for richer information environment firms. Bushman *et al.* (2004) show a positive relationship among analyst coverage, disclosure quality and minority shareholder protection. In a study of 20 countries, Hope (2003a) shows that voluntary disclosures help analysts issue their forecasts and make buy and sell recommendations.

In concentrated ownership structures, conflicts of interests arise between large and small shareholders. Information asymmetry is likely to be high, because large shareholders may retain information and expropriate private benefits of control (Dyck and Zingales, 2004). This poor information environment coupled with poor legal protection increases the costs of analyst coverage which can act as a monitoring device. Minority shareholders would then ask for more analyst services to bridge the information asymmetry gap caused by the poor quality of publically available information (Boubaker and Labegorre, 2006). Accordingly, the informational environment would be richer in response to a greater demand for analyst services from minority shareholders.

The relationship between analyst coverage and corporate disclosures is ambiguous, because it depends on the supply and the demand for analyst services. Bhushan (1989) finds that the equilibrium number of analysts following a particular firm is determined by the aggregate demand and supply curves for analyst services. High-disclosure levels increase both the supply of and the demand for analyst services (Lang and Lundholm, 1996). However, Lang and Lundholm (1996) describe how analysts are reticent to follow firms with a poor informational environment as these analysts have to then pay high fees to collect private information. This information is offered to shareholders at a high price given that analysts in this case are primary information providers. The above discussion leads to the following hypothesis:

H1. There is a relationship between voluntary earning disclosures and analyst coverage.

2.2 The characteristics of analyst forecasts and voluntary earning disclosures

The models of Milgrom (1981) and Grossman (1981) suggest that managers choose to disclose corporate information to reduce information asymmetry, and subsequent empirical studies have tested these predictions. Ajinkya and Gift (1984) suggest that management forecasts are provided to narrow the expectation gap between market and managers (the expectation hypothesis). Voluntary disclosures aim at reducing information asymmetry in the market (Verrecchia, 2001) and therefore, at reducing investor's uncertainty (Ajinkya and Gift, 1984 and Ruland *et al.*, 1990). Empirical studies such as Christie (1987), Atiase and Bamber (1994) and Soffer *et al.* (1999), show that analyst forecast characteristics, including forecast error and forecast dispersion, are used as proxies for investor expectations.

In the USA, Lang and Lundholm (1996) find ratings of annual report disclosures (a subset of the overall AIMR ratings) to be negatively associated with forecast dispersion, but not significantly related to forecast accuracy. The authors show that analyst forecasts differ less as firms increase their disclosures. Piotroski (1999) finds that discretionary expansion of segment reporting is also, on balance, associated with an increase in analyst forecast accuracy and a decrease in forecast dispersion. Similarly, Bushman *et al.* (2004) show that financial analysts provide accurate earnings forecasts for firms disclosing high-quality information. The relationship between earnings forecasts and voluntary disclosures was also tested and confirmed by Hope (2003b). However, for Swedish firms, Adrem (1999) finds no significant relationships between information disclosure strategy and forecast accuracy.

The effect of additional information on forecast dispersion is measured by differences in forecasts issued by each analyst. These forecasts may differ as a result of various assessments of the same set of information, or to different sets of acquired private information Lang and Lundholm (1996) show that high levels of forecast dispersion are associated with high-market uncertainty. Ang and Ciccone (2001) examine international differences of analyst forecast dispersion. They show that forecast dispersion greater when the informational environment of the firm is poor. Swaminathan (1991) finds a decrease in dispersion among analyst forecasts for multiple segment firms after the implementation of the Securities Exchange Commission's (SEC) business disclosure requirements. Lastly, using an international sample, Chang *et al.* (2000) find a positive and significant relationship between dispersion and corporate disclosures in 47 countries. In light of these arguments, these two hypotheses were tested:

H2. There is a negative relationship between forecast error and voluntary earning disclosures.

H3. There is a negative relationship between forecast dispersion and voluntary earning disclosures.

2.3 Analyst coverage and analyst forecast characteristics determinants

Analyst coverage and analyst forecast characteristics are not influenced solely by corporate disclosure policy. We rely on prior research to consider control variables for the extent of analyst coverage and their forecast characteristics. These control variables include: firm size, earnings variability, the proportion of institutional investors in total capital, US listing, the book-to-market ratio and a dummy variable for negative earnings.

Firm size. Firm size is an important determinant of analyst coverage. Previous studies, of analysts' forecast characteristics and coverage, including that of Bushan (1989) have shown that analysts follow small firms less than large ones. Furthermore, Doukas *et al.* (2005) show that the acquisition of information is relatively more costly for small firms. Lang *et al.* (2003) find a positive and significant relationship between firm size and analyst coverage. They suggest as Ackert and Athanassakos (2003) that large firms are more transparent to investors. Firm size is also regarded as a major factor for analyst forecast error and dispersion. According to Lang and Lundholm (1996), large firms have a richer informational environment. This is likely to help analysts provide accurate and less dispersed forecasts. The empirical study of Rajan and Servaes (1997) also shows that earning per share of large firms is more predictable than that of small firms. Subsequently, we expect a positive relationship between firm size, analyst coverage and the characteristics of analyst forecasts.

Earning surprise. On the one hand, analysts are more likely to follow firms with highly predictable earnings because the cost of private information gathering is low. Several studies including O'Brien and Bhushan (1990), Lang and Lundholm (1996), Marston (1997) and Lang *et al.* (2003, 2004) show that analysts prefer following firms with less variable earnings. On the other hand, earning surprise is shown to be positively related to analyst forecast characteristics. According to Hope (2003b), earning surprise increases market uncertainty due to high-analyst forecasts dispersion and error. We measure earning surprise as the absolute value of the difference between the current earning per share and the lagged earning per share scaled by the firm's stock price at the beginning of the fiscal year. Earning surprise is expected to be negatively associated with analyst coverage and positively associated with forecast error and dispersion.

US listing. Firms listed on the US market are more followed than others, because they are likely to generate high fees for financial analysts. Lang *et al.* (2003, 2004) find that foreign firms listed on the US market are more heavily followed by analysts. Financial analysts are attracted by US listing firms as the disclosure quality is enhanced. Firms listed on the US market are likely to have more accurate analyst predictions, because the rich informational environment of such firms enhances the ability of analysts to predict earnings (Lang and Lundholm, 1996; Marston, 1997). We expect then a positive relationship between US listing and analyst coverage, and a negative relationship between US listing and forecast error and forecast dispersion.

Market-to-book ratio. Empirical studies find that analyst coverage is associated with the market-to-book ratio. According to Krische and Lee (2000), high market-to-book firms receive more recommendations from analysts, because these firms earn higher returns than low book-to-market firms (Fama and French, 1992). McNichols and O'Brien (1997) find similar results. They show that analysts follow stocks for which seem more likely to yield good returns. We introduce the value of market-to-book to control for analyst-coverage decisions and we expect a positive relationship between this ratio and analyst coverage.

The proportion of institutional investor ownership. Bhushan (1989) shows that analyst coverage is associated with the increasing institutional investor's ownership. For a sample of 1,409 American firms, he finds a positive relationship between the proportion of institutional investors and analyst coverage. Similarly, Ackert and Athanassakos (2003) show that institutional investors ask for more analyst services to cover the firm. Within this study, the proportion of foreign institutional investors was used to control for analyst-coverage decision. These investors offer a high guarantee for minority shareholder protection and can influence managers to enhance their corporate disclosure policies (Lakhal, 2005). We would therefore expect a positive relationship between the proportion of foreign institutional investors and analyst coverage.

Negative earnings. Most analysts are reluctant to estimate earnings for loss firms. Hope's (2003b) study highlights the positive relationship between negative earnings and forecast accuracy and that negative earnings positively influence analyst forecast dispersion. Hope suggests that loss firms have a greater earning variability than profitable firms. This may increase the forecast error and dispersion between analysts. This variable is a dummy that equals to 1 for negative earnings and to 0 otherwise, and we assume that there is a positive relationship between negative earnings and analyst forecast error and dispersion.

3. Sample, data selection and methodology

3.1 Sample and data selection

Our sample includes both manufacturing and commercial companies listed on the SBF 250 index. Financial and insurance firms were excluded, because they are subject to specific disclosure requirements. The sample period is 1998-2001. Our final sample includes 154 companies. Data related to analyst forecasts were extracted from the Institutional Brokers Estimate System database. Stock prices were collected from the ABC-bourse database. Accounting information was extracted from the Worldscope database and data related to ownership structure and institutional investors were hand-gathered from annual reports.

Non-mandatory earning disclosures were examined. French-listed firms are required to release their annual reports in the BALO (*Bulletin des Annonces Légales et Officielles*). They must also issue their earnings reports half-yearly (according to the law 24 July 1966 and the decree 23 March 1967). The AMF (*Autorité des marchés financiers*) requires the quarterly announcements only to include revenue. The SEC requirements in the USA are more stringent, where companies are required to release formal annual reports and quarterly ones with a homogenous form. The analysis of earnings disclosures practices in the French market shows that there are two forms of non-mandatory earnings disclosures: quarterly earnings announcements, and management forecasts. These voluntary disclosures were hand-gathered from the daily financial press.

Our variables were computed for the fiscal years 1998-2001[2]. Analyst forecast characteristics include: the forecast dispersion and forecast error. The former is measured each fiscal year for each sample firm, using annual forecasts. The dispersion is calculated as the standard deviation of all individual forecasts available to a firm in the last fiscal month of the related fiscal year scaled by share price at the beginning of the year. The standard deviation is the absolute value of the simple average of forecasts in the last fiscal month of the fiscal year. The forecast error is computed as the difference between actual earnings and the average of individual earnings forecasts issued in the last fiscal month of the related fiscal year. This number is scaled by the share price of the beginning of the year. Finally, financial analyst coverage is measured by the Log of the number of financial analysts (Table I).

3.2 Methodology

Prior to studying the relationship between voluntary disclosures and analyst coverage, we tested for the existence of the endogeneity problem. The Durbin-Wu-Haussman test

Variable	Definition	Measure
Dependent variables		
NAF	Analyst coverage	The mean number of analysts following the firm each month
MFE	Mean of error forecasts	The absolute value of the difference between actual EPS and mean forecasts, scaled by the share price at the beginning of the year
DISP	Forecast dispersion	The standard deviation of annual analysts forecasts divided by the share price at the beginning of the year
DISC	Voluntary disclosure's decision	A dummy variable that equals to 1 if the firm discloses voluntarily its earnings and 0 otherwise
Independent variables		
SURPRISE	Earning surprise	The difference between actual EPS and the EPS of previous year, scaled by the EPS of previous year
NEGATIVE	Negative earnings	A dummy variable coded as 1 if the annual earning per share is negative and 0 otherwise
NREV	The number of analysts' revisions	The mean number of analysts' recommendations
FLOAT	Ownership structure	The percentage of shares dispersed in public
CONTROL[a]	Controlled shareholder	A dummy variable equals to 1 if there is a controlling shareholder and to 0 otherwise
FORII	Foreign institutional investors	The percentage of shares held by foreign institutional investors
LOGTA	Firm size	The log of total assets
USQUOT	US listing	A dummy equals to 1 if the firm is listed on the US market and to 0 otherwise
LEVERAGE	Leverage	The total long-term debts by the total assets
MTB	Market-to-book	The market value divided by the book value

Notes: [a]According to the French legislation, a two-thirds majority is required to overtake any decision at the special shareholders general meeting. Shareholders that own one-third of the shares can block these decisions. The controlling shareholder holds then at least a third of the shares, when no other shareholder holds a third of the shares

Table I.
Definition and variable measures

of Davidson and Mackinnon (1993) was used. This test was run to check whether our two variables are endogenously determined. The results do indeed show the existence of the endogeneity problem. Therefore, in order to estimate these effects correctly, a simultaneous equations model was estimated. The dependent variable of the first equation in our model is analyst coverage. The voluntary disclosure decision is the dependent variable of the second equation. Analysts are attracted by the firm's disclosure reputation. At the same time, French firms could decide to disclose their earnings voluntarily, because of the increasing need for information by analysts. The simultaneous equation model is estimated as follows:

$$\begin{aligned}\mathrm{LOG}(1+\mathrm{NAF}) = {} & \beta_1\mathrm{DISC}+\beta_2\mathrm{SURPRISE}+\beta_3\mathrm{LOGTA}+\beta_4\mathrm{USQUOT}\\ & +\beta_5\mathrm{FORII}+\beta_6\mathrm{MTB}+u_2\end{aligned} \tag{1}$$

$$\begin{aligned}\mathrm{DISC} = {} & \alpha_1\mathrm{LOG}(1+\mathrm{NAF})+\alpha_2\mathrm{FLOAT}+\alpha_3\mathrm{LOGTA}+\alpha_4\mathrm{LEV}\\ & +\alpha_5\mathrm{USQUOT}+\alpha_6\mathrm{HIGHTECH}+u_1\end{aligned} \tag{2}$$

With, DISC, voluntary disclosure decision; Log(1 + NAF), analyst coverage; DISP, dispersion; FLOAT, float; LOGTA, firm size; MTB, market-to-book; LEV, leverage; USQUOT, US listing; HIGHTECH, high-tech industry; and SURPRISE, earning surprise.

A large number of empirical studies have found that voluntary disclosures are not only associated with analyst coverage; but that firm characteristics are also likely to influence the disclosure policy. These include firm size, float, industry type, US-listing and leverage:

- *Firm size*. Firm size and voluntary disclosures have been found in several studies to be positively associated. Large firms report regular financial information since they face lower costs than small firms (Lev and Penman, 1990; Lang and Lundholm, 1993; Xiao *et al.*, 2004).
- *Free float*. Voluntary disclosure policy is influenced greatly by the form of ownership and management structure. Firms with highly diffused capital disclose regular information in order to decrease the conflicts of interests between managers and shareholders (Jensen and Meckling, 1976; Chau and Gray, 2002; Ho and Wong, 2001).
- *Industry type*. Industry type also affects disclosure choices, particularly in the high-tech industry. High-tech firms voluntarily disclose information, because they are subject to high-earnings fluctuations (Haven *et al.*, 2002; Lakhal, 2005).
- *US-listing*. The disclosure requirements of US markets are greater than those of the French Stock Exchange. US-listed firms have to abide by the USA. Generally accepted principles leading to a higher level and quality of disclosures than those listed on the French market (Raffournier, 1995; Joos, 2000; Xiao *et al.*, 2004).
- *Leverage*. There is a negative relationship between voluntary disclosures and debt level. Firms with high debts are more likely to provide debt-holders with more private information; there is then less need for additional public disclosures (Wallace *et al.*, 1994; Eng and Mak, 2003).

The models of analyst forecasts error and analyst forecasts dispersion were estimated by using a one-equation regression and the ordinary least square (OLS) method as follows:

$$\mathrm{MEF} = \mu_0 + \mu_1\mathrm{DISC} + \mu_2\mathrm{SURPRISE} + \mu_3\mathrm{NEGATIVE} + \mu_4\mathrm{LOGTA} + \mu_5 NREV + u_3$$

$$\mathrm{DISP} = \lambda_0 + \lambda_1\mathrm{DISC} + \lambda_2\mathrm{SURPRISE} + \lambda_3\mathrm{NEGATIVE} + \lambda_4\mathrm{LOGTA} + \lambda_5\mathrm{NREV} + u_3$$

With, DISC, voluntary disclosure decision; MEF, mean forecast error; DISP, forecast dispersion; LOGTA, firm size; NEGATIVE, loss firms; NREV, analyst estimation revisions; USQUOT, US listing; and SURPRISE, earning surprise.

4. Analysis and discussion

4.1 Descriptive analysis

Our sample includes 57.1 per cent companies that disclosed at least one earning forecast or quarterly earning announcement during the period of the study (1998-2001). Table II shows that about 13 per cent of the sample firms are listed on the US market. This dummy variable controls for the existence of listed companies in the US market

	Variable	Frequency	Percentage	Total
DISC	Disclosure	88	57.1	154
	No disclosure	66	42.9	
USQUOT	US listed	20	13	154
	Not US listed	134	87	
CONTROL	Controlled	125	81.8	154
	Not controlled	29	18.2	
HIGHTECH	High-tech industry	28	18.2	154
	Other industries	126	81.8	
NEGATIVE	Negative earnings	14	9.09	154
	Positive earnings	140	90.91	

Notes: This table reports descriptive statistics on categorical variables. DISC is equal to 1 for firms disclosing voluntarily their earnings and to 0 otherwise. USQUOT is equal to 1 for firms listed on the US market and to 0 otherwise. CONTROL takes the value of 1 if the firm is controlled by a large shareholder or a family holding at least the third of shares and 0 otherwise. HIGHTECH takes the value of 1 for firms belonging to the high-tech industry and 0 otherwise. NEGATIVE is equal to 1 if the annual EPS is negative and 0 otherwise

Table II.
Descriptive statistics of nominal variables

that already disclose mandatory quarterly earnings disclosures. French firms are mostly controlled by families or institutional investors. The percentage of firms with concentrated ownership structures is 81.8 per cent. Among industry dummies, only firms belonging to the high-tech industry are retained. Firms belonging to this sector provide regular disclosures because their earnings are subject to high-earnings fluctuations. Lastly, loss firms present a low percentage of 9.09 per cent of the total sample.

Table III reports descriptive statistics for the entire sample. Panel A includes statistics for our dependent variables and Panel B shows statistics for the independent variables. The mean number of analysts following a firm's stock is 18.2 analysts. For a sample of 20 countries, Hope (2003a) shows that France has the seventh position. According to Hope (2003a), the mean number of analyst coverage in France is 22.4. The Netherlands occupies the first position with 29.5 analysts, followed by Germany with 28.8. Switzerland comes after that with 24.8, followed by Singapore, Spain and Hong Kong with 23.4, 23.2, and 23.1, respectively. The mean (median) value of error forecasts is 0.07 (0.03) of the share price. The mean dispersion of forecasts between analysts is about 0.54 of the share price.

Table IV reports the Pearson correlation matrix which was used to check for multi-collinearity. Table IV indicates that voluntary disclosure decision is positively correlated to financial analyst coverage. Furthermore, there is a negative relationship between voluntary disclosures and analyst forecasts dispersion. These preliminary results confirm our hypotheses. The correlation coefficients are, however, low (0.21 and 0.17, respectively). With the exception of firm size, which is correlated with most of our independent variables, the correlations among explanatory variables are relatively low. A serious problem of multicolinearity exists according to Gujarati (1988) if the correlations between the independent variables exceed 0.80. All correlations between independent variables are less than this threshold. The VIF values were computed to check for the existence of this problem and are all far below the critical value of ten (Neter *et al.*, 1989).

	Mean	Median	SD	Minimum	Maximum	Quartile 25%	Quartile 75%
Panel A: dependent variables							
NAF	18.2	15	13.539	1	57	6.75	27
MFE	0.0732	0.03179	0.2002	0.0011	1.910	0.0172	0.0553
DISP	0.5486	0.0719	1.5136	0	14.00	0.0168	0.3264
Panel B: control variables							
SURPRISE	0.8456	0.2036	9.4773	−11.6145	116.142	−0.0538	0.500
NREV	0.0918	0.040	0.152	0.00	1.39	0.020	0.0925
FLOAT	0.2730	0.2360	0.1750	0.00	0.869	0.1587	0.3540
MTB	0.6816	0.5144	0.6819	−2.1129	3.9339	0.3297	0.8261
FORII	0.1589	0.1076	0.1666	0.00	0.688	0.0401	0.2089
LOGTA	7.2368	6.8604	1.8525	3.8916	11.8289	5.8770	8.5982
LEVERAGE	173.73	14.02	499.45	0	4,657	3.49	90.96

Notes: This table indicates descriptive statistics of continuous variables used in the current study. NAF is the mean number of financial analysts following the firm each month. MEF is the mean error forecast that equals to the absolute value of the difference between actual EPS and mean forecasts, scaled by the share price at the beginning of the year mean error forecasts. DISP is forecasts' dispersion calculated as the standard deviation of annual analysts forecasts divided by the share price at the beginning of the year. SURPRISE is earning surprise that equals to the difference between actual EPS and the EPS of previous year, scaled by the EPS of previous year. NREV is the mean number of analysts' recommendations. FLOAT is the proportion of shares available for purchase. MTB is the market value scaled by the book value. FORII is the percentage of shares held by foreign institutional investors. LOGTA is firm size and LEVERAGE is total long-term debts per total assets

Table III. Descriptive statistics of quantitative variables

4.2 Multivariate analysis and discussion

4.2.1 Analyst coverage and voluntary disclosures. We use the method of least squares to test the effect of the voluntary disclosure decision on analyst coverage. The results in Table V shows that voluntary disclosures are positively and significantly associated with analyst coverage. A simultaneous equation model for both decisions (following a firm and disclosing information) was then estimated. The method of three-least squares indicates a positive and significant relationship between analyst coverage and the decision to issue voluntary earning disclosures. Financial analysts are attracted by transparent firms. The costs of collecting information are low when firms disclose regular and additional information. This finding is consistent with the one found by Hope (2003a) on a multi-country sample. This author concludes that analysts follow firms with better accounting disclosure policies. Furthermore, according to Healy *et al.* (1999), disclosure policies attract financial analysts. Our *H1* is thus corroborated. Accordingly, there is a positive relationship between analyst coverage and voluntary disclosure decisions.

The simultaneous equation model also reveals that the number of analysts following the firm does not influence the disclosure decision. This result is in line with Hope (2003a) and Lang and Lundholm (1996) studies. They show that there is no simultaneous effect of analyst coverage and the disclosing decision. We therefore conclude that there are no causal relationships between these two variables. Consequently, the disclosure decision influences, but is not influenced by, the number of analysts following a firm. The positive relationship between analyst coverage and voluntary disclosures is consistent with the claim raised by Lang and Lundholm (1996) suggesting that voluntary disclosures and analyst coverage are complementary in the USA. In a concentrated ownership structure, analyst coverage does not substitute for

Notes: The correlation is significant at *10, **5, and ***1 per cent levels, respectively. This table displays the Pearson correlation matrix. NAF is the mean number of analysts following the firm each month. MEF is the mean error forecast that equals to the absolute value of the difference between actual EPS and mean forecasts, scaled by the share price at the beginning of the year mean error forecasts. DISP is forecasts' dispersion calculated as the standard deviation of annual analysts forecasts divided by the share price at the beginning of the year. DISC is equal to 1 for the disclosing firms and 0 otherwise. NREV is the mean number of analysts' recommendations. SURPRISE is earning surprise that equals to the difference between actual EPS and the EPS of previous year, scaled by the EPS of previous year. NEGATIVE is equal to 1 when the annual EPS is negative and 0 otherwise. LOGTA is firm size. FLOAT is the proportion of shares available for purchase. USQUOT is coded as 1 for firms listed on the US market and 0 otherwise. LEVERAGE is total long-term debts per total assets. MTB is the market value scaled by the book value and FORII is the percentage of shares held by foreign institutional investors

Notes: The coefficient is significant at *10, **5 and ***1 per cent levels, respectively. This table provides multivariate statistics using 3SLS and OLS regressions. DISC is equal to 1 for the disclosing firms and 0 otherwise. Log(1 + NAF) is the Log value plus one of the mean number of analysts following the firm each month. SURPRISE is earning surprise that equals to the difference between actual EPS and the EPS of previous year, scaled by the EPS of previous year. MTB is the market value scaled by the book value. LOGTA is firm size. USQUOT is coded as 1 for firms listed on the US market and 0 otherwise. FORII is the percentage of shares held by foreign institutional investors. FLOAT is the proportion of shares available for purchase. HIGHTECH stands for companies that belong to the high-tech industry and LEVERAGE is total long-term debts per total assets

Table V. Simultaneous equation model

voluntary disclosures as well. Analysts do not supply their services to firms with a poor environmental record and minority shareholders do not request costly analyst services.

Moreover, our results show that the number of analysts following a firm increases as the firm size increases. The coefficient of firm size is positive and significant at the 1 per cent level. This finding shows that firm size is an important determinant of analyst coverage. It is similar to prior findings in different contexts. Studies carried out by Lang and Lundholm (1996) and Lang *et al.* (2003) in the USA, Hope (2003a) in an international context, and Marston (1997) in the UK, show that analysts are more likely to follow large firms, because these firms offer better disclosure policies than small firms. Our results also indicate that there is a negative relationship between analyst coverage and earning surprise. It seems that analysts are attracted by firms with low-earning variability. Financial analysts are also likely to follow firms with predictable earnings. Lang *et al.* (2003, 2004) confirm this finding. They suggest that analysts differ in their earnings estimations when there is uncertainty about firm performance. We notice, however, that the effects of the market-to-book ratio and US listing on analyst coverage are not significant.

Table V reports the effects of firm characteristics on the voluntary disclosure decision. The free-float, measured by the proportion of shares available for purchase, is positively and statistically associated with the probability of issuing voluntary earning disclosures. This result backs up the theory that large shareholders are less reliant on minority shareholders interests and are able to obtain private information internally.

Our result is in line with the assumption that ownership structure affects corporate financial reporting. Chau and Gray (2002) and Ho and Wong (2001) find similar results. The proportion of foreign institutional investors is statistically significant with the expected sign. This result shows that as major actors in corporate governance structures, these investors are likely to influence managers to disclose their earnings voluntarily. The findings also show that large firms and those listed on the US market are likely to make voluntary disclosures. French firms listed on the US market comply more closely with International Accounting Standards. The relationship between leverage and voluntary earnings disclosures is negative. The agency costs of free cash flow are indeed controlled by debt, which plays a substitutive role to control managers. Our finding is consistent with Eng and Mak (2003), who argue that leverage lessens incentives for voluntary disclosures, because it helps control the free cash flow problem in Singapore. Finally, the high-tech industry is positively associated with the voluntary disclosure decision. Such firms belong to a sensitive sector and are inclined to have large price fluctuations, which lead them to inform the market regularly about their earnings.

4.2.2 Analysts forecast characteristics and voluntary disclosures. Table VI reports the results on whether a disclosure policy influences analyst forecast dispersion and error and reduces then market uncertainty. The estimated coefficients on accounting policy disclosures are negative and significant in both OLS regressions. Voluntary earning disclosures are negatively associated with both: forecast error and analyst forecast dispersion. This finding shows that voluntary earning disclosures influence the variations in analyst estimations. These outcomes further support the hypothesis that voluntary earnings disclosures reduce analyst uncertainty about firms' future prospects. Lang and Lundholm (1996) and Hope (2003b) find similar results.

	Mean error forecast OLS		Forecast dispersion OLS

SURPRISE is earning surprise that equals to the difference between actual EPS and the EPS of previous year, scaled by the EPS of previous year. LOGTA is firm size. USQUOT is equal to 1 for firms listed on the US market and 0 otherwise. NEGATIVE is coded as 1 when the annual EPS is negative and 0 otherwise and NREV is the number of revisions made by analysts

Table VI.
Linear regression of mean error forecast and forecast dispersion

They show that additional information is helpful for financial analysts, given that it allows them to correct their earnings estimations and therefore reduces information asymmetry. The more analysts have access to regular information about firm performance, the less-frequent dispersion and error occur in their earnings forecasts. We conclude that even though voluntary earnings disclosures are a small proportion of the total information provided to the market, they are likely to influence analyst forecasts characteristics.

We find a positive relationship between forecast error and earning surprise. The more earnings vary from one year to another, the more analysts are likely to provide different earnings estimations. The variability of earnings was found by Huberts and Fuller (1995) to influence forecast accuracy. These authors suggest that analysts provide the market with optimistic earning per share for firms with high-earnings fluctuations. Finally, there is a negative relationship between negative earnings and error forecasts. The accuracy of earnings forecasts is affected by negative earnings, given that analysts find it difficult to estimate future earnings for loss firms.

Forecast dispersion is positively associated with firm size which is a major determinant of analyst coverage. It is obvious then that the increase in the latter would bring about high dispersion in analyst earning forecasts. As the number of analysts increases, the probability of diverse opinions increases, because analysts are able to acquire various private information or to use differing estimation models. The number of revisions by financial analysts was introduced as a control variable. This variable captures for the information asymmetry effects on the market. The number of revisions is a new indicator. It could be used in subsequent studies as a proxy for the degree of transparency of firm disclosures. The results presented in Table VI show that the number of analyst revisions is negatively and significantly associated with analyst forecast dispersion. This finding suggests that the more analysts revise their estimation about firm value, the more informational uncertainty is reduced.

5. Conclusion

The relationships among voluntary earning disclosures, analyst coverage and the characteristics of analysts' forecasts have attracted little attention in literature. To the best of our knowledge, no studies have been carried out in France to test whether analysts are sensitive to firm disclosure policies or not. Existing literature shows that corporate disclosures enhance analyst coverage as well as the accuracy of their earnings forecasts and mitigate the dispersion between analyst forecasts.

Our findings show that financial analysts choose to follow firms with high-disclosure policies. Earning information is used by analysts to estimate earnings more accurately. This result suggests that financial analysts increase the supply of their services in response to a rich informational environment. However, analysts' services become costly for poor informational environment firms which decrease the supply and demand services. Moreover, we find that earning forecast characteristics are influenced by the disclosure decision. Voluntary earnings disclosures are positively associated with forecast accuracy and negatively associated with forecast dispersion. These disclosures help decrease market uncertainty by enhancing the accuracy of shared information. The results generally suggest that managers are more likely to disclose their earnings voluntarily, in order to reduce information asymmetry and to avoid earning surprises for investors.

One of the limitations of this study is that we did not control for other forms of voluntary disclosures. Besides, voluntary disclosure determinants examined in the present study do not include corporate governance mechanisms such as the characteristics of the board (Karamanou and Vafeas, 2005; Ajinkya *et al.*, 2005; Eng and Mak, 2003).

To sum up, voluntary earnings disclosures are a major determinant of analyst coverage decision, forecast accuracy and forecast dispersion. Although prior research has examined, the relationship between firms' overall disclosure levels and the characteristics of analyst forecasts, there is no prior empirical evidence on the importance of disclosing additional earnings in concentrated ownership structures. A lack of disclosure increases information asymmetry and reduces the level of analyst coverage. As a consequence, investors would be less interested in such firms, and this would probably mitigate market liquidity.

Notes

1. Quarterly earning announcements are not mandatory in France. According to the French legislation, French-listed firms are only required to disclose their annual and semi-annual reports.
2. Cross-sectional data were used and three dummy variables were introduced to control for year effects. The results show that these variables are not significant at usual levels. They were dropped from analysis.

CAPITAL MARKET RESEARCH IN ACCOUNTING: EVIDENCE FROM THE TEHRAN STOCK EXCHANGE

Mohammad Namazi[1*] and Amin Nazemi[2]

[1] *Department of Accounting, College of Economics, Management and Social Sciences, Eram Sq., Eram Paradise, Shiraz University.*
[2]*Department of Accounting, School of Management, University of Tehran Nasr Bridge.*

ABSTRACT

The major purpose of this study is to classify and analyse capital market research conducted in the Tehran Stock Exchange Market (TSEM). Similar to Namazi and Nazemi's (2005) review of Finance Studies on the TSEM in 1991–2003, we review, classify and analyse the significant Accounting Studies related to the TSEM. Consequently, by both employing content analysis and archival methodology and considering academic accounting courses and programs established by the Ministry of Science, Research and Technology (MSRT), the studies are classified into four main topics: financial accounting, auditing, managerial accounting and other subjects. The significant results reported in each of the above groups of studies are presented. It is concluded that, in recent years, the amount of research conducted and the research techniques utilised concerning TSEM-related accounting issues have rapidly improved in various significant aspects of the capital market; yet, much more in-depth research must be carried out.

Keywords: Capital market research, Tehran Stock Exchange Market, financial accounting, auditing, and managerial accounting

INTRODUCTION

A review of historical capital markets studies in accounting can provide a relevant classification system for accounting research findings and their implications. It also discloses the important roles that accounting techniques play in capital markets. Furthermore, it provides an excellent reference by which researchers and financial professionals can review their perceptions and become interested in new topics. Therefore, we collect and review major studies that have been performed on the Tehran Stock Exchange Market (TSEM). Namazi and

Nazemi (2005) concentrated on TSEM *finance* studies, but we concentrate on major *accounting* research, including financial accounting, auditing, managerial accounting and other accounting topics, and summarise the major conclusions that can be drawn from these studies.

REVIEW OF THE LITERATURE

Numerous reviews of market research have been conducted. For example, Lev and Ohlson reviewed accounting market research in the US during the period 1960–1980. They categorised relevant studies into four groups: (i) the information content of accounting information, (ii) the effects of differences in information disclosure and changes in accounting methods on decision making processes, (iii) the effects of making accounting rules on capital markets, and (iv) the impacts of accounting market research on other fields. They found that accounting data have useful and timely content for investors. Although the results are consistent with the hypothesis that accounting numbers are useful, the informational content of accounting information other than values reported in financial statements is uncertain. They also found that functional fixation of investors is unavoidable. They also showed that, for extreme cases (such as oil and gas industries, replacement costs and segmental reporting), regulation carries clear consequences. Consequently, they had suggested that finance theories such as the Capital Asset Pricing Model (CAPM) and Efficient Market Hypothesis (EMH) to be revised.

Kothari (2001) also reviewed capital market research in accounting based on an economic framework (i.e., supply and demand for information). He investigated the relationship between financial statements and the role of capital markets during the 1985–2000 period. His major finding was that the main objectives of capital market research in accounting are valuation, fundamental analysis, EMH testing, and the role of accounting numbers in contracting and regulating. Fundamental analysis, efficient market and value relevance were found to be the topics most frequently investigated by accounting researchers.

Holthausen and Watts (2001) reviewed the value relevance of information and its effects on standard setting. Based on accounting theories, the value relevance of accounting variables and equity valuation has limited implications for the standard setters. They reviewed results in three categories: (i) the incremental association of accounting variables and stock returns, (ii) marginal information content, and (iii) the relationship between accounting variables and equity valuation parameters.

Barth et al. (2001) criticised Holthausen and Watts (2001) and argued that value relevance studies offer informational content for the standard setters. They argued that Holthausen and Watts' (2001) work is not a comprehensive review of value relevance studies in accounting.

Shackelford and Shevlin (2001) reviewed the empirical tax accounting studies in the US and found that three categories of studies were being performed in this domain: (i) coordinating tax and non-tax issues, (ii) the effect of tax on asset prices, and (iii) international and interstate taxation.

Healy and Palepu (2001) investigated discretionary information disclosure by managers. They argued that the demand for financial reporting and disclosure is the result of information asymmetry and agency conflicts between managers and investors. They also showed that earnings, book values and other required information possess informational content. Financial analysts also have provided new valuable information for predictions. Other results were as follows:

i. Auditing reports are perceived to increase the validity of the financial reports, but empirical results are rare;
ii. Accounting decision making can be influenced by compensation and lending contracts, and political costs are also important in this process;
iii. The discretionary information provided by management is considered valid information by investors.

Fields et al. (2001) investigated factors affecting accounting choices. They argued that agency costs, information asymmetry and outside information are important. They showed that only 10% of the articles in the top three accounting journals were related to accounting choices. In addition, the designated empirical research contained some problems that have caused researchers to replicate prior studies instead of developing new ideas. Therefore, the progress of this line of research has been very slow.

RESEARCH METHODOLOGY

This study employs content analysis and an archival methodology (Smith, 2003). We chose the methodology used by Kothari (2001) and modified it based on our national classification of accounting areas. This framework was selected because it is matched with the national and international accounting classifications (Noravesh, 2004).

The time period of 1991–2003 was investigated to obtain enough information related to our topic. Multiple data sources were employed. First, we gathered 205 empirical theses from the Iranian Information and Documentation Center (Irandoc), which maintains a large collection of dissertations. Second, we augmented our information base by reviewing the databases of the accounting research centre of the Audit Organisation of Iran and major Iranian accounting journals and magazines (including *Accounting and Auditing Review*, *Accountant Magazine*, *Auditor Magazine, The Journal of Financial Research, Bourse Magazine, Economic News, Today Message, Planning and Budgeting Magazine, Journal of Humanities and Social Science of Shiraz University, Economy and Management*, and some other academic journals published by Iranian universities). Because we found no comprehensive database of accounting research classification, we chose different databases and compared them to ensure that we obtained the most relevant studies. In addition, we have also used the database of the Shiraz Library of Regional and Science and Technology, which is a comprehensive international database. Finally, after controlling for overlaps between the studies cited in different databases, we found 405 studies for classification and analysis. Table 1 provides general information about these databases and journal articles.

Table 1
Classification of articles and theses.

Number	Resource	Frequency of Articles and Theses	Percentage
1	Iranian Center (Irandoc)	205	50.6
2	Audit Organization Research Center	49	12.1
3	Accounting Journals	68	16.8
4	Shiraz Regional Library of Science and Technology	83	20.5
Total		405	100.0

We collected studies from the 1991–2003 period because TSEM was reactivated in 1991 and accounting studies increased significantly in number thereafter. Furthermore, it was during this period that the number of entities listed in the TSEM increased through the establishment of local stock exchanges, which improved the availability of financial information.

To classify and investigate the main conclusions of these 405 studies, we chose a content analysis and a substantive analysis framework (Smith, 2003). Thus, we attempted to classify these studies based on their areas of focus and their major contributions. This classification, however, is relative and may be changed based on individual judgments.

CLASSIFICATION OF THE STUDIES

Following Namazi and Nazemi (2005), we chose a descriptive framework for the content analysis that encompasses a description of the contents of the articles and classification based upon the topics studied, not on its classification in an ideal situation. Table 2 shows the frequency of accounting and finance studies on the TSEM. Four major topics of study were identified:

i. Financial Accounting;
ii. Auditing;
iii. Managerial Accounting; and
iv. Other Accounting Topics.

Table 2
Frequency of the major topics considered in TSEM.

Number	Topics	Frequency of Articles and Theses	Percent
1	Finance	231	57.04
2	Financial Accounting	58	14.32
3	Auditing	22	5.43
4	Managerial Accounting	17	4.20
5	Other Subjects	77	19.01
Total		405	100.00

The preceding classification system was selected because it is based on the Ministry of Science, Research and Technology (MSRT) academic programs in accounting, and it is expected that the majority of the studies conducted on the TSEM are carried out by the accounting programs of Iranian universities and research centres (Noravesh, 2004).

These findings are briefly presented as follows:

Financial Accounting

Based on our classification, approximately 15% of all TSEM studies during the selected time period were related to financial accounting and specifically investigated balance sheet and income statement items. We further divided these studies into two sub-groups based on their frequency and content. In the first section, we present the "decision making and financial reporting" topics. We then will review "other subjects" in the second section. Table 3 presents a summary of the classifications of studies in this group.

Table 3
Subjects and classification of capital market research in TSEM (1991–2003).

Financial Accounting	Auditing	Managerial Accounting	Other Subjects
Decision Makings and Financial Reporting	Audit reports (64%)	Cost accounting (29%)	Other subjects (58%)
Information System (18%) *	Audit attitudes (14%)	Other subjects (29%)	Impact of economic indicators (18%)
Information Production (12%)	Operating auditing (5%)	Productivity (18%)	Privatisation (17%)
Decision Makers (6%)	Legal inspectors (5%)	Management accounting Obstacles (18%)	Stock Exchange rules (7%)
Other Subjects	Market for auditors (4%)	Management information technology (6%)	
Inflation reporting (14%)	Managerial letter (4%)		
Declaration of dividend (12%)	Audit risk (4%)		
Taxation (9%)			
Consolidated financial statements (7%)			
Liquidity (7%)			
Accounting standards (4%)			
Development reserves (4%)			
Inventory valuation (3%)			
Intangible assets (2%)			
Advertisement costs (2%)			
Total 100%	100%	100%	100%

***** Frequency of studies

Part 1: Decision making and financial reporting

According to the Iranian Accounting Standards, the major objective of financial statements is to present summarised and classified information about the financial position, financial performance and financial flexibility of an entity that is provided to many users to help them make better economic decisions (Accounting Standards, 2007). Therefore, the usefulness of a particular piece of information for decision making is a significant criterion for its presentation. In effect, given the results of a content analysis, it became necessary to classify relevant studies into three categories: information systems, information providers and decision makers.

(a) Information systems

Sahrapour (1993) and Ahmadi (1998) investigated the implications and difficulties of exploiting accounting information systems in the TSEM. Keshavarznejad (1996) studied provision of information to users for decision making purposes. She showed that external users of financial information demand timely information about the actual and expected results, and the lack of this demanded information, along with the inaccuracy and irregularity of information provided to users, are the major problems of Iranian entities' information systems. She suggests that recourse to different means of presenting the required information to external users is the key solution to these problems. Saffarian (2004) reviewed the policies and requirements for disclosures in the TSEM and compared these requirements with other selected stock exchanges' requirements. He maintains that a framework for disclosing information in the TSEM is necessary to harmonise the Iranian information disclosure policies with global international standards.

(b) Information production

A major characteristic of efficient markets is the assimilation of suitable and sufficient financial and non-financial information for decision making. The standard-setters and regulatory agencies, like the FASB and the SEC in the US, the Audit Organisation and Tehran Stock Exchange Committee in Iran and other organisations, attempt to promulgate rules and standards required for disclosure. For example, Iranian Accounting Standard No. 22, entitled *Interim Reporting*, requires selected entities to prepare interim financial statements. Some TSEM studies have focused on this issue.

Hemati (1996), Saghafi and Rahimian (1998) and Zandieh (1998) examined the requirement for providing interim reporting. Hemati (1996) showed that both interim reports exert a significant effect on stock price changes and that entities that publish their interim reports maintain relatively persistent price changes.

Yarmohammadi (2001) investigated major factors that affect timely interim reporting of the TSEM entities. She found that: (i) the firm size, profitability and complexity of activities based on the product type do not affect timely interim reporting; (ii) frequency of stock transactions is positively affected by timely reporting; and (iii) centralised capital structures and the existence of efficient cost accounting systems do not affect timely interim reporting.

The Information Disclosure Act requires listed Iranian companies to publish quarterly non-audited financial statements one month after the selected quarter period and quarterly audited financial statements two months after that period (Davani, 2004). TSEM regulators believe that the disclosure of such information would affect stock prices. Fakhari (1993) and Mokarrami (2000) have investigated this subject.

Mokarrami (2000) found that interim financial reporting contains informational content and affects stock prices at the publication date. Fakhari (1993) conducted a similar study. On the other hand, Zalghi (1996) examined the effect of the accountant's skills on preparation of quarterly financial reports. He did not find a significant relationship between accountants' qualifications and the quality of financial reporting.

(c) Decision makers

The major goal of information assimilation is to provide a basis for decision making. In effect, the primary qualitative characteristics of information will be dismissed if the disclosed information is not relevant.

Dolatshahi (1997), Farrokhnia (2001), and Khoshtinat (1999) investigated these issues. Dolatshahi showed that both investors and auditors employ accounting information such as tax income and extraordinary items, sales, net income, earnings per share, dividends per share and total assets for decision making.

Khoshtinat (1999) showed that financial accounting information can be extracted to decrease the observed bias in judgments and the required education to exploit financial statements. Such changes would not only provide more reliable information, but also cause users to rely more on the information provided in financial statements when making decisions.

Farrokhnia (2001) also investigated the role of financial information in decision making and revealed that investors do not employ any specific technical models in their decision making. He also argued that a lack of specialised knowledge, insufficient information concerning stock exchange databases, a low level of satisfaction with stocks' returns and the ability to earn more profits in other investments, such as bank deposits, bonds, automobiles and mobile phones, have had negative effects on stock market prices.

Saghafi and Malekian (1998) investigated the characteristics of the financial reports of listed Iranian companies and found a significant relationship between the size (total assets), debt to equity, net sales, income before taxes to net sales ratio and the full disclosures of the annual reports. However, they did not find a significant relationship between income before taxes to equity ratio and the comprehensiveness of the reports. Some other conclusions relating to this topic are as follows:

i. There is a need for a database that facilitates analysing the information provided in financial statements. For example, Zaiffard and Arabmazar (1994) investigated this subject and showed that only a few companies prepare and publish such databases; thus, there is a strong need for restructuring of existing accounting information databases;

ii. The harmonisation of information settings at an international level provides a suitable framework for accounting information disclosures. In this manner, investment at a global level is also enhanced;

iii. Interim reporting would affect stock prices of the TSEM; and

iv. Some financial statement items (total assets, debt to equity, net sales and income before taxes to net sales) are employed more than other items for the purpose of financial decision making.

Part 2: Other subjects of financial accounting

We describe other subjects of financial accounting that have been investigated in the context of the TSEM. These subjects, listed according to their frequency (shown in table 3), are as follows: inflation reporting, dividend policies, taxation, consolidated financial statements, liquidity, accounting standards, development reserves, inventory valuation, intangible assets and advertisement costs.

Table 4
Summary of Information System studies.

Title	Author(s)	Objectives	Findings
A) Information systems The investigation of the available methods to assess information used by major users	Keshavarznejad (1996)	The suitable conditions of information reporting to decision makers	Lack of knowledge about asymmetry of real and expected information, different needs of stock holders and lack of needed information, inaccuracy and irregularity in providing information to users, are the major problems.
Policies and required information disclosure in TSEM	Saffarian (2004)	Harmonization of disclosure policies with global standards	A disclosure framework is required.
B) Information production Interim financial statements	Saghafi and Rahimian (1998)	Requirements for preparing interim financial statements	Appropriate interim reports are not prepared in TSEM.
Requirements for preparing interim financial statements by TSEM's listed companies.	Hemati (1996)	The relationship between interim reports and price changes	Relative stability in preparing interim reports.
Factors affecting timely interim reports in TSEM's listed companies.	Yarmohammadi (2001)	The relationship between firms' characteristics and timely interim reports	There is no relationship between the firm's size, profitability, and complexity of products, ownership structure, timely reporting, and stock transaction recordings.
The impact of interim financial reporting on stock prices.	Mokarrami (2000)	The relationship between stock prices and interim reports	Information content of interim reports is shown.
Relationship between the financial reporting quality and the numbers of qualified accountants	Zalghi (1996)	Financial reporting quality	There is no significant relationship between the qualified accountants and the reporting quality.
The impact of accounting information on decision making process in TSEM	Dolatshahi (1997)	Decision making process	Sale items, net incomes, Earnings per share (EPS), DPS and total assets are used for external decision making.

(continued)

Table 4 *(continued)*

Title	Author(s)	Objectives	Findings
The comprehensiveness of annual reports and financial characteristics of the listed companies.	Saghafi and Malekian (1998)	Financial characteristics of the companies	There is a significant relationship between the firm's size, debt to equity ratios, net sales, incomes before taxes to net sales ratios, and full disclosures of the annual reports. There is not a significant relationship between incomes before taxes and stock holders' equity.
The effects of financial accounting presentations on investors' judgments for decision making.	Khoshtinat (1999)	Investors' judgments	Financial accounting information would cause decreasing biases, and the education of using financial statements, would enhance reliability.
The role of financial information in making decisions in TSEM.	Farrokhnia (2001)	Decision making process	Lack of special knowledge, insufficient databases, unsatisfied returns on investments and inconsistency between markets, would cause investors do not use specific models in buy/sale decisions.

(a) Inflation reporting

Financial statements are prepared based on the historical costing approach, but changes in prices and decreases in purchasing power caused by inflation have affected financial information and reduced the relevance of historical cost information. Thus, SFAS No. 33 in the US, for example, required enterprises to present supplementary adjusted financial statements based on general price levels. However, presentation of such information became discretionary because of pressure from lobbying groups. Thus, researchers have sought to find answers to such questions as whether presentation of the adjusted information (based on the price level changes) affects investors' decisions.

Mostophi (1993) attempted to determine whether adjusted income statements based on general price changes are more useful for predicting future earnings than historical cost information. He found that adjusted income statements indeed contain little information for predicting future earnings and therefore, the relevance of the qualitative characteristics of such information is in doubt.

In another study, Moradinia (1994) investigated the types of information employed in decision making. She showed that investors utilise more non-financial information and consider this type of information to be more reliable. In addition, she reported that nearly all users adjust the financial statements before decision making. These adjustments include: (i) fixed assets revaluation and consideration of foreign liabilities and their effects on net income, (ii) adjustments based on the qualified paragraphs in the audit reports, (iii) adjustments based on the inflation rate, (iv) adjustments based on the deferred taxes, and (v) adjustments based on the foreign exchange rates.

Asgharian (1994) tested the impacts of the general price index financial accounting items on price settings in the cement industry. He found that these adjustments cause increasing stock prices of the listed companies. However, he referred to the cost-benefit concept and concluded that historical information was suitable for price setting. Johari (1996) and Ghanavati (1996) also investigated this question in the textile industry.

In summary, there is no distinct evidence about the effects of general price level changes on financial statements and decision making. However, it seems that revaluation of assets that has been deemed legitimate by the national accounting standards setter (the Audit Organisation) somewhat decreases the inflation effects of the financial accounting statement items.

(b) Earnings declaration and dividends

As a general rule, entities distribute earnings between their stockholders through cash or stock dividends. Thus, Samadzadeh (1993) studied earnings distribution policies and their effects on the stock values for TSEM companies. He found that managers were not familiar with earnings distribution policies and did not follow the prescribed policies for presentation of the financial positions of the entities.

On the other hand, stockholders did not pay attention to cash dividends and their changes as an adjustment signal. In addition, he showed that earnings distribution did not affect stock returns because of the legitimacy of earnings distribution time lags (the National Business Act permits entities to delay cash dividend distribution for eight months after approval). Therefore, stockholders are not interested in earnings distribution. Abbasi (1991), Gholipour (1995), Abdollahpoor (1997) and Rohanipoor (1999) also conducted studies in this line of research and reported similar results.

One of the most common objectives of earnings distribution studies is to investigate the relationship of earnings distributions with stock prices and stock returns and, therefore, market efficiency. Namazi (2004) and Namazi and Shooshtarian (1996) investigated this subject and showed that:

i. The concept of efficiency and its different levels (weak, semi-strong and strong forms) is complex, and it depends on different contexts, such as competitive markets, efficient information systems, and correct understanding of financial information by its users; and

ii. Market-based research shows that the TSEM is not efficient in the weak form, but it is moving towards efficiency by increasing local stock markets' development and improving information systems - especially for accounting information. However, at present, the efficiency evidence is not statistically significant.

(c) Taxation

Despite the importance of tax incomes for the listed companies (at least for reporting to the government), studies in this area are scarce. Tax allowances of the listed companies and indirect use of tax information by investors in decision making are two major topics that have been addressed by this field of research. In addition, preemptive right taxes, investment taxes and tax laws have been studied by Iranian accounting researchers.

Golestani (1996) showed that tax assessments of nearly 87% of the listed companies are based on their journals and ledger books, and the remainder (13%) are based on tax officials' assessments. About 63 percent of the listed companies follow Generally Accepted Accounting Principles (GAAP). However, they are aware of the existence of conflicts between the GAAP-based and tax-based income numbers and the probable losses resulting from these discrepancies. About 63% of the listed companies have sufficient knowledge about acceptable expenses and depreciations and have some experience with declaring assessment notices, but they do not sufficiently record the required tax provision caused by the tax differences.

In addition, about 42% of the managers argued that tax rates are high and that there is a need to revise the tax rates. Importantly, 98% of the managers argued that tax problems are the main obstacle for asset revaluations. In addition, 48% of the listed companies do not employ tax exemptions for development reserves because they are not acceptable by the Ministry of Economics and Finance.

The revaluation obstacles and non-tax exemptions showed that revaluation of assets would not lead Iranian companies to revaluate and present their financial statements based on the current values. Therefore, historical costs are the prevalent method for preparing financial statements. Given the tax assessment legitimacy of the Iranian Certified Accountants, conducting more research on tax problems and their obstacles seems necessary. Consequently, creation and development of an efficient tax system that supports investment in financial assets also seems very desirable.

(d) Consolidated financial statements

In Iran, when an entity obtains control over another entity, consolidated financial statements are required. In recent years, the number of companies that are required to consolidate their financial statements has increased. Thus, Khoshyomn (1998) investigated the extent to which parent companies rely on their subsidiaries' financial information. He found that for 89% of the sampled companies, auditors reported a qualified opinion, and returns on the investments in investees' companies were less than 20%. He also discovered that approximately 35 to 42.5% of the financial statements of the investees were used by the investors for decision-making purposes.

Langari (1994) and Samarbakhsh (2001) also studied the role of the consolidated financial statements in decision making. Langari (1994) showed that although consolidated financial statement information is needed for decision making, it is not exploited appropriately. He argued for the following causes of this problem:

i. The public sector's management of business units;
ii. A lack of sufficient knowledge relating to consolidation;
iii. A lack of authoritative requirements;
iv. A failure to reflect the subject in the audit and legal inspectors' reports;
v. The existence of surrogate information;
vi. The existence of unsuitable and inefficient accounting systems;
vii. Inefficiency of personnel and accounting systems of the parent companies; and
viii. A failure to implement financial management ratio analysis.

Unfortunately, studies on this topic are scarce, and therefore we cannot assess its findings extensively. More research in this area is required.

(e) Liquidity

Mansoori (2003) and, recently, Namazi and Mansoori (2007) investigated cash flows and liquidity cycles of listed companies for the period of 1997–2001. They showed significant positive relationships between cash flow cycles and current ratios, accounts receivable and inventory turnover. They also found significant negative relationships between cash flow cycles and acid test ratios, accounts payable turnover, gross profit sales ratios, return of investment (ROI) and leverage ratios. However, there was no significant relationship between cash flow periods and return of assets (ROA) ratios.

(f) Accounting standards

The Audit Organisation is a government agency in Iran that is authorised to enforce accounting and auditing standards. Accounting standards have been prescribed since 2002, and so far, this organisation has published 29 standards and 3 other promulgations that are in due process (concerning EPS, impairment of assets, the disposal of noncurrent assets held for sale, and discontinued operations).

Alizadeh (1997) revealed that the disclosure standards were used in preparation and presentation of the balance sheet by 95% of the sample companies. Furthermore, these standards were exerted in preparing income statements by 90% of the companies and were used for cash flow statements by 75% of them. He concluded that the implementation rate of the disclosure standards in preparing and presenting financial reports by the listed companies was 80%.

(g) Development reserves

Mahooti (1996) investigated 23 listed companies during the period of 1992–1994 and found no significant correlations between raising capital resources and the development of physical assets. On the other hand, resources that were provided by capital increases were not implemented to develop and complete fixed assets. He also showed that there was no significant relationship between proposed dividends and dividends payable and distributed earnings for the listed companies.

(h) Inventory

Very limited research in this area was found. Evazi (2002) investigated factors affecting inventory accounting choices. He revealed that there were no significant relationships between accounting choices (such as the FIFO and average methods) and the firm size, debt to working capital ratio and industry type.

(i) Intangible assets

Boghaddareh (1995) studied accounting for intangible assets for the listed companies and showed that companies employed traditional accounting methods that were not based upon a uniform criterion for valuation and bookkeeping purposes; therefore, intangible assets were not presented properly.

(j) Advertisement costs

Ebrahimi (1995) investigated the application of the recognition method for advertisement costs (i.e., capitalising or expensing advertisement costs) and found that advertisement costs could be capitalised in some industries. He investigated four industry groups during the period of 1977 to 1993, including: (i) chemical, (ii) food and beverages, (iii) textile, and (iv) household appliances. Except for the chemical industry, in which advertisement costs had a significant influence on future revenue distributions and should be expensed in the current period, advertisement costs had no influence on revenue distributions.

Summary Check Points in Financial Accounting

We can briefly conclude that, except for reporting, there are only a few studies on financial accounting in the Iranian context. Therefore, Iranian researchers should consider other topics within financial accounting and concentrate more on investors' decision-making demands. The most important results of the financial accounting section can be summarised as follows:

i. Earnings distribution does not affect stock returns, and stockholders are not interested in the dividend policies because of multiple problems;
ii. Tax acts are the major obstacle to revaluation of assets;
iii. Despite the importance of the consolidated financial information, it is not properly utilised for decision making;
iv. Resources raised by equity holders are not employed for development and equipment costs;
v. There are no significant relationships between accounting choices and firm size, debt to working capital ratio and industry type;
vi. Intangible assets are not valued and presented properly in the financial statements of the listed companies;
vii. Advertisement costs can be capitalised in some industry groups.

Auditing

As table 3 shows, auditing reports are the second major topic considered by Iranian researchers. Alizadeh (1995) investigated auditors' attitudes towards major factors that would cause earnings changes that affect decision making processes. He concluded that a proper information presentation in financial statements, especially earnings changes caused by sales price variations, production and sales volume and changes in costs of goods sold items, were useful in the decision making processes of the financial statements' users.

Rahimi (1996) investigated the impact of the audit evidence on audit reports. Jamshidi (1993) and Tabibi (1993) also reviewed problems confronting the exploiting of audit reports for the listed companies and the reasons for adverse (or qualified) reports.

Rajabi (1997) analysed audit service markets in Iran and showed that the client, firm size and type of the firm significantly affected the audit fees. He argued that the Audit Organisation, which is a governmental organisation, provides major auditing services in the country, and therefore the audit market is not competitive. (This research, however, was conducted ten years ago, and currently a segment of the audit services have been transferred to private auditing firms).

Golnari (1997) selected 60 companies listed during 1991–1995. He reviewed their audit reports and found that, in recent years, most of the auditors and legal inspectors' reports were routine, and stockholders did not pay attention to these reports. Ebrahimi (1999) also showed that auditing and legal inspector reports were not considered by common stockholders; but Mousavi (1999) showed that lenders, stockholders and investors rely on the audited financial reports.

Noravesh and Fiali (1997) investigated the entropy of the balance sheet items and auditing correction notes and reported a significant relationship between the entropy of other assets, accounts payable and auditing correction notes.

Nick-khah and Mojtahedzadeh (1998) reviewed the responsibilities of the independent auditors and argued that the auditors’ most important responsibilities include audit assessment, evaluation of internal control structure, detection of misstatements (errors and fraud), evaluation of social responsibility and accountability of the clients.

Shabahang and Khatami (1999) tested the effects of the qualified opinions on stock prices and on stockbrokers' analysis of the annual financial statements. They found that audit paragraphs affected clients' stock prices, but stockbrokers did not consider audit paragraphs in their analysis. Thus, audit qualification paragraphs are only effective in changing institutional investors' behaviours.

Azgoli (2000) also investigated the impact of auditing reports on the stock prices of the TSEM listed companies and reported that the type of information reflected in auditing reports can change stock prices.

Kadkhodaee and Mohammadi (2001) studied the relationship between stock returns and the type of audit assessments for the listed companies. They concluded that:

i. A significant portion of the audit reports (approximately 68.5%) were issued by the Audit Organisation; and
ii. There was no significant relationship between audit assessments and stock returns.

They recommended that authoritative bodies support and develop suitable rules and regulations and train stakeholders to improve the efficiency and usefulness of the auditing reports.

Mirmotaharri (2001) studied 50 actively traded companies from 1998 to 2000. He revealed that, in nearly all selected samples, *qualified* audit reports were issued. In addition, the number of qualification paragraphs in manufacturing companies' reports was greater than in the investment companies' reports. Finally, he argued that tax qualified paragraphs (in the audit reports) were the most frequently appearing paragraph in audit reports of the sampled companies.

Summary Check Points of Auditing

The most frequent topic considered by auditing researchers in the TSEM context is the content of auditing reports. The existing findings do not support any hypothesis with certainty. Therefore, there is a need for in-depth studies to be conducted in the future. In these studies, the roles of the Audit Organization and the Iranian Certified Public Accountants (IACPA) should also be considered. Table 5 summarises the major findings of this line of research.

Table 5
Summary of the auditing research findings.

Title	Author(s)	Period (year)	Findings
An analytical study of the auditing attitudes towards the effect of disclosing significant factors in earnings changes.	Alizadeh	1995	Appropriate disclosures in financial statements (specifically earnings changes, sales price changes, sales volume changes and changes in the costs of goods sold items) are useful in decision makings.
Studying the relationship between the entropy of financial positions and auditing correction notes.	Noravesh and Fiali	1997	There is a significant relationship between some balance sheet items and audit correction notes.
The effectiveness of the auditor and legal inspectors' reports in common stockholders' decisions.	Golnari	1997 (1991-1995)	Most of the reports issued during recent 5 years, are repetitive and therefore, they are not used for decision makings.
Auditing markets in Iran	Rajabi	1997	Size of the firm is a significant factor affecting the audit fees.
Identifying auditing responsibilities based on the auditing users and auditors' views.	Nick-khah and Mojtahedzadeh	1998	Audit assessment, evaluation of the internal control structures, fraud detection, evaluation of the social responsibility and client accountability are the most important responsibilities
The effect of auditing reports on stock prices and annual financial statements analysis by stock brokers.	Shabahang and Khatami	1999	There is a significant relationship between the auditing qualification reports and stock prices.
Auditing reports in TSEM	Mirmotaharri	2001 (1998-2000)	Nearly all samples received a "qualified report". The most frequent qualified paragraph is relating to the "tax" paragraph. The number of the "qualified paragraphs" for manufacturing companies is more than the investment companies.
The effect of auditing assessments on stock prices.	Kadkhodaee and Mohammadi	2001	There is no significant relationship between audit assessments and stock prices.

Managerial Accounting

As table 3 shows, most managerial accounting studies of the TSEM have concentrated on cost accounting. Jalilpour (1995) investigated the application of a *master budget program* in the tire and plastic industry. He showed that implementing a master budget improves performance and increases efficiency. He also pointed out the role of the human aspect of the budgeting process and argued that managers' communication would improve their knowledge on the objectives and permit problems and constraints to be overcome.

Khajavi (1995) found that the managers of the manufacturing companies in the TSEM do not possess sufficient knowledge about different management accounting concepts and methods. He maintained that the most important restrictions against the development of management accounting concepts in manufacturing companies are as follows:

i. Lack of necessary information for predicting the required variables;
ii. Lack of cooperation and coordination between different manufacturing departments;
iii. Problems in training managers to understand what is being implemented in practice (i.e., practical management accounting methods); and
iv. Difficulties in separation of the fixed and variable costs that arise because of internal and external problems.

Ebrahimi (1997) argued that an Activity Based Costing (ABC) system could provide vital information for managers to enable them to concentrate on customers, identify opportunities and create improvements in the organisation. He studied the possibility of implementing ABC in a particular company (Gas-Butan Manufacturing Co.). He concluded that there were two prerequisites for implementing ABC in this company: (i) the existence of various management styles and accountability for employing the system and (ii) data availability and an appropriate environment for designing and establishing ABC. Managers of the selected company had sufficient knowledge to implement ABC. Furthermore, it was possible to identify activities and cost drivers in the company to compute the ABC costs.

Masoumian (1997) focused on other aspects of the management accounting methods. He studied the capital project evaluation methods in the TSEM. He reported that the selected managers mostly exerted two capital budgeting methods, the net present value (NPV) and the profitability index (PI), and they did not employ other analytical methods of evaluating the projects. In addition, managers argued that the PI index was the most important method and that NPV, internal rate of return, payback period, accounting rate of return and reverse payback period were the next most important methods that could be exercised by TSEM companies.

Gholipour (1997) reviewed the role of management cultures in improving human resource productivity among the listed companies. He argued that religious aspects of the culture affect productivity and that nearly all productivity problems result from management weaknesses. Hajikarimi (1992) gathered nine years of time series data to investigate the relationships between productivity, employee training, compensation and corporate culture. He reported a positive relationship between productivity, training and compensation, but he found no relationship between productivity and cooperation. Esmaeelpour (1994) also reviewed the role of effective communication in increasing productivity and investigated the contributions of the significant factors affecting productivity.

Summary Check Points in Managerial Accounting

Limited study of TSEM managerial accounting issues has been attempted. The studies conducted are mainly related to the extent of management knowledge about information technology, the role of cost accounting systems in management control, cost control processes in the automobile industry, and empirical research on total quality management (TQM) in the pharmacy industry. Table 6 provides a summary of the findings.

One can conclude that the major managerial accounting studies are related to cost accounting issues and problems and obstacles hindering the implementation of cost accounting systems. However, few studies exist in the field of management accounting. Therefore, it is imperative that researchers pay more attention to this field. Also, it seems that the TSEM listed companies face different problems in applying advanced managerial accounting techniques such as the ABC. These problems are mainly related to employee resistance to change and a lack of knowledge about the necessary techniques, productivity and information updating.

Table 6
Summary of management accounting research findings.

Title	Author(s)	Period (year)	Findings
Designation of a human resource productivity model in the industry.	Hajikarimi	1982–1991 (1992)	Productivity is related to training and non-fixed compensation fees directly, but it is not related to corporation's environment.
Budgeting process in the tire and plastic industry.	Jalilpour	1995	Master budget improves performance and increases efficiency.
The investigation of management accounting obstacles in TSEM' listed companies.	Khajavi	1996	Managers do not have sufficient knowledge about management accounting concepts and methods. Lack of necessary information, Lack of managers' understanding of practical methods, Lack of separation of fixed and variable costs are essential problems.
The relationship between strategic decision making models and productivity in the mineral industry.	Gholipour	1997	Management weaknesses would cause less productivity.
Long-term investment evaluation methods (capital projects) in TSEM.	Masoumian	1998	Companies mainly use only two methods for capital investment evaluation; NPV and PI.
Required conditions for implementing ABC in the house appliance industry.	Ebrahimi	1997	Managers had sufficient knowledge about ABC. In addition, it was possible to identify activity cost drivers in selected companies.

Other Subjects

In this section, we review other important topics: macroeconomic variables, privatisation and other related subjects (see Table 3). These studies are listed in table 7.

Table 7
Summary of other economic subjects in TSEM.

Subjects	Author(s)
Comparison of the TSEM with other stock exchange markets	Dorodi (1995), Arman and Salehi tabar (1999), Ekbatani (2001)
The need for other exchange markets (agricultural and metal products)	Rasoolof (2002), Eskandari (2003)
Stock insurance	Valibeigi (2002), Ghazizadeh (2003), Talebi (1997)
Stock exchange based on the religion and law views	Mirnasiri (2003), Karimi (1996), Emamgholi (1997)
Stock exchange and automobile industry	Arman (1997)
Women participation in the stock exchange	Shahrokni (1999)

The effect of macroeconomic variables

Economic factors affect society as a whole. In Iran, oil revenues are the major income source of the government. Therefore, changes in oil prices affect economic welfare nationwide. In addition, gold prices, foreign currency prices, inflation, real estate conditions and fuel prices are the most important economic variables and thus, they have been investigated in the context of the TSEM.

Lotfi (1997), Badkobehi (1995) and Yahyazadehfard (1999) studied the effects of inflation and prices. Taghavi (2001), Khodaei (1999), Jalali and Ghalibaf (2002), Noormohammadi (1995) and Allahbakhshi (1996) investigated the effects of foreign currencies on stock prices and returns.

Javadpour (1996) found that forward index changes and stock price variations are not correlated. On the other hand, except for the two indices that did match the signs of stock price changes, other index changes were not significant; the first index was the number of building permissions for the private sector and the second was the number of licenses for new industries.

Lotfi (1997) studied stock return time series trends. He found that the rate of return growth was greater than the inflation rate. Also, the stock price index growth far exceeded the inflation rate and the net income growth rate and the dividend growth rate was indeed greater than the inflation rate. He also concluded that the stock price growth rate was abnormal in selected samples. Badkobehi (1995) and Yahyazadehfard (1999) also considered this subject and reported similar results.

The preceding findings suggest both that economic factors affect financial parameters and stock market variables and that stockholders should utilise hedging policies to minimise economic effects. However, more in-depth research is required to identify the effects of other economic factors, such as inflation, oil prices and foreign currency prices.

Privatisation

In recent years, the Iranian government has tried to increase its efficiency and effectiveness by transferring governmental holdings to private sectors. An important question, however, is how to privatise. Generally, stock markets are integrated and organised markets that are structured by many investors. These markets can be extracted for privatisation. Therefore, the government has attempted to privatise governmental entities through the TSEM. The government has also attempted to monitor governmental entities that become private companies to assure an increase in their efficiency and effectiveness. Aminimehr (1994) investigated the efficiency of privatisation and revealed that privatisation through the TSEM has not been truly efficient.

Miri (1995) investigated privatisation trends in manufacturing entities and concentrated on their efficiency and effectiveness. He discovered that the profitability and production ratios increased after privatisation.

Talebi (1997) compared market values based on the initial public offering (IPO) prices of private companies and discounted cash flows. He showed that stock price changes were not related to predicted rate of returns. Therefore, it was not possible to determine stock prices based on financial and economic variables. He argued that accounting and economic valuation techniques would create significant problems for price detection.

Arabi (1996) showed that privatising manufacturing companies would improve their performance. He studied this subject in the chemical, food and beverage, tile, mineral and packaging industries and found that except for the chemical industry, performance increased following privatisation.

On the other hand, Almasi (2001) considered the effect of privatisation policies based on the Economic and Social Development Plans and extracted three criteria (EPS, ROA and return of equity (ROE)); he reported that the selected companies' performances did not improve after privatisation.

Table 8 shows a summary of the findings for this section.

Table 8
Major results of privatisation in TSEM.

Title	Author(s)	Period (year)	Findings
Comparison of privatisation methods and trend reviews.	Aminimehr	1995 (two period)	Privatisation methods are not appropriate in spite of the acceptance of provisions in TSEM.
The effects of privatisation on the efficiency of manufacturing companies.	Miri	1995	Profitability and production ratios have been increased after privatisation.
IPO (Initial Public Offering) pricing problems and suggestions for an appropriate method.	Talebi	1997	Comparison on the first price and present value of discounted cash flows shows that financial and economic information are not sufficient for price detection.
The effects of industry type on performance after privatisation.	Arabi	1997	Privatisation concepts for pharmacy industry would improve performance.
The effects of privatisation on financial performance in TSEM.	Almasi	2001	After privatisation, financial performances (ROE, EPS, and ROA) have not been improved.

Based on these results, one can conclude that the efficiency of privatisation has not been significant because of the lack of appropriate monitoring mechanisms, the use of an inappropriate privatisation framework, errors in pricing and mistakes in firm selection. These factors should be seriously considered by the government because if public reliance on privatisation decreases, it would be difficult to restore it and the advantages of privatisation would be diminished.

SUMMARY AND CONCLUDING REMARKS

The TSEM has an important role in merging small investments and it provides an efficient capital allocation mechanism. Various researchers have studied different accounting-based variables pertinent to the TSEM companies. In this study, we have cited and categorised these subjects and findings published during the 1991–2003 period based on content analysis and archival evidence. We believe this classification will be useful and effective for future research by categorising the major studies and their findings.

The major objectives of this study were to compile a relevant database of studies conducted on the TSEM and to report the significant findings of these studies and their implications for the capital market. In approaching these objectives, after reviewing different databases and published articles, following Namazi and Nazemi (2005), we based our classification system on the content and frequency of the articles and we classified the relevant studies into four groups: financial accounting (14.3% of studies), auditing (5.4%), management accounting (4.2%) and other subjects (19.0%). Finance studies (57.1%), which comprise the majority of TSEM studies, were not considered because Namazi and Nazemi (2005) presented these results.

The finance studies, however, make up the majority of the reviewed literature. According to Namazi and Nazemi (2005), information content studies (16%) were the most frequent studies in this section. Stock prices and stock returns predictions (9%) and market efficiency (8%) were the next most frequent topics considered by the researchers (Namazi and Nazemi, 2005).

Financial accounting is the second most popular area of study. Financial reporting, information disclosure and decision making (totalling nearly 40%) were the major topics studied based on the number of published studies. Financial reporting studies are divided into three groups: information provider, information users and information systems. Accounting standards, taxation and consolidated financial statements are also included in this section.

Auditing studies of the TSEM are concentrated on auditing reports. Auditing reports provide a summary of auditors' findings. The reliability of audit reports is increased if they are assessed by independent auditors because they must be independent and qualified to provide an accurate assessment. However, in the future, more research must be conducted in this venue because the auditing profession involves other aspects worthy of study.

Cost and management accounting were introduced as the third most frequent topic studied in the TSEM context. Budgeting methods, the ABC system, decision making techniques, and human aspects are the major topics in this section. It seems that researchers have not extensively studied managerial accounting topics because of the difficulty or impossibility of collecting the required information from the TSEM companies.

Finally, we presented research on other topics, such as economic factors and privatisation. Based on the results, we can conclude that privatisation mechanisms are inefficient because of the lack of an appropriate monitoring framework, the use of inappropriate privatisation mechanisms, errors in pricing, and mistakes in firm selection. These findings could help the government to improve the efficiency and effectiveness of the economic resources involved in the privatisation process.

We should note that these findings are relevant to a specific period (1991–2003) and are not comprehensive. We only attempted to explain the major studies and results. We also encountered many restrictions when attempting to access databases. These databases, in some cases, were not complete, and therefore it is probable that some relevant studies are not included in this review. Furthermore, access to the results of past studies was not easy to obtain. Unfortunately, even the most complete academic database (i.e., irandoc.ir) contains a substantial amount of missing data. Therefore, we could not obtain complete information about some studies. Finally, we found that some researchers' names were repeated two or three times because their topics were not new and/or their studies were published in different sources.

In summary, in recent years, the number of studies relating to different aspects of the TSEM has increased significantly, and the research techniques and approaches used in these studies have also improved greatly. They have provided useful knowledge about the capital market and the functions of accounting areas. However, much more research is necessary. We suggest the following areas for future investigations:

i. Creation of a more comprehensive database of TSEM studies;
ii. An in-depth analysis of each area of the studies identified in this article;
iii. Studies of different accounting standards and values relating to the TSEM and its efficiency;
iv. Research on the implications of the auditing standards, managerial accounting data and systems, tax laws, etc. for the efficiency and effectiveness of the TSEM; and
v. Creation of EMH mechanisms in the TSEM.

ACKNOWLEDGEMENT

This article is the revised version of the paper titled, The Implications of the Accounting Research in Tehran Stock Exchange Market, presented in Asian Pacific Conference on International Accounting Issues, November 9–12, 2008, Paris, France. The authors express their gratitude to the Conference participants, the editor of AAMJAF journal, and anonymous referees for their constructive suggestions.

Evidence on the Dark Side of Internal Capital Markets

Oguzhan Ozbas
University of Southern California

David S. Scharfstein
Harvard Business School and NBER

This article documents differences between the Q-sensitivity of investment of stand-alone firms and unrelated segments of conglomerate firms. Unrelated segments exhibit lower Q-sensitivity of investment than stand-alone firms. This fact is driven by unrelated segments of conglomerate firms that tend to invest less than stand-alone firms in high-Q industries. This finding is robust to matching on industry, year, size, age, and profitability. The differences are more pronounced in conglomerates in which top management has small ownership stakes, suggesting that agency problems explain the investment behavior of conglomerates. (*JEL* D21, D23, G31)

There is wide variation in the way firms are organized. For example, in 2005, Anadarko, Murphy Oil, and Kerr-McGee were all engaged in oil and gas exploration and production (E&P). However, while E&P was Anadarko's only line of business, Murphy Oil was integrated downstream into oil refining and marketing, and Kerr-McGee had unrelated operations in titanium dioxide. This variation in organizational form suggests some important questions: Did Anadarko, Murphy Oil, and Kerr-McGee manage their E&P businesses differently because they were parts of different types of organizations? Did their performances differ as a result?

Answering these types of questions is a central goal of organizational economics. It is also central to corporate finance: mergers and acquisitions, divestitures, spin-offs, and management buyouts all change organizational structure in ways that are designed in part to affect firm behavior and performance. Indeed,

This article is an extensive reworking of "The Dark Side of Internal Capital Markets II: Evidence from Diversified Conglomerates," National Bureau of Economic Research Working Paper No. 6352. We are grateful to the National Science Foundation, the MIT Financial Services Research Center, the Harvard Business School Division of Research, the Walter A. Rosenblith Fellowship Fund, and the Marshall General Research Fund for financial support and to numerous seminar participants for their comments on the prior version of the article. Judy Chevalier, Robert Gertner, Julio Rotemberg, Henri Servaes, and Jeremy Stein provided very useful feedback on the prior version of this article, as did Michael Weisbach (the editor) and an anonymous referee on the present version. Send correspondence to Oguzhan Ozbas at the University of Southern California, Department of Finance & Business Economics, Marshall School of Business, University Park Campus, Building HOH 514, Mail Code: 0804, Los Angeles, CA 90089; telephone: 213-740-0781; fax: 213-740-6650. E-mail: ozbas@usc.edu

doi:10.1093/rfs/hhp071 Advance Access publication September 23, 2009

in 2006 Kerr-McGee spun off its titanium dioxide business to become focused on E&P and was then sold to Anadarko. Was this because Kerr-McGee's diversified structure was inefficient?

This article analyzes the relationship between organizational form and efficiency by comparing the investment behavior of stand-alone businesses to the investment behavior of businesses that function as part of a diversified conglomerate. Williamson (1975) suggests that the internal capital market of diversified firms might allocate capital more efficiently than the external capital market because top management of a diversified firm is better informed about investment opportunities than external investors. Along these lines, Gertner, Scharfstein, and Stein (1994) and Stein (1997) present models that identify circumstances under which internal capital markets lead to more efficient investment decisions. In particular, Stein (1997) argues that managers of stand-alone firms will be reluctant to cut investment when they have no good investment opportunities. An internal capital market comprised of multiple business lines allows managers to redeploy capital from divisions with poor investment opportunities to those with good investment opportunities without compromising the overall capital budget.

There is also a theoretical literature that suggests just the opposite—that internal capital markets function less efficiently than the external capital market. Scharfstein and Stein (2000) argue that when firms are composed of divisions with good and bad investment opportunities, rent-seeking behavior on the part of divisional managers will lead top management to overinvest in the weak division and underinvest in the strong division. Meyer, Milgrom, and Roberts (1992) and Rajan, Servaes, and Zingales (2000) make similar predictions.

Given the competing theories, the answer is ultimately an empirical one. Thus, we compare the investment behavior of stand-alone businesses (such as Anadarko) with comparable business segments of diversified companies (such as Kerr-McGee's E&P business). We start by estimating the responsiveness of capital expenditures to industry investment opportunities, as measured by industry Q. Our basic finding is that the investment of stand-alone businesses is more responsive to industry Q than is the investment of "unrelated" segments of conglomerate firms. This finding is driven mainly by the fact that unrelated segments of conglomerate firms tend to invest less than stand-alone firms in high-Q industries. This fact is robust to careful matching of unrelated segments to stand-alone firms based on size, profitability, and age.

The lower investment of unrelated segments relative to stand-alone firms in high-Q industries could be a symptom of underinvestment by unrelated segments or overinvestment by stand-alone firms. To distinguish between these two interpretations, we examine whether this finding is more pronounced in diversified firms with low management ownership. If it is the unrelated segments that are investing inefficiently, and not the stand-alone firms, we should find more pronounced differences in diversified firms with low management ownership. This is indeed what we find. The finding is in line with the prediction of

Scharfstein and Stein (2000), who argue that one must have agency problems both at headquarters and at divisions to give rise to the inefficient allocation of capital.

A number of other papers have presented evidence of inefficient internal capital markets. Lamont (1997) shows that when oil prices are high, the non-oil divisions of diversified oil producers seem to invest more than their industry peers. Shin and Stulz (1998) find similar evidence in a broader sample: small divisions of conglomerates invest more when other divisions have high cash flows, but the extent of their investment does not depend on Q. Rajan, Servaes, and Zingales (2000) find that when divisions are in low-Q industries relative to other divisions in a firm, they tend to invest more than their stand-alone counterparts, and they tend to invest less when they are in high-Q industries relative to others in the firm. Billett and Mauer (2003) find that firms that they deem to have more efficient internal capital markets are more highly valued. The results are also related to those of Gertner, Powers, and Scharfstein (2002), who show that when divisions of diversified conglomerates are spun off, their investment becomes more sensitive to industry Q.

We see three main contributions of our article relative to the existing literature: the measurement of relatedness, our matching procedure, and the identification of the role of management incentives. With respect to relatedness, we are careful to identify segments of diversified firms that are truly unrelated to other segments by using information in the Input-Output Benchmark Surveys of the Bureau of Economic Analysis. The surveys provide data on the flow of goods and services among industries and allow us to identify significant vertical and horizontal industry relationships (Matsusaka 1993; Fan and Lang 2000).[1] As we argue, it is important to identify segments that are unrelated to others to ensure that there are no transfer pricing and co-investment decisions that introduce more measurement error into the accounting data of diversified segments than those of stand-alone firms.

Our matching procedure is also an improvement over the existing literature, which typically just adds linear industry and profitability controls. Instead, we use matching estimators (as described by Abadie and Imbens 2007) to compare the investment behavior of diversified segments and stand-alone firms that are similar on the basis of size, age, and profitability. The advantage of this nonparametric approach is that unlike parametric approaches, it does not rely heavily on extrapolation—which is problematic when there is imperfect overlap in the covariate distributions of comparison groups, as there is with unrelated segments and stand-alone firms.

Finally, our article appears to be the first to show that there are differences in the functioning of internal capital markets based on management incentives. This finding provides support for the view that the results are not driven by

[1] We use six different surveys in total (1977, 1982, 1987, 1992, 1997, and 2002), each covering panel years starting the year of the survey and ending the year before the next survey. For panel years 1979–1981, we use the 1977 survey. For panel years 1982–1986, we use the 1982 survey, and so on.

spurious measurement issues but rather are tied to the workings of internal capital markets.

The rest of the article is organized as follows. In the next section, we describe our data sources and relatedness measure. In Section 2, we document the basic finding that stand-alone firms are more responsive to industry Q than are the unrelated segments of conglomerate firms. In Section 3, we show that this basic result is robust to industry, size, and age matching. In Section 4, we show that our findings are more pronounced for conglomerate firms in which management has only a small stake. Section 5 concludes the article.

1. Data

Our segment-level data come from Compustat segment files covering the period 1979–2006. For each segment, these files provide basic accounting information such as sales, assets, capital expenditures, operating profits, and depreciation along with a pair of Standard Industrial Classification (SIC) codes for the entire panel and a pair of North America Industry Classification System (NAICS) codes starting in 1990 and onward. As is standard practice, we cross-validate observations in the segment files with observations in the annual files and drop observations for which the sum of reported segment sales do not fall within 25% of total firm sales in the annual files. We further drop segments with (i) name "other," (ii) primary SIC code equal to zero, (iii) incomplete accounting data (sales, assets, capital expenditure, depreciation, operating profits), (iv) anomalous accounting data (zero depreciation, capital spending greater than sales or assets, capital spending less than zero), (v) sales less than \$20 million in 1982 dollars using the Bureau of Labor Statistics producer price index for finished goods (WPUSOP3000). We also exclude from the analysis segments that operate in regulated industries, specifically Transportation (SIC codes 4000-4799), Telecommunication Service (4800-4899), Utilities (4900-4999), Banking (6000-6199), and Insurance (6300-6499).

To assess the functioning of internal capital markets, we compare unrelated segments of conglomerate firms with stand-alone (single segment) firms. We focus on the unrelated segments of conglomerate firms instead of their related segments for two reasons. First, the theories discussed in the introduction suggest that resource allocation inefficiencies will be greater in diversified firms. Second, from a practical empirical measurement perspective, transfer pricing and asset allocation make it difficult to accurately assign profits and capital to a particular segment. For example, a vertically integrated chemical manufacturer might source inputs for its downstream unit from its upstream unit at below market transfer prices (Eccles 1985), thus inflating downstream profits and deflating upstream profits relative to stand-alone chemical firms. Or, the upstream unit might add production capacity to meet the specific input needs of the downstream unit, as shown by Mullainathan and Scharfstein (2001) in their study of the chemical industry.

For the empirical validity of our approach, we need a reliable indicator of whether segments are related. The standard methodology classifies segments as unrelated if they are in different two-digit industries. However, there are many two-digit industries that are clearly related, and there are some three- and four-digit industries within two-digit industries that are not related. For example, SIC 13, Oil and Gas Extraction, is certainly related to SIC 29, Petroleum Refining and Related Industries. And, although they are both in SIC 28, SIC 281, Industrial Inorganic Chemicals (such as chlorine), is arguably not related to SIC 283, Drugs.

We use an alternative method, which builds on the relatedness measure of Matsusaka (1993) and Fan and Lang (2000). We first identify vertically related industries using data from the Input-Output Benchmark Surveys of the Bureau of Economic Analysis. Specifically, we assume that two input–output (I-O) industries are vertically related if one of the industries buys more than 10% of its inputs from the other industry or sells more than 10% of its outputs to the other industry (the Appendix provides further details). We then consider each segment within a firm and determine whether it is related to another segment within the firm by way of operating either in vertically related I-O industries or, alternatively, in the same I-O industry. Our unrelated sample consists of segments that we cannot relate to any other segment within the firm after systematically enumerating every possible within-firm pairwise connection.

Table 1 provides descriptive statistics on sales, assets, cash flow, capital expenditures, capital expenditures divided by sales, cash flow divided by sales, and lagged industry Q (as a result, our sample effectively starts in 1980). We measure cash flow as operating profits plus depreciation. This measure of cash flow is standard in the literature and does not adjust cash flow for taxes, working capital investments, and other factors because those data are not available. We winsorize the ratio of cash flow to sales at the 1% level in both tails to deal with extreme values. We define industry Q as the median bounded Q of stand-alone firms within the same I-O industry. In calculating stand-alone Q's, we follow the data definition of Kaplan and Zingales (1997), but bound it above at 10 to reduce the effect of potential measurement error in the book value of assets. Specifically, we compute bounded stand-alone Q as $MVA/(0.9BVA + 0.1MVA)$, where the book value of assets equals Compustat item 6 and the market value of assets equals the book value of assets plus the market value of common equity (item 25 times item 199) less the book value of common equity (item 60) and balance sheet deferred taxes (item 74).[2] Note that this simple market-to-book ratio definition of Q differs from the standard measure of Q in that we do not estimate the replacement cost of fixed assets nor adjust for taxes. Previous studies have shown that these adjustments are not essential (see Perfect and Wiles 1994).

[2] Bounding Q in this way has the same basic effect as winsorising Q at the extremes as described in Baker, Stein, and Wurgler (2003). None of the results change if we winsorize at the 99th and 1st percentiles of Q.

Observations are by segment and year (Compustat segment files, 1980–2006). Segment cash flow is defined as segment operating profits plus segment depreciation. Segment sales, assets, capital expenditure, and cash flow are in millions of dollars. Industry definitions follow the Input-Output Benchmark Surveys of the Bureau of Economic Analysis. Industry Q in a given year is the median bounded Q of stand-alone firms in the industry. A segment is defined to be unrelated if it is not related to any other segment of the firm. Two segments are related if they operate in vertically related industries or the same industry. Mean comparison tests between stand-alone firms and unrelated segments are performed without the assumption of equal variance. Asterisks indicate statistical difference at the 10% (*), 5% (**), and 1% (***) levels using a two-tailed test.

As shown in Table 1, stand-alone firms are smaller than unrelated conglomerate segments on the basis of both sales ($779 million vs. $1150 million) and assets ($773 million vs. $932 million). These differences are statistically significant at the 1% level. Stand-alone firms appear to be less profitable than unrelated segments as measured by the cash flow to sales ratio (12.1% vs. 13.9%). In addition, stand-alone firms appear to operate in industries with better investment opportunities than those of unrelated segments; the median industry Q of stand-alone firms is 1.42 as compared with 1.31 for unrelated segments. The difference is statistically significant at the 1% level. All of these differences exist within the subsample of segments in manufacturing industries (I-O industries 13–64 covering SIC codes 2000–3999).

2. Panel Analysis

Our main objective in this section is to determine whether there are systematic differences in the investment behavior of stand-alone firms and the unrelated segments of conglomerate firms. For this purpose, we use standard investment regressions and focus on the Q-sensitivity of investment. We estimate variants of the following panel regression:

$$cxs_{i(j)t} = a_j + b_t + c_0 * U_{it} + c_1 * Q_{j,t-1} + c_2 * Q_{j,t-1} * U_{it} + d_1 * cfs_{it} + d_2 * cfs_{it} * U_{it}. \tag{1}$$

The dependent variable $cxs_{i(j)t}$ is the sales-normalized capital spending of segment i (operating in industry j) in year t. a_j and b_t are industry and year fixed effects, respectively. We follow the industry definitions of the Input-Output Benchmark Surveys. In some specifications, we include segment fixed effects instead of industry fixed effects. The purpose of including industry or segment fixed effects is to address the possibility that time-invariant (perhaps technology-driven) differences in investment levels among industries or segments may explain our results. We include year fixed effects to deal with changing tax regimes and changing state of the business cycle during our sample period.

In addition, U_{it} is an indicator variable equal to one for unrelated segments. We include both the direct and interaction terms of U_{it}. Our key explanatory variable $Q_{j,t-1}$, the median bounded Tobin's Q of stand-alone firms in industry j in year $t-1$, proxies for investment opportunities. Because our sample provides us with a cross-section of segments facing similar investment opportunities in a given industry j and year t, we compute robust standard errors that allow for correlated error terms at the industry-year level. We also include cfs_{it}, sales-normalized cash flow of segment i in year t. We normalize by segment sales instead of segment assets because firms may have more discretion in allocating assets across their segments than they have in allocating sales. Nevertheless, we obtain qualitatively similar results when we normalize our variables using segment assets instead.

Table 2 presents the results of our panel analysis for the full sample (columns 1 and 3) and the restricted sample of manufacturing industries (columns 2 and 4). In column 1, unrelated segments exhibit lower Q-sensitivity of investment than stand-alone firms, as evidenced by a statistically significant negative value of c_2 (-0.017), the coefficient on $Q_{j,t-1} * U_{it}$. This result continues to hold (-0.016) for the manufacturing subset in column 2. Moreover, c_0 is positive and statistically significant (0.017 and 0.010 in columns 1 and 2, respectively), indicating that unrelated segments invest more (less) than their stand-alone counterparts in sufficiently low-Q (high-Q) industries.[3] All of these results are robust to the inclusion of segment fixed effects, which we report in columns 3 and 4.

[3] Our sample includes segment observations with $Q_{j,t-1}$ as low as 0.47 and as high as 4.66. At both extremes, the difference in investment levels between unrelated segments and their stand-alone counterparts (as implied by $c_0 * U_{it} + c_1 * Q_{j,t-1} + c_2 * Q_{j,t-1} * U_{it}$) is statistically different from zero at the 1% level. Moreover, the breakeven $Q_{j,t-1}$ (at which investment by unrelated segments and stand-alone firms equals each other; about 1.00 in column 1 and 0.63 in column 2) is generally lower than the median $Q_{j,t-1}$ (1.40). Thus, the coefficient estimates imply that for our sample of unrelated segments, the underinvestment effect in high-Q industries is more prevalent than the overinvestment effect in low-Q industries.

Table 2

Obs	74,267	40,623	74,267	40,623

Unrelated segments and stand-alone firms are compared (Compustat segment files, 1980–2006). Dependent variable is capital spending over sales. Industry definitions follow the Input-Output Benchmark Surveys of the Bureau of Economic Analysis. Industry Q in a given year is the median bounded Q of stand-alone firms in the industry. Columns 2 and 4 restrict the sample to manufacturing industries. Heteroskedasticity-robust standard errors are in brackets. Standard errors are corrected for clustering at the industry-year level. Asterisks indicate significance at the 10% (*), 5% (**), and 1% (***) levels.

These effects are also economically significant. Based on the estimates in column 1, at the means of all of the explanatory variables including $Q_{j,t-1}$ at 1.40, unrelated segments are predicted to invest at a lower rate than stand-alone firms (0.062 vs. 0.072). More interestingly, this difference increases with $Q_{j,t-1}$. A one-standard-deviation (0.40) increase in $Q_{j,t-1}$ to 1.80 increases the investment rate of unrelated segments by 0.003 to 0.065, while it increases the investment of stand-alone firms by 0.010 to 0.082. At this higher level of $Q_{j,t-1}$ the difference in investment rates is 0.015, while the difference is 0.010 at the mean.

In column 2, which restricts the sample to manufacturing segments, the difference between stand-alone firms and unrelated segments in their Q-sensitivity is much larger in percentage terms. In particular, at the means of all the variables including $Q_{j,t-1}$ at 1.40, unrelated segments invest at the rate of 0.047, while stand-alone firms invest at the rate of 0.058. At higher levels of $Q_{j,t-1}$ the difference is even larger—a one-standard-deviation (0.40) increase in $Q_{j,t-1}$ to 1.80 increases an unrelated segment's investment to 0.050, a modest increase of 0.003, while a stand-alone firm's investment increases by 0.010 to 0.068. At this increased level of $Q_{j,t-1}$, the difference of 0.018 is 26% of stand-alone investment.

In the rest of the article, we build on these results to address two further issues. First, we investigate whether the results are robust to matching on observable characteristics such as industry, size, and age. Second, we test whether agency-based theories such as that of Scharfstein and Stein (2000) can explain the observed low Q-sensitivity of investment of conglomerate firms.

3. Matching Analysis

We know from Table 1 that the unrelated segments of conglomerate firms are on average larger than stand-alone firms. It is possible that larger segments exhibit lower Q-sensitivity of investment because they face larger technological adjustment costs for some reason. If this is the case, it would be a mistake to attribute differences in the Q-sensitivity of investment to a shortcoming of internal capital markets. Moreover, there may be differences in Q-sensitivities across industries (perhaps because of differences in adjustment costs or in the importance of physical capital). If unrelated segments are more prone to operate in industries with low Q-sensitivity of investment, it would be wrong to attribute our findings to the effects of internal capital markets. Similarly, there may be differences between young and old firms.

To address these problems, we form matched samples of unrelated segments and stand-alone firms based on observable characteristics such as industry, year, age, and size that are *a priori* important determinants of investment. These matched samples allow us to difference out a broad class of level and slope effects that might be driving our results.

To see the general form of confounding effects that our matching approach allows us to control, suppose that investments by unrelated segments and stand-alone firms are driven by the following two equations:

$$\begin{aligned} cxs_{U(j)t} &= a_U + b_{jt}(observable) \\ &\quad + [c_U + c_{jt}(observable)] * Q_{j,t-1} + d * cfs_{Ut}, \end{aligned} \tag{2}$$

$$\begin{aligned} cxs_{S(j)t} &= a_S + b_{jt}(observable) \\ &\quad + [c_S + c_{jt}(observable)] * Q_{j,t-1} + d * cfs_{St}. \end{aligned} \tag{3}$$

Taking the difference of matched pairs removes the potentially confounding effects of $b_{jt}(observable)$ and $c_{jt}(observable)$, whose functional forms are generally unknown and therefore difficult if not impossible to control directly. For example, if age and industry are the observable variables, the matching procedure will eliminate their effect on the intercept and slope terms, b_{jt} and c_{jt}:

$$\Delta cxs_{US(j)t} = \underbrace{[a_U - a_S]}_{a} + \underbrace{[c_U - c_S]}_{c} * Q_{j,t-1} + d * \Delta cfs_{US(j)t}. \tag{4}$$

In Table 3, we run this differenced specification for matched samples of unrelated segments and stand-alone firms formed on the basis of industry, year, size, and age. Matching is always exact for industry and year, and without replacement. When matching on the basis of size, we require that matched segments have sales within 10% of each other. When matching on the basis of age, we require that matched segments be in the same age category where the three broad age categories are 1–5 years, 6–10 years, and 10+ years. We

Unrelated segments are matched with stand-alone firms (Compustat segment files, 1980–2006). In column 1, unrelated segments are matched with stand-alone firms based on industry and year. In column 2, unrelated segments are matched with stand-alone firms based on industry, year, and sales. In column 3, unrelated segments are matched with stand-alone firms based on industry, year, age, and sales. Age categories are 1–5, 6–10, and 10+ years. Size matching threshold is ±10% of sales. Repeat matches are not allowed. Dependent variable is the difference in the capital spending over sales ratio of the matched pair, unrelated segment minus stand-alone firm. Industry Q in a given year is the median bounded Q of stand-alone firms in the industry. Panel B restricts the sample to manufacturing industries. Panels C and D repeat the analysis in Panels A and B, respectively, with a relatedness threshold of 5% instead of 10%. Heteroskedasticity-robust standard errors are in brackets. Standard errors are corrected for clustering at the industry-year level. Asterisks indicate significance at the 10% (*), 5% (**), and 1% (***) levels.

use three age categories due to sample size considerations. Using different size criteria to match segments (for example, assets rather than sales, matching threshold as small as 5% or as large as 20%) results in qualitatively similar results.

In column 1 of Panel A, where matching is performed on the basis of industry and year, we find a coefficient on $Q_{j,t-1}$ of −0.022, indicating that unrelated segments exhibit lower Q-sensitivity of investment than stand-alone firms. Also, the intercept is positive (0.021) and statistically significant, indicating as before that unrelated segments invest more (less) than their matched stand-alone counterparts in sufficiently low-Q (high-Q) industries. Column 2 reports results where we further match on the basis of size.[4] Both the coefficient on $Q_{j,t-1}$ (-0.019) and the intercept (0.021) are statistically significant. Finally, in column 3, we match on the basis of industry, year, age, and size. Both the coefficient on $Q_{j,t-1}$ (-0.012) and the intercept (0.014) are statistically significant. Restricting the sample to manufacturing industries in Panel B also yields similar results. Overall, the matching analysis confirms that our basic results are robust to heterogeneity in observable characteristics such as industry, size, or age.[5] In addition, we investigate the robustness of our relatedness methodology by lowering the 10% cutoff used to determine relatedness to 5%. This reduces the sample of unrelated segments by about three-fourths but yields similar results, which are reported in Panels C and D.

Recent work by Abadie and Imbens (2006), however, shows that commonly used matching procedures like ours may entail a bias term that converges at a rate slower than $N^{1/2}$. Abadie and Imbens (2007) propose a matching estimator to correct this bias, while taking account of inexact matching. We use this estimator to investigate the robustness of our results. In particular, we estimate average treatment effects, which in our context measure differences in capital spending between unrelated segments and observationally similar stand-alone firms.

Based on our prior results, we expect the average treatment effect to be positive in low-Q industries (where unrelated segments invest more than their stand-alone counterparts) and negative in high-Q industries (where unrelated segments invest less than their stand-alone counterparts). To accommodate this relation, we form two subsamples of segments with industry Q below and above the sample median industry Q in each year and estimate an average treatment effect for each subsample. We require matches to four other stand-alone firms in the sample because Abadie and Imbens (2007) find four matches to perform well in terms of mean-squared error in their simulations. We require an exact match on industry and year but allow for inexact matches on other attributes—namely, sales, age, and profitability (cash flow over sales ratio).[6]

[4] In the size-matched sample of column 2, unrelated segments have average sales of \$557.6 million (with a standard deviation of \$2401.3), compared with \$555.6 for stand-alone firms (with a standard deviation of \$2410.7). The difference in means is not statistically significant. We check and confirm that the matching procedure ensures that all of our matched samples have differences in means that are statistically indistinguishable from zero along the matched dimensions.

[5] Instead of taking the difference of matched pairs of unrelated segments and stand-alone firms, one could estimate pooled specifications similar to Equation (1) with matched pair fixed effects. Indeed, this alternative pooled approach is numerically equivalent to the differenced approach we report here.

[6] It is also possible, at least in principle, to match on lagged investment. The reason we do not match on lagged investment is that in our sample it is not common for segments to change their status from related to unrelated.

Table 4
Bias-corrected matching estimates

Abadie and Imbens (2007) bias-corrected estimates for the average treatment effect for treated unrelated segments relative to control stand-alone firms (Compustat segment files, 1980–2006). Treatment outcome is capital spending over sales ratio. Matching is continuous with respect to sales, age, and profitability (cash flow over sales ratio) and exact with respect to industry and year. Number of matches is four. Low- and high-Q bins are based on the annual sample median of lagged industry Q. Panel B restricts the sample to manufacturing industries. Standard errors are in brackets. Comparisons between low- and high-Q bins assume independence of estimated average treatment effects. Asterisks indicate significance at the 10% (*), 5% (**), and 1% (***) levels.

The results in this analysis are reported in two panels of Table 4. Panel A reports results based on the whole sample, whereas Panel B restricts the sample to manufacturing industries. In both panels, as predicted, we consistently find that unrelated segments in high-Q industries invest less than matched stand-alone firms—the estimates range from −0.0097 to −0.0031 depending on which set of matching variables is used and are always significant at conventional levels. In low-Q industries, we find somewhat mixed and usually insignificant treatment effects. This is not surprising in light of the fact that unrelated segments invest more than stand-alone firms only in very low-Q industries, well below the median of roughly 1.40. Indeed, when we define low-Q industries as those in the bottom quartile, we find consistently positive treatment effects (results not in table). Regardless, the difference in average treatment effects between high-Q and low-Q industries is always negative (ranging from −0.0063 to −0.0050) and statistically significant, as shown in the third column of Table 4. This is consistent with our core finding that unrelated segments are more prone to invest less than stand-alone firms in high-Q than in low-Q industries.

4. Evidence of Agency

In this section, we explore whether agency problems could explain the differences in the investment behavior of conglomerates and stand-alone firms. Our tests are motivated by the multi-tier agency model of Scharfstein and Stein (2000), which predicts that conglomerate firms will invest less than stand-alone firms in high-Q industries and more than stand-alone firms in low-Q industries. In particular, we posit that when top management of conglomerates have large ownership stakes, their firms will exhibit a greater Q-sensitivity of investment.[7] We obtain management ownership data from the ExecuComp database.

Using our previously matched samples of unrelated segments and stand-alone firms, we estimate variants of the following specification:

$$\Delta cxs_{i(j)t} = a + b * Q_{j,t-1} + c * MO_{it} + d * Q_{j,t-1} * MO_{it} + e * \Delta cfs_{it}, \quad (5)$$

where $\Delta cxs_{i(j)t}$ is the difference between the sales-normalized capital spending of unrelated segment i (operating in industry j) in year t and that of its matched stand-alone counterpart, $Q_{j,t-1}$ is the median bounded Tobin's Q of stand-alone firms in industry j in year $t-1$, MO_{it} is management ownership by top officers of the conglomerate firm that owns unrelated segment i, and $\Delta cfs_{i(j)t}$ is the difference between the sales-normalized cash flow of unrelated segment i in year t and that of its matched stand-alone counterpart. As before, our differencing approach removes potentially confounding level and slope effects.

Columns 1–3 of Table 5 report results for the industry–year-, industry–year–size-, and industry–year–age–size-matched samples, respectively. Panel A uses the whole sample, whereas Panel B restricts the analysis to manufacturing industries. Overall, the results lend strong support to agency-based explanations for the observed investment behavior of conglomerate firms in their unrelated segments. Consistent with our earlier findings, the unrelated segments of conglomerate firms exhibit lower Q-sensitivity of investment than stand-alone firms, as evidenced by statistically significant negative coefficients on $Q_{j,t-1}$. The statistically significant positive intercept terms indicate that unrelated segments in sufficiently low-Q (high-Q) industries invest more (less) than stand-alone firms. More important, Table 5 demonstrates that, consistent with the agency view, unrelated segments of conglomerate firms with high management ownership appear to suffer less from this allocative inefficiency, as evidenced by statistically significant positive coefficients on the interaction term $Q_{j,t-1} * MO_{it}$ and negative coefficients on MO_{it}. The only exception is column 2 in Panel B, where the coefficients of interest have the predicted signs but lack statistical significance.

The coefficient estimates in Panel A, however, imply unrealistically high levels of management ownership at which a conglomerate firm would have the same Q-sensitivity of investment and roughly the same level of investment as a stand-alone firm. For example, in Panel A, column 3, management ownership as high as 16.5% (about the 85th percentile in the distribution of management ownership) would erase the negative coefficient on $Q_{j,t-1}$ (−0.040) given

[7] Note that several other theoretical models also predict inefficient allocation of capital in internal capital markets, but they build on agency problems lower down in the organization for which we have no data. For models that involve strategic interaction among multiple managers, see Rajan, Servaes, and Zingales (2000) and Ozbas (2005). For models that analyze a single manager in isolation, see Harris and Raviv (1996); Bernardo, Cai, and Luo (2001); and Marino and Matsusaka (2005).

Unrelated segments are matched with stand-alone firms (Compustat segment files, 1980–2006). The matching procedure is described in Table 3. Dependent variable is the difference in the capital spending over sales ratio of the matched pair, unrelated segment minus stand-alone firm. (Using Standard & Poor's ExecuComp database) Management Ownership is defined as the sum of stocks and options held by top officers as a fraction of outstanding shares. Panel B restricts the sample to manufacturing industries. Heteroskedasticity-robust standard errors are in brackets. Standard errors are corrected for clustering at the industry-year level. Asterisks indicate significance at the 10% (*), 5% (**), and 1% (***) levels.

the positive coefficient on the interaction term $Q_{j,t-1} * MO_{it}$ (0.243) and at the same time almost offset the level effect in the intercept (0.059) given the negative coefficient on MO_{it} (−0.349). By comparison, the results in Panel B for manufacturing industries indicate that lower levels of management ownership (about 7.9% in column 3—about the 75th percentile in the distribution of management ownership) would achieve similar effects.

Finally, we check the robustness of our results about managerial ownership using the bias-corrected matching estimator of Abadie and Imbens (2007). The same rationale for estimating average treatment effects separately for low-Q and high-Q industries applies here as well. In addition, because our results suggest that the treatment effect is different depending on the level of managerial ownership, we estimate average treatment effects separately for low- and high-managerial ownership subsamples comprising observations with managerial ownership below and above the sample median in each year. As before, we require four exact matches on industry and year. In addition, we add managerial ownership to the set of continuously matched covariates—namely, sales, age,

Abadie and Imbens (2007) bias-corrected estimates for the average treatment effect for treated unrelated segments relative to control stand-alone firms (Compustat segment files, 1980–2006). Treatment outcome is capital spending over sales ratio. Matching is continuous with respect to sales, age, management ownership, and profitability (cash flow over sales ratio) and exact with respect to industry and year. Number of matches is four. Low- and high-Q bins are based on the annual sample median of lagged industry Q. Low- and high-management ownership bins are based on the annual sample median of management ownership. Panel B restricts the sample to manufacturing industries. Standard errors are in brackets. Comparisons between different bins assume independence of estimated average treatment effects. Asterisks indicate significance at the 10% (*), 5% (**), and 1% (***) levels.

and profitability (cash flow over sales ratio)—to address a potential concern that managerial ownership may proxy for unobserved firm characteristics that change the Q-sensitivity of investment (rather than treatment).

Table 6 presents our results in two panels. Panel A uses the whole sample, and Panel B restricts the sample to manufacturing industries. In both panels, we continue to find that unrelated segments in high-Q industries invest less (−0.0085 in Panel A and −0.0159 in Panel B) than matched stand-alone firms. This is similar to Table 4 except that managerial ownership is added to the set of continuously matched covariates. Consistent with the agency explanation, the effect appears to be strong especially when managerial ownership is low (−0.0130 in Panel A and −0.0221 in Panel B) and disappears when managerial ownership is high. We find some evidence that unrelated segments in low-Q industries invest more than matched stand-alone firms when not conditioning on managerial ownership (statistically significant in Panel A, but not in Panel B). Strikingly, the results strengthen when managerial ownership is low (0.0222 in Panel A and 0.0090 in Panel B, both significant at conventional levels) and disappear when managerial ownership is high. Also, the difference between high-Q and low-Q industries is always significantly negative when not conditioning on managerial ownership (−0.0231 in Panel A and −0.0209 in Panel B). The relation strengthens when managerial ownership is low (−0.0352 in Panel A and −0.0311 in Panel B) and disappears when managerial ownership is high, consistent with the agency explanation.

In interpreting these results, it is important to keep in mind that we do not have exogenous variation in managerial ownership. It is possible that managerial ownership proxies for another factor that affects investment. One concern is that an unrelated segment of a high-managerial ownership firm may be large relative to the overall firm. In this case, there would be less scope for cross-subsidization in an internal capital market. As a result, the investment of unrelated segments of high-managerial ownership firms would appear to be more similar to stand-alone firms. However, we find that unrelated segments of high-managerial ownership firms account for 38% of firm sales, while unrelated segments of low-managerial ownership firms account for 35% of firm sales. The difference is small and therefore unlikely to explain our findings. Of course, it is possible that managerial ownership proxies for other factors that are themselves related to the difference in the investment of unrelated segments and stand-alone firms (after matching on size, age, industry, and profitability), but it is not apparent to us what these factors might be.

5. Conclusion

This article presents evidence of inefficiencies in internal capital markets. The investment of stand-alone firms is more sensitive to industry Q than the investment of unrelated segments of conglomerate firms. In addition, the unrelated segments of conglomerate firms tend to invest less than stand-alone firms in high-Q industries, and more than stand-alone firms in low-Q industries. These findings are robust to industry, size, and age matching. In addition, these findings are more pronounced in conglomerate firms in which managers have small ownership stakes, suggesting that the inefficient investment behavior of conglomerate firms is, at least in part, due to agency problems at the top of conglomerates.

There are a number of directions in which one can take the research question of this article. First, our findings point to inefficiencies in corporate resource allocation, but they do not provide nearly the full account that one would like. For example, our findings are consistent with there being agency problems among top managers. But theoretically, this is not sufficient to generate inefficient resource allocation. A good example of this is Stein (1997). In his model, external capital markets ration resources to a CEO who is prone to overinvest. But because the CEO prefers managing a more profitable empire over a less profitable empire, resources flow from divisions with poor investment opportunities to divisions with good investment opportunities.

Stein's model is a useful benchmark in that it shows that agency problems lower down in the organization are necessary to generate inefficient resource allocation. Thus, one would like to know more about the nature of the agency problem lower down in the organization as well as the kinds of organizational processes and structure that firms use to mitigate agency problems within. Manager promotion and rotation policies across divisions may be one way to mitigate divisional incentives for overinvestment (Xuan 2006), as would more high-powered incentives for divisional managers (Palia and Ye 2003). The formal and informal rules companies use to make capital allocation decisions are also likely to have an important impact on investment behavior (Bower 1970; Ozbas 2005; Stein 2002).

Second, our focus here has been on analyzing the effect of internal capital markets on capital investment. Yet, there are many other types of investments that firms undertake, such as research and development, marketing, and certain pricing policies. Analyzing these decisions in the context of internal capital allocation is also an important avenue for future research.

Finally, papers such as Berger et al. (2005), Guedj and Scharfstein (2005), Khanna and Tice (2001), and Mullainathan and Scharfstein (2001) have shown the benefit of analyzing rich industry-specific data sets and also of having a specific industry context in which to interpret the results. More industry-focused work along these lines would be useful in identifying the costs and benefits of internal capital markets.

Appendix: Relatedness Measure

The standard two-digit SIC approach is somewhat limited when it comes to identifying vertical relationships because the SIC numbering system is organized horizontally. For example, drilling oil wells and other exploration services have the same two-digit SIC code, but the next vertical stage of petroleum refining does not. To establish vertical relationships that the two-digit SIC approach seems to miss, we use the Input-Output Benchmark Surveys conducted by the Bureau of Economic Analysis.

The Use Table of the Input-Output Benchmark Surveys is our main data source for identifying significant vertical relationships that are not captured by the two-digit SIC approach. Essentially, the Use Table is a matrix that contains the dollar value of commodity flows measured in producers' prices between what are called the Input-Output Accounts of the US economy. These I-O accounts are defined by the survey and represent industries that are significant enough to be classified as a separate account. While the number and definition of I-O accounts change from survey to survey, a table that lists I-O account numbers, titles, and associated SIC or NAICS codes is provided in each survey.

We identify significant vertical relationships first by looking at the Use Table from the perspective of a purchasing industry. We calculate use coefficients by dividing the purchases of an industry by its total purchases and keep the I-O pairs with use coefficients above 10%, which is the cutoff used by Matsusaka (1993). We then look at the Use Table from the perspective of a selling industry. Similar to use coefficients, we calculate make coefficients by dividing the sales of an industry by its total sales and keep the I-O pairs with make coefficients above 10%.

The Bureau of Economic Analysis publishes a new Input-Output Benchmark Survey roughly once every five years to coincide with the Economic Census conducted by the US Census Bureau, and we draw on six different surveys (2002, 1997, 1992, 1987, 1982, and 1977) on a rolling basis to identify vertical relationships. We adopt this approach primarily to improve measurement accuracy because each survey provides a historical snapshot and thus may be inadequate for describing the structure of the US economy for our entire sample period from 1979 to 2006. We use data from a given survey until a new snapshot is provided by the following survey. Specifically, we rely on 1977 data between 1977 and 1981, 1982 data between 1982 and 1986, and so on.

When calculating use and make coefficients, we exclude I-O accounts greater than 77 (1992, 1987, 1982, 1977) or labeled S (2002, 1997). These are mainly government accounts without an associated SIC or NAICS code. Also excluded are accounts that are related to inventory adjustments, employee compensation, and industry value-added. These accounts have nothing to do with the vertical relationships we are trying to identify. Including them would introduce an unnecessary source of measurement error.

Key accounting value drivers that affect stock returns: evidence from Greece

Christie Florou and Constantinos Chalevas
Department of Accounting and Finance,
Athens University of Economics and Business, Athens, Greece

Abstract

Purpose – This paper seeks to investigate the accounting factors that affect the value of a firm.

Design/methodology/approach – Cross-sectional analysis is employed to investigate the association between critical accounting ratios and stock returns.

Findings – This study finds that the operating performance of a company, its growth opportunities and its capability to generate profits from its sales affect stock returns.

Practical implications – This study provides insights regarding the extent that policies concerning operating, investment and working capital management affect stock returns. The findings of this study can be helpful to managers for selecting and implementing the appropriate business policies. Besides, current shareholders and investors may find the results of this study useful in identifying the drivers of stock values.

Originality/value – The paper tests, empirically, the effect of the key value drivers on stock returns in a developing stock exchange.

Keywords Accounting, Stock returns, Capital markets, Greece

Paper type Research paper

1. Introduction

The present study investigates the factors that lead to an increase in the value of a firm and as a consequence contribute to an increase in the shareholders' wealth. In particular, this study focuses on the financial statements figures that influence firms' stock value. In addition, it is examined whether investors take into consideration accounting data when they value firms' stock. It is considered the extent to which policies relating to operating, working capital and financial management influence firms' value.

The findings of this study can be particularly helpful for managers and investors. The findings of this study could facilitate firms' managers to identify the strength and weaknesses of the firms they manage. As a result, they would be in a position to apply the policies that are appropriate for achieving the growth and profit targets they have set for the firms. On the basis of the findings of this study, shareholders would be in position to recognize the value drivers of the shares they own. They could evaluate current firm performance and estimate whether this performance will remain steady or it will change in the future as a consequence of a change in the strategy of a firm. Investors will be able to detect the factors that affect stock returns.

This study contributes to the international literature since it investigates the association between accounting disclosure and stock returns in a developing stock exchange. Furthermore, since the study covers the period 2004-2006, it provides implications about the quality of accounting data immediately after the beginning of application of International Financial Reporting Standards in the financial statements of companies of the Greek Stock Exchange.

The rest of the paper is organized as follows: section 2 reviews the main arguments that have been developed regarding the factors that influence stock returns. In addition, in section 2 are presented the hypotheses that have been tested in this study. The methodology applied in this study is presented in section 3. The findings of the empirical

investigation are reported in section 4. The main conclusions of this study are discussed in section 5.

2. Previous research and hypotheses

The form of the capital market affects managers' ability to affect the market price of the firm's outstanding shares. In efficient capital markets, the prices of capital market securities fully reflect all the available information (Fama, 1970, 1976). The efficient market hypothesis (EMH) assumes that investors are sophisticated enough to decode published accounting figures and to be in position to discern the true cash flow implications of accounting data (Hand, 1990). According to the EMH, stock prices will react to the announcement of reported figures, only in the case that those figures include information about unanticipated changes in the probability distribution of future cash flows of the firm, and provided that this information was not previously available to the market from other non-accounting sources, with equal precision (Tinic, 1990). Despite the empirical evidence that supports EMH, there is no universal acceptance of the model (Foster, 1986; Kothari, 2001).

An alternative hypothesis is the mechanistic one, which is not consistent with EMH model. According to this hypothesis the capital market is fixated to reported profits. The market prices of the common stock of a firm are determined exclusively on the basis of the earnings reported by the firm, without paying any consideration to the accounting methods employed in order to calculate those earnings. A similar approach is adopted by the functional fixation hypothesis (FFH). According to this approach investors are unsophisticated and are not able to detect the true cash flow implications of reported figures (Watts and Zimmerman, 1986). The mechanistic hypothesis differs from that functional fixation hypothesis in that the latter allows that there are two types of investors: the sophisticated and the unsophisticated ones. Yet, it is the group of the unsophisticated investors that determines the market pricing of common stock (Hand, 1990). The implication of both hypotheses is that different accounting methods would have an impact on stock prices despite the fact that the true cash flow implications of these methods are the same (Tinic, 1990). According to Belkoui (1992):

> The functional fixation and the naïve investor hypotheses assume that a sufficient number of investors are unable to perceive the cosmetic nature of certain accounting changes or are "fixated" on the bottom figure of net income (p. 150)

Empirical evidence indicates that accounting information contains useful information about cash flows and as a consequence influences securities prices (Watts and Zimmerman, 1986). A number of empirical studies found that market can discern whether a choice of accounting method has real cash consequences. For instance, market appears to anticipate the impact of pension liabilities even before they appear on financial statements (Dhaliwal, 1986). In addition, market appears to value research and development expenditures as assets despite the fact that a firm may decide to present them as expenses in its financial statements (Dukes, 1976; Lev and Sougiannis, 1996; Aboody and Lev, 1998). The choice between the purchase and the pooling-of-interests accounting methods for mergers and acquisitions has attracted researchers' attention. If the market were functionally fixated it would react negatively to the amortization of goodwill, which appears in case a firm adopts the purchase method for mergers and acquisitions. A number of studies provided evidence, which is not consistent with the hypothesis that the market is fixated on reported earnings (Hong *et al.*, 1978; Davis, 1990; Rau and Vermaelen, 1998). On the other hand, some empirical findings are not inconsistent with FFH. Jennings *et al.* (1996) and Vincent (1997) find that the price-earnings ratios of the firms that adopted the purchase method are lower than the corresponding ratios for the firms that employed the pooling-of-interests method. Andrade (1999) found a positive and statistically significant association between the stock abnormal return and the change in firms' earnings, attributable to the choice of accounting method for mergers and acquisitions. The magnitude of the association, however, is limited. Hand (1990) proposed an extended version of FFH, under which the extent to which a market is functionally fixated is related to the sophistication of investors. When the unsophisticated investors set the stock prices the market is likely to be fixated. The probability that the unsophisticated investors will set the stock prices is conditioned upon the proportion of firm's share capital controlled by unsophisticated investors. Hand (1990) tested the extended functional fixation with the data on stock returns on the reannouncement date of quarterly earnings, in the quarters in which a sample of firms adopted a policy of swapping equity-for-debt. Hand (1990) argues that results of the statistical test are consistent with the extended FFH. Harris and Ohlson (1987) provided evidence that the stock returns for a sample of firms in the oil and gas industry are significantly associated with book values. Furthermore, in the same study they showed that the market could rationally distinguish between the successful effort and the full cost methods of accounting used by oil and gas companies. In a later study Harris and Ohlson (1990) investigated whether the observed relationship between book values and market values can be attributed to the value content of the book values or to functional fixation of investors. Harris and Ohlson (1990) argue that they did not find evidence that allows them to ascribe the observed relationship to a functional fixation of investors on book values. They conclude that investors do not appear to assign substantial importance to book values.

It has been suggested that functional fixation results from lack of experience or relevant data. As a consequence, this fixation should be eliminated as market participants acquire sufficient experience and data (Gupta and King, 1997; Waller *et al.*, 1999; Chen and Schoderbek, 2000). Yet, empirical research indicates that the behaviour of market participants, such as financial analysts, who are supposed to have opportunities to acquire sufficient experience and data, still exhibits characteristics of functional fixation when predicting securities prices on the basis of accounting information (Hopkins, 1996; Hirst and Hopkins, 1998; Hopkins *et al.*, 2000). Luft and Shields (2001) experimentally investigated whether individuals display fixation when they decide to capitalize or instead to expense intangible expenditures. The findings of the experiment indicate that the acquisition of additional data and experience does not mitigate fixation on accounting figures.

It should be pointed out, however, that is not necessary for the stock market's price formation process to exhibit functional fixation in order to establish incentives for firms to select particular accounting policies. It is sufficient for firms' managers to believe that securities prices are affected by reported figures (Beattie *et al.*, 1994). A number of studies have indicated that managers are not wholly convinced with the regard to the efficiency of capital markets (Mayer-Sommer, 1979; O'Keefe and Soloman, 1985). Kothari (2001) argues that although empirical findings have not offered a convincing indication that market is not efficient, there is a strong evidence that firms' managers behave as if market was fixated to reported earnings. For instance, the common wisdom regarding the choice between the purchase and the pooling-of-interests accounting methods for mergers and acquisitions, is that stock market will prefer the pooling-of-interest method because this method has a positive impact upon reported income and as result on the prices of the common stock (Kothari, 2001). It appears that the pricing of acquisitions is affected by the choice between the purchase and the pooling-of-interests methods.

Empirical evidence suggests acquirers pay a premium when the acquisition will be accounted according the pooling-of-interest method (Nathan, 1988; Robinson and Shane, 1990; Lys and Vincent, 1995; Ayers *et al.*, 1999).

When managers believe that the market is fixated to reported accounting figures are more likely to engage in earnings management by making the appropriate accounting policy choices (Beattie *et al.*, 1994). According to Leuz *et al.* (2003) the extent to which a firm will engage in earnings management is associated with certain characteristics of the business environment prevailing in the country in which the particular firm operates. Firms in countries with developed equity markets, dispersed ownership structures, strong investors rights and strong legal enforcement are less likely to adopt earnings-management policies. A distinct characteristic of the Greek business environment is the high level of ownership concentration. Furthermore, the equity market is not particularly developed, while the investor rights and the legal enforcement is weak (Leuz *et al.*, 2003). Within this context the Greek firms expected to exhibit high levels of earnings management. Findings of empirical research are consistent with this prediction. In the study of Leuz *et al.* (2003) Greek firms appear to achieve the highest aggregate earnings management score among firms from 31 countries. Bhattacharya *et al.* (2003) provide similar evidence, since in their study Greek firms are the most engaged in earnings management among firms from 34 countries. Koumanakos (2007) provides evidence that Greek firms engage not only in earnings management but they attempt to manage other accounting figures as well, e.g. sales turnover. According to the Greek financial and political press, accounting figures have a dominant influence on the firm's stock value. Furthermore, it has been asserted that it is not uncommon for listed companies to get involved in income management through the selective application of accounting policies (Zopounidis *et al.*, 2002; Konstantinidis, 2004). The effectiveness of Greek capital market is assessed by the extent to which firms' market value is in accordance with the value of a firm as this can be estimated on the basis of accounting figures included in firms' financial statements. Accounting ratios that include two or more accounting figures are less susceptible to be target of earnings management. Therefore, it could be accepted that they provide an objective measure of firm's financial position and performance.

This study aims to empirically investigate the efficiency of the Greek capital market by examining the association between policies that concern operating, investment and working capital management, with stock returns within the context of the Greek capital market.

2.1 Operating management

Operating management includes the following ratios:

- *Return on sales (ROS)*: This ratio shows the association between profitability of a firm and its operating activity. In particular, it provides an indication of the capability of a firm to generate profits from each euro of sales.
- *Asset turnover*: This ratio shows how effectively a firm employs its assets in order to increase its sales. In particular this ratio indicates whether a firm has made excessive investments in relation to the level of its sales.
- *Return on assets (ROA)*: This ratio indicates how much profit a company is able to generate for each euro of assets invested. This ratio can be decomposed as a product of the following two factors: ROS* asset turnover.
- *Financial leverage*: This ratio indicates how many euros of assets a firm generates for very euro invested by its shareholders.

- *Return on equity (ROE)*: This ratio indicates how profitably a firm uses the funds invested by the firm's shareholders its assets. This ratio can be decomposed as a product of the following two factors: ROA* financial leverage.
- *EBITDA margin ratio*: This ratio provides an indication of the operating performance of a company by comparing its sales with earnings.

2.2 Investment management

Investment management can be evaluated by the following ratios:

- *Operating working capital turnover*: This ratio indicates what amount of sales has been achieved by each euro of working capital.
- *Inventory turnover*: This ratio indicates how effectively a firm employs its working capital.

2.3 Financial management

Financial management is approached by the current ratio. This ratio provides an indication of firm's liquidity, and the firm's ability to repay its current liabilities. The higher the value of this ratio the less likely is for a firm to face liquidity problems.

Hypothesis. The ratios that concern policies about operating, investment and working capital management are positively associated with stock returns

3. Data and methodology

Data regarding stock returns have been derived from the commercial database of "Datastream".

3.1 The sample

The sample includes companies that were listed in the Athens Stock Exchange for the period 2004-2006. The year 2004 was the first year that Greek listed firms implement international financial reporting standards (IFRS). Thus, the inclusion in the sample of firm-year observation for the period before 2004 would hinder the comparability of the sample. The sample does not include 55 companies from the following sectors: banking sector, insurance sector, investment companies, and financial leasing companies. By excluding the above companies from the sample the findings of this study are comparable with the results of other studies. From the total number of 313 companies listed in the Athens Stock Exchange, were excluded 26 firms because datastream does not provide data regarding their stock returns. The final set of data consists of 287 companies or 861 firm-year observations.

Table I presents the variables that have been calculated for the purpose of this study.

3.2 The methodology

In order to investigate whether stock returns include information regarding the financial position of a firm the following model has been developed and estimated:

$$\begin{aligned} SR_{i,t} = {} & b_0 + b_1\ ROS_{i,t} + b_2\ CURRENT\ RATIO_{i,t} + b_3\ ASSET\ TURNOVER_{i,t} \\ & + b_4\ FINANCIAL\ LEVERAGE_{i,t} + b_5\ OPERATING\ WORKING_{i,t} \\ & + b_6\ INVENTORY\ TURNOVER_{i,t} + b_7\ EBITDA\ MARGIN_{i,t} \\ & + b_8\ MV/BV_{i,t} + e_{i,t} \end{aligned}$$

The dependent variable stock return (SR), is calculated by the following formula:

$$SR_t = (P_t + D_{t-}P_{t-1})/P_{t-1}$$

where SR_t is the daily return on day t, P_t the share price in the last day of exchange t (price on ex-date), P_{t-1} the share price in the previous day, and D_t the dividend paid on the last year of the financial year.

The term MV/BV has been added to the above model in order to control for the growth opportunities of the firms. It is estimated by dividing the market value of equity of company i for the year $t-1$ by the book value of equity of company i for the year $t-1$.

Two of the independent variables that were initially intended to be included in the regression model, i.e. return on assets and return on equity, were not included in it for purely technical reasons. Crucial elements that are necessary for calculating those ratios are already included in other variables. The inclusion of all variables in the model could create a autocolinearity problem between the independent variables of the model. Thus, it has been decided to include only the basic ratios ROS, asset turnover and financial leverage, which are used for the computation of the other ratios.

Table II presents the descriptive statistics of the variables used in this study.

4. Empirical findings

In order to investigate which accounting-numbers based variables influence stock returns, the model (1) has been estimated by using as a dependant variable the stock returns of the companies listed in the Athens Stock Exchange and as independent variables certain accounting ratios (Table III).

The value of *F*-statistic indicates that the particular regression model explains 18.4, 13.6, and 23.0 per cent of stock returns for years 2004, 2005, and 2006, respectively. It appears that the main value driver of stocks' value is EBITDA margin. This variable appears to have a statistically significant association with stock returns. The values of the *t*-statistic for this variable are 2.952 (2004), 2.735 (2005), and 4.215 (2006). The association has a positive sign for all years in the period 2004-2006. This result, which is consistent with the formulated hypothesis, indicates that stock returns are positively affected by the ability of a firm to generate positive cash flows.

The growth of firm as depicted by the variable MV/BV appears to be positively associated with stock returns. In particular, the values of the coefficients in years 2004, 2005, and 2006 are 0.098, 2.249, and 0.147, respectively. The values of the *t*-statistic for this variable are 1.276 (2004), 2.733 (2005), and 2.221 (2006). These results suggest that there is a statistically significant association between the two variables for the years 2005 and 2006. It can be concluded, therefore, that the value of MV/BV provides to

Table I.
Variable definitions

Variables	Definitions
ROS	Net profit/sales
Current ratio	Current assets/current liabilities
Asset turnover	Sales/assets
Financial leverage	Assets/shareholders' equity
EBITDA margin	Earnings before interest, taxes, depreciation and amortization/sales
Operating working capital turnover	Sales/operating working capital
Inventory turnover	Cost of sales/inventories

	Average	Median	Standard deviation	Lower quartile	Upper quartile
Year 2004					
Asset turnover	0.82	0.70	0.52	0.52	1.00
Current ratio	1.82	1.43	1.51	1.09	1.95
EBITDA margin	0.29	0.14	0.56	0.06	0.27

SR	3.76	1.05	7.82	0.47	3.28

Table II.
Descriptive statistics

investors an indication of the future value of the firm's share price. It appears that on an average the firms with high MV/BV value have higher stock returns.

ROS appears to be positively associated with stock returns. In particular, the values of the coefficients in years 2004, 2005, and 2006 are 3.656, 2.337, and 2.778, respectively. The values of the t-statistic for this variable are 1.718 (2004), 1.054 (2005), and 1.816 (2006). These results suggest that there is a statistically significant association between the two variables only for the years 2004 and 2006. This observation is in line with the hypothesis that the ratio that links the profitability of a firm with its operating activities is positively associated with the stock return of the firm.

Some of the observed associations are not consistent with the expected ones. However, these associations are statistically insignificant. In particular, it is logical to

Table III.
Cross-sectional OLS regression results (model 1)

Independent variables	Dependent variable ln(RI) Years 2004	2005	2006
(Constant)	0.909 (1.572)*	−0.087 (−0.128)	0.123 (0.179)
MV/BV	0.098 (1.276)	0.249 (2.733)***	0.147 (2.221)**
ROS	3.656 (1.718)**	2.337 (1.054)	2.778 (1.816)**

Inventory turnover	−0.025 (1.331)*	−0.024 (−1.016)	−0.022 (−1.230)
EBITDA margin	0.018 (2.952)***	0.015 (2.735)***	0.013 (4.215)***
Adjusted R-squared	0.184	0.136	0.230
F-statistic	4.645	3.377	5.822
Prob(F-statistic)	0.000	0.002	0.000

Notes: White's (1980) t-statistics in parentheses; *Significant at the 10 per cent confidence level; **Significant at the 5 per cent confidence level; ***Significant at the 1 per cent confidence level

expect a positive association between current ratio and the stock returns. Yet, this study found that the association between the two variables was negative for firms included in the sample used in this study. Similarly, a negative association was found between stock returns and inventory turnover, while a negative association was found between working capital turnover and stock returns. In both cases, it would have been sensible to expect a positive association between the two variables. It has been expected a positive association between assets turnover and stock returns. However, the results provided by this study do not fully support the above argument. In 2004 the association between the two variables was negative. The association between the financial leverage of firms and their stock returns was negative, in spite of the fact that a positive association was expected between the two variables.

According to Belsey *et al.* (1980), an indication of multicolliniarity exists when condition index takes a value above 30. The condition indices for the model (1) in years 2004, 2005, and 2006 were 19.320, 18.391, and 18.206, respectively. Therefore, no indication has been found that the model suffers from a multicolliniarity problem.

5. Summary and conclusions

This paper attempted to investigate the association between stock returns and certain accounting-numbers based variables for Greek listed firms in the period 2004-2006. The results indicates that the disclosure that concerns the operating performance of a company, its growth opportunities and capability to generate profits from its sales affect stock returns. It seems, therefore, that market participants (shareholders, investors, analysts, etc.) take into consideration accounting data when they value firms' stock. It should be noted, however, that the impact of this disclosure is not always the expected one. The findings of this study are not consistent with the notion that Greek capital markets are wholly efficient. It is likely that pockets of inefficiency exist within the Greek financial system. The findings of this study can be helpful to managers for selecting and implementing the appropriate business policies. Besides, current shareholders and investors may find the results of this study useful in identifying the drivers of stock values. Furthermore, since the study covers the period

2004-2006, it provides implications about the quality of accounting data immediately after the beginning of application of International Financial Reporting Standards in the financial statements of companies of the Greek Stock Exchange.

An Investigation of the Balanced-Scorecard's Applications for Performance Measurement of the Firms Accepted in the Tehran Securities Exchange Market

[1]Dr. Mohammad Namazi (Ph.D., AICPA) and [2]Hamid Allahyari Abhari

[1]Professor of Accounting Shiraz University, Shiraz, Iran
[2]MA in Accounting (Shiraz University)

Abstract: The major purpose of this study is providing a suitable response to this inquiry: What performance evaluation criterions are currently prevalent by various companies listed in the Tehran Stock Exchange (TSE)? And to what extent, do they have adapted the Balanced Scorecard (BSC) mechanism for performance evaluation of their operations and departments? The significant objectives of this research are: 1) seeking to exploit practical performance evaluation techniques, and 2) reporting the BSC'S adaption among the TSE firms. In effect, four perspectives of the BSC, promoted by Kaplan & Norton (1992, 1996 & 2004), including financial, customer, internal process, and learning & growth, are extracted in the framework of different hypothesis. The population of this research encompasses all firms listed in the TSE for the year 2006. Totally, 200 qualified and active firms were identified, and a valid and reliable questionnaire was conveyed to them. However, only 68 of the questionnaires were complete and, therefore could be extricated in this study. The generated data were analyzed by t-test, binominal test and Analysis of Variance (ANOVA) statistical techniques. The major findings of the study revealed that the most dominant traditional performance evaluation measures employed by the TSE firms are: 1) "Net income" (35.3%), 2) "Operating income" (32.4%), and 3) "Total income" (23.5%) accordingly, and only 4.4% of them are exploiting "cash flows" and "ROI" as their first priority. In addition, 38.2% of the respondents have indicated that they are utilizing "Operating income" as the second priority, and 39.7% of them are exerting "Net income" as the third priority. On the other hand, almost 92.6% of selected companies are not explicitly engaged with the BSC. However, most of them are embarking some non-financial measures in their performance evaluation systems. Age, educational degree, field of the study, and years of practical experience of the respondents were not statistically significant in providing the aforementioned results, but "organizational position" demonstrated a significant effect on the BSC'S adaption.

Key words: Performance Measurement System, Balanced Scorecard (BSC), Tehran Stock Exchange (TSE), Traditional Performance Evaluation Measures

INTRODUCTION

Today, companies have proceeded the era of "industrial competition" and have been infatuated with the era of "information". In the new era, manufacturing as well as service companies, would tend to be equipped with contemporary and advanced abilities in order to be successful in the world-wide competition. The companies' focus in exploiting intangible assets is also much more indispensable than the management of the physical and tangible assets[16].

Although various companies have typically invested heavily on their information systems, programs and innovative techniques, but most of them, particularly in developing countries, are still operating based upon primitive performance evaluation systems and they utilize traditional annual reports, quarterly reports, monthly reports and measures for this purpose [12,13]. On the other hand, currently leading companies around the world, are embarking and implementing the Balanced- Scorecard (BSC) to perform their performance evaluation functions and other managerial duties[9,17,3].

The major aim of this study is to determine empirically: what performance evaluation criteria are presently being implemented by various companies listed in the Tehran Stock Exchange (TSE)? And how much do they have adapted the BSC for the purpose of their performance evaluations of departments and operations?

In effect, the significance of this research is providing comprehensive empirical information about the kind and extent of the financial and non-financial performance evaluation measures, which have been

E-mail: mnamazi@rose.shirazu.ac.ir

presently adapted by the TSE firms. It would also assimilate a hierarchical preference in applications of the performance evaluation techniques of the TSE firms. In addition, it would disclose the implementation status of the BSC, as a leading contemporary technique, by the TSE companies. Hence, as a first and pioneering empirical study in this area in Iran, it would furnish a suitable international knowledge about this significant, challenging and cultivating managerial accounting technique. In effect, benchmarking in this research domain can also be extended.

2. Theoretical Development & Prior Studies: Prior to 1992, various absolute and relative accounting measures were being utilized for managements' performance evaluations. Prominent accounting measures were "total income", "operating profit", "net profit", "cash flows", "Return on investment", "residual income", and "value-added" income[7,11,10]. However, with the advent of BSC in 1992, limitations of employing accounting measures were shown more clearly on the grounds that they are solely based upon past quantitative accounting information and short-views of the firm's operations.

In 1992, BSC was promoted by Kaplan and Norton in an attempt to provide a more refined, complete and accurate performance criterion mechanism. The major philosophy of BSC is that evaluation is a necessary condition for management. If something cannot be evaluated, it cannot be managed either[12]. In essence, BSC is an integrated system, which makes a balance between the following elements:

1) financial and non-financial (qualitative) performance measures,
2) short-term and long-term criteria,
3) interest of stockholders, as well as customers, employees, and other stakeholders, and
4) valuation of tangible as well as intangible assets. As Figure 1 shows, it actually translates the firm's strategy into the objectives and carefully selected balanced measures in four perspectives:

1) financial,
2) customer,
3) internal process, and
4) learning and growth[15].

These four perspectives together would describe how companies can create a greater value for shareholders and other stakeholders and at the same achieving alignment, process improvement, and an effective communications among the employees[16].

In 1993, Kaplan & Norton investigated the real applications of the BSC in 3 different firms operating in different industries. They concluded that in different market conditions and various production strategies, an appropriate BSC mechanism which would be compatible with the nature of the firm's business, must be implemented.

In 1996, Kaplan & Norton, extended the BSC role as a performance evaluation technique to a "strategic management system", and this novel feature was emphasized by other scholars including Marthinson, *et al*.[20]. Mooraj *et al*.[21] also introduced BSC as an item for today's organizations in which increases the value of the firms. Their major finding was that a BSC implementation depends on the formal & informal process, strategic procedures, social aspects, and management control systems.

In 2000, Libby & Salterio investigated the effect of performance evaluation measures on the BSC judgments. They concluded that only "common measures" are effective for performance evaluation. In 2004, Kaplan & Norton, described the concept of "strategy map" and extended it to four perspectives of the BSC. Libby *et al*.,[18] tested two approaches for reducing variances from "common measures". They showed that by employing "unique measures" the necessity of managers to be hold responsible for their performances would be enhanced. Banker *et al*.,[2] also investigated the relationship between managers' personal performance evaluations and the BSC's strategies. They found that when evaluators do maintain some information about firms' strategies, they would utilize more from those performance evaluation criterion which are directly related to the firms' strategies than the common measures.

Chen *et al*.,[5] investigated the role of significant factors affecting the BSC implementation, and concluded that participation of financial managers, administrative managers, CEOS' support, and size of the company are significant elements. Othman[25] arrived at this conclusion that a successful implementation of the BSC, requires the development of a detailed causal model in the organization.

Papalexandris *et al*.[26] introduced a methodology for applying BSC. A new BSC system was based upon evaluation of the BSC elements, project management, change management, risk management, quality control & information technology. Fernandes *et al*.[6] investigated the BSC application in small and medium size manufacturing companies. They found that BSC could be applied well for small & medium size manufacturing firms. Gumbus & Lussier[9] also investigated the BSC implementation in small, medium and large size companies. Their findings was that BSC application did actually increased the firms' performance, and although 50% of 1000 firms listed in Fortune employed the BSC, only a limited number of small and medium size companies utilized the BSC. Bhagwat and Sharma[3] investigated the BSC implementation in small and medium size companies in India, and introduced relevant measures for evaluating small and medium size supply chain companies.

Kohlbeck *et al*.[17] implemented the residual income model, and considered the effect of unrecorded intangible assets, abnormal earnings and valuation on banking industry. They concluded that the consistency of abnormal profit and multiple valuation in abnormal profit has a significant relationship with the level of unrecorded intangible assets. Thus, the role of intangible assets is vital.

In Iran, just recently a limited number of articles[22,23] has been appeared in the accounting literature which have described major premises of the BSC and its elements, and no empirical work has yet been reported in the leading accounting journals.

In sum, some of the important conclusions which can be drawn from the BSC literature are as follows:

1. BSC is a useful technique for performance evaluation.
2. BSC has suggested the development of different performance evaluation measures in each of it's four perspectives (financial, customer, internal process, and learning & growth) for each industry and each even firm.
3. BSC has actually been applied extensively in practice. However, the degree of it's adaption depends on the social culture, internal structure, size of the company, top managements' support, and even employees' involvement in implementing BSC.
4. Since it's introduction in 1992 to present, BSC has pursued the following four consecutive eras[22]:

1. First era (1992-1996)- employing BSC as an advanced performance evaluation technique.
2. Second era (1996-2004)- exploiting BSC as a potent strategic management system.
3. Third era (2004-2007)- embarking BSC as a strategy map and providing an effective organizational framework.
4. Fourth era (2007-now)- implementing BSC as a vital technique for attaining alignment and coordination of the organization strategies and it's sub-departments.

3- Research Methodology: This study is a practical-based research focusing on a one shot exposit-design only[1,27], and consists of the following sections:

3.1. Research Hypothesis: Following our research questions raised in Section 1, reported results of prior studies relating to BSC, and extricating content of different leading managerial accounting text books in this area[7,10,11], the following research hypothesis were formed:

First Main Hypothesis: TSE firms are exerting traditional accounting performance evaluation techniques for evaluating their operations and different departments.

The minor hypotheses are:

1. TSE firms are exerting "**Total income**" information for evaluating their operations and different departments.
2. TSE firms are exerting **"Operating profit"** information for evaluating their operations and different departments.
3. TSE firms are exerting **"Net profit"** information for evaluating their operations and different departments.
4. TSE firms are exerting **"Cash flows"** information for evaluating their operations and different departments.
5. TSE firms are exerting **"Return on Investments (ROI)"** information for evaluating their operations and different departments.
6. TSE firms are exerting **"Residual Income (RI)"** information for evaluating their operations and different departments.
7. TSE firms are exerting **"Value-Added (VA)"** information for evaluating their operations and different departments.

Second Main Hypothesis: TSE firms are exerting the Balanced Scorecard (BSC) technique for evaluating their operations and different departments.

The minor hypotheses are:

2.1- TSE firms are exerting **"Financial Perspective"** information of the BSC for evaluating their operations and different departments.

2.2- TSE firms are exerting **"Customer Perspective"** information of the BSC for evaluating their operations and different departments.

2.3- TSE firms are exerting **"Internal Process Perspective"** information of the BSC for evaluating their operations and different departments.

2.4- TSE firms are exerting **"Learning and Growth Perspective"** information of the BSC for evaluating their operations and different departments.

3.2. Population of the Study: The population of this research encompasses all companies listed in TSE in the year 2006. No sampling was exploited in order to provide a more valid, reliable, and comprehensive study. Following observation of a total list of TSE active companies, and their information, only 200 firms were qualified, and then selected.

3.3. Methods of Information Gathering: In conducting this study, the "mailed questionnaire" technique[27,8] was deployed. First, a questionnaire was devised based upon selected interviews and a content analysis of the performance evaluation literature. It consisted of three distinct parts. In the first part, general information pertinent to respondents including sex, age, years of experience, field of the study, and certificate of the study, were devised. The second section was devoted to professional information, presenting a brief explanation of the BSC system and its four perspectives (financial, customer, internal process, and learning & growth). In the third section, 11 general closed or structured multiple Liker type questions along with their details relating to BSC and its four perspectives, were presented. A total of 66 choices concerning 11 general questions were established in the questionnaire. In addition, a total of 18 "open questions" relating to BSC and its four perspectives were also designed in order to provide indebt knowledge about the BSC implementation among the TSE firms.

The Validity of the questionnaire was followed via the "construct validity" approach[27,8] by inquiring expert accounting professors, accounting graduate students, and practitioners to review and comment about the form and content of the questionnaire. As a result, the questionnaire was revised. Consequently, a new questionnaire was distributed among 20 selected firms as a pilot study in order to determine the reliability of the questionnaire. The reliability criterion, based upon the "Crohnbach's a" was %81.1 and %76.5 for the first and second hypothesis, respectively. Thus, the questionnaire was approved, and it was mailed to 200 selected firms. However, only 94 complete questionnaires (after a frequent contact and follow-ups) were returned in which 68 of them could be expended.

The generated data was processed by SPSS and MINITB. The statistical t-test, Binominal-test and Analysis of Variance (ANOVA) were employed to test the hypothesis.

4. Research Findings & Analysis: Important results are presented in the following sections:

4.1- General Information: Table 1 illustrates general characteristics of the respondents.

This information clearly reveals that the respondents were qualified to participate in this study.

4.2- Descriptive Information: In this section, the respond to each professional inquiry relating to each hypothesis is presented.

Table 2, represents the TSE firms' replies to the first hypothesis' questions. The results would indicate that, among other things, 35.3% of the respondents have selected "net profit" as the first measure of performance evaluation, 32.4% "operating profit", 23.5% "total revenue", and only 4.4% are exploiting "cash flows" and "ROI" as their first priority. Also, 38.2% of the respondents have indicated that they utilize "operating profit" as the second priority and 39.7% of them exert "net profit" as the third priority.

Tables 3, 4, 5 and 6 assimilate findings relating to the second major and its minor hypothesis. Table 3 indicates that no firm has actually implemented BSC fully with all of its four perspectives, and only 7.35% of them have adapted it "to some extent".

With respect to the customer's perspective in BSC, table 4, among other things, demonstrates that 58.8% respondents have indicated "customers' satisfaction", 23.5% "number of customers' complains" and 17.6% "market share", accordingly as their first priority that must be/are considered in the BSC system. Also, 42.6% of them have mentioned "market share", 25% "customer satisfaction", and "number of complains" and 7.4% "percentages of new customers" as their second priority. Furthermore, 36.8% of the respondents have identified "number of customer complains", 32.4% "percentages of new customers", 16.2% "customer satisfaction", and 14.7% "market share" as their third priority.

Results of the internal process perspective of the BSC are shown in table 5. It reveals that 36.8% of the respondents have selected "unfavorable variances from standard costs", 32.4% "percentage of sales of new products", 22.1% "production cycle efficiency", and 8.8% "time required for producing a unit of goods", accordingly as their first priority to be included in the BSC system. Furthermore, 26.5% of them have pointed out "percentage of sales of new products", 23.5% "unfavorable variances from standard costs", 17.6% "time required for productizing a unit of goods", and 14.7% "production cycle efficiency" as their second priority. In addition, 19.1% of them have identified "unfavorable variances from standard costs", 16.2% "percentage of sales of new products", and 10.3% "production cycle efficiency" as their third priority.

Findings regarding the "learning & growth" perspective of the BSC are shown in table 6. It reveals that 41.2% of the respondents have indicated "employees education hours", 32.4% "listening to employees ideas and suggestions", and 26.5% "employees value added" accordingly as their first priority. Furthermore, 57.4% of them have mentioned "employees education hours" 22.1%, "listening to employees ideas and suggestions" and 19.1% "employees value added" as the second priority. In addition, 45.6% of them have identified "employees turn-around", 20.6% "employees value added" and 19.1% "listening to employees ideas and suggestions" as their third priority.

Table 1: General Characteristics of the Respondents

		Frequency	Percentage
Sex	Male	68	100
	Female	0	0
	Total	68	100
Age	Between 25 to 30 years	4	5.09
	Between 30 to 45 years	49	72.0
	Between 45 to 55 years	14	20.6
	More than 55 years	1	1.5
	Total	68	100
Educational Degree	Doctorate	5\4	5.9
	Master	55	80.9
	Bachelor	9	13.2
	Total	68	100
Field of the Study	Accounting	37	54.4
	Finance	14	20.6
	Management	14	20.6
	Economics	3	4.4
	Total	68	100
Years of Experience	More than 20 years	10	14.7
	Between 15 to 20 years	14	20.6
	Between 10 to 15 years	18	26.5
	Between 5 to 10 years	15	22.0
	Less than 5 years	11	16.2
	Total	68	100
Position	Financial Managers	36	52.9
	Head of Accounting	25	36.8
	Treasurer	7	10.3
	Total	68	100

4.3. Statistical Hypothesis Testing:

4.3.1. First Hypothesis: The first major null hypothesis can be presented as follows:

The average TSE firms are not exerting traditional accounting performance evaluation techniques for their operations and different departments.

Since for this hypothesis, 7 hierarchical measures are considered, and their score values are from 1 to 7, the average score for the hypothesis is equal to 3.5 times 7, i. e., 24.5. Thus, the null hypothesis and its alternative hypothesis could be formally expressed as follows:

H_{01}: $\mu \le 24.5$

H_{11}: $\mu > 24.5$

Table 7 and Figure 2 illustrate the findings and a relevant graph for the first major hypothesis.

Consequently, it can be concluded that the TSE firms are utilizing traditional performance evaluation techniques for evaluating their operations and different departments.

Results of the binomial tests (H_0: $P \le ½$ and H_1: $P > 1/2$) for the minor hypotheses of the first hypothesis are shown in table 8.

From the above table, it can be inferred that H_0 is rejected; this indicates that, more than half of the respondents, have replied to traditional performance measures criterion positively; therefore, the average active TSE firms are utilizing the traditional performance evaluation techniques.

Table 2: The TSE Firms' Applications of the Traditional Performance Evaluation Techniques

First hypothesis question: Do you use any performance evaluation measures in your company for the purpose of evaluating the performance of your departments' operations? If yes, currently which of the following financial measures are being employed by your company for the purpose of departments' performance evaluation operations? Please answer based upon your hierarchy, accordingly.

		Net profit		Operating profit		Total revenue		Cash flows		Return on Investment		Residual Income		Economic value added	
	Hierarchy	Frequency	Percentage	Frequency	Percentage	Frequency	Percentage	Frequency	Percentage	Frequency	Percentage	Frequency	Percentage	Frequency	Percentage
Yes	1	24	35.3	22	32.4	16	23.5	3	4.4	3	4.4	0	0	0	0
	2	9	13.2	26	38.2	23	33.8	3	4.4	7	10.3	0	0	0	0
	3	27	39.7	11	16.2	22	32.4	5	7.4	3	4.4	0	0	1	1.5

Table 6: Information Relating to the BSC (Learning & Growth Perspective)

Second hypothesis question: Which of the following criteria are currently being employed by your company for performance evaluation of your departments? Please indicate your answer based upon a hierarchical order.

		Employees education hours		Listening to employees ideas and suggestions		Employees value added		Employees turn-around	
	Hierarchy	Frequency	Percentage	Frequency	Percentage	Frequency	Percentage	Frequency	Percentage
Yes	1	28	41.2	22	32.4	18	26.5	0	0
	2	39	57.4	15	22.1	13	19.1	0	0
	3	0	0	13	19.1	14	20.6	31	45.6
	4	0	0	8	11.8	13	19.1	18	26.5
No	For some reasons we are not using these measures	0	0	0	0	0	0	7	10.3
	We would like to use	1	1.5	10	14.7	10	14.7	12	17.6
	We would not like to use	0	0	0	0	0	0	0	0
	Total	68	100	68	100	68	100	68	100

Table 7: Result of the First Major Hypothesis

Results (at a=%5)	P-Value	t-Value	Standard deviation	Average Score	Number of respondents
H_0 Rejected	0.000	10.51	2.193	27.29	68

Table 8: Results of the Binomial Test for the Minor Hypothesis of the First Hypothesis

Currently which of the following performance criteria are being employed for evaluating the performance of your departments?	Number of answers	Ratio of yes answers	Significance	P-value	Conclusion at α = %5
Total revenue	68	0	1	0.000	H_0 Rejected
Operating profit	68	0	1	0.000	H_0 Rejected
Net profit	67	1	0.98	0.000	H_0 Rejected
Cash flows	65	3	0.95	0.000	H_0 Rejected
Return on Investment (ROI)	62	6	0.91	0.000	H_0 Rejected
Residual Income (RI)	62	6	0.91	0.000	H_0 Rejected
Economic Value Added (EVA)	53	15	0.78	0.000	H_0 Rejected

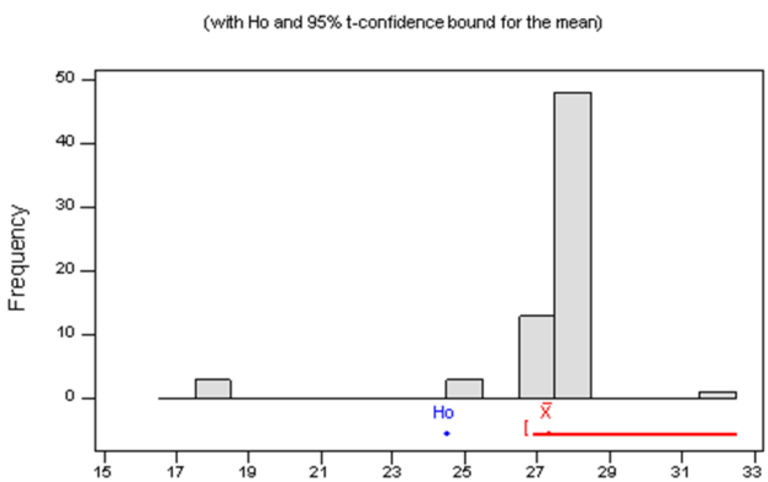

Fig. 2: Histogram of the First Major Hypothesis

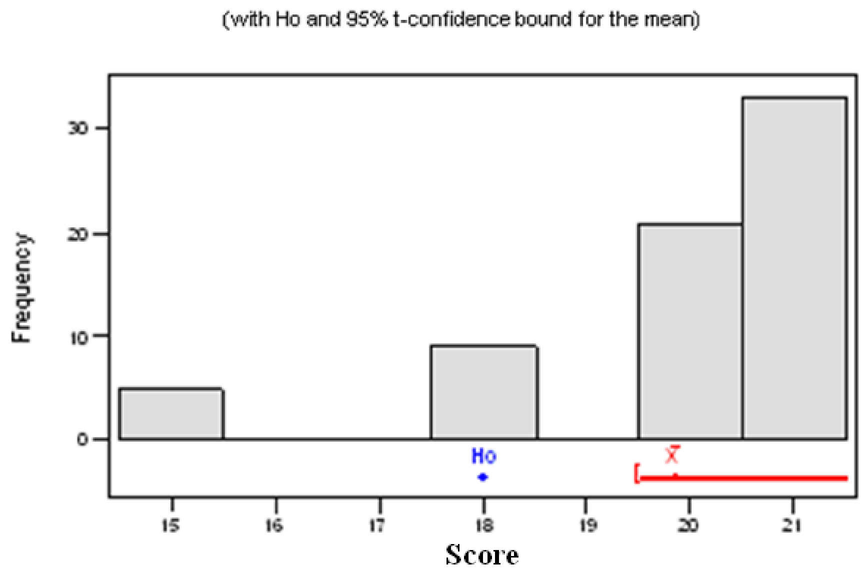

Fig. 3: Histogram of the "Customer Satisfaction" Hypothesis

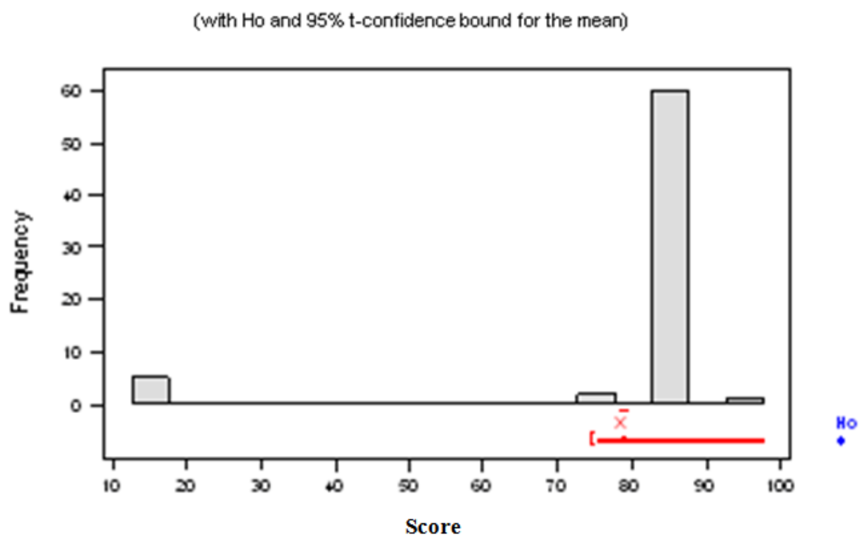

Fig. 4: Histogram of for "Internal Process" Hypothesis

4.3.2. Second Hypothesis: Results of the binomial test for the second hypothesis (H_{02}: P ≤ ½ , H_{12}: P > ½) is shown in table 9. From the information presented, it can be concluded that the average TSE firms are not expending BSC for performance evaluation of their operations.

Important findings of the minor hypothesis relating to the second major hypothesis are as follows:

Results of the first minor hypothesis ($H_{02\text{-}1}$) are actually the same as the H_{01}, which was presented earlier. Thus, it can be concluded that the average active firms in the TSE are utilizing some elements of the BSC "financial perspective" in their performance evaluation systems. Table 10 shows the results of the second minor hypothesis ($H_{02\text{-}2}$: μ ≤ 18, $H_{12\text{-}2}$ μ >18, 6 questions times the average score 3). Its graph is shown in Figure 3. Consequently, it can be concluded that the average TSE firms are employing some measures of the "customer perspective" in their performance evaluation system, even though they are not formally applying the BSC.

Table 11 and Figure 4 shows the results and a graph of the third minor hypothesis ($H_{02\text{-}3}$: μ ≤ 112.5, $H_{12\text{-}3}$: μ > 112.5; 15 measures times the average score value of 7.5). From this information, it can be concluded that the average active TSE firms do not

Table 9: Results of the Binomial Test for the Second Major Hypothesis

	Number of response		Ratio of yes answers	P-value	Results at α = %5
	Yes	No			
Is BSC currently being used in your company for performance evaluations of the departments' operations?	5	63	0.0735	1.00	H_0 cannot be rejected

Table 10: Results of the Customer Satisfaction Hypothesis

Result (at α =%5)	P-Value	t-Value	Standard deviation	Average	Number of respondents
H_0 Rejected	0.000	9.01	1.69	19.85	68

Table 11: Results of the "Internal Process" Perspective

Resultat α = %5	P-Value	t-Value	Standard deviation	Average	Number of respondents
H_0 cannot be rejected	1.000	-15.22	18.25	78.82	68

Table 12: Results of the "Learning and Growth" Perspective

Resultat α = %5	P-Value	t-Value	Standard deviation	Average	Number of respondents
H_0 rejected	0.000	8.5	1.20	9.23	68

Table 13: Results of ANOVA for Determining the Significance of the Respondents' General Characteristics

Variable	Hypothesis	F-Value	P-value	Result (at α = 5%)
Age	1	0.731	0.535	H_0 Not Rejected
	2	0.650	0.584	H_0 Not Rejected
Educational degree	1	0.746	0.526	H_0 Not Rejected
	2	2.964	0.134	H_0 Not Rejected
Field of the study	1	0.510	0.729	H_0 Not Rejected
	2	1.428	0.228	H_0 Not Rejected
Years of practical experience	1	1.150	0.336	H_0 Not Rejected
	2	0.587	0.672	H_0 Not Rejected
Organizational position	1	2.143	0.121	H_0 Not Rejected
	2	1.264	0.026	**H_0 Rejected**

adequately implement the "internal process perspective" in their performance evaluation systems.

Table 12 and Figure 5 reveal findings and graph of the fourth minor hypothesis (H_{02-4}: $\mu \le 8$, H_{12-4}: $\mu > 8$; 4 measures times the average score 2). This information indicates that the average active TSE firms are exerting some elements of the "learning & growth perspective" in their performance evaluation systems.

4.3.3- Determining the Significance of the Respondents' Characteristics: In order to determine the importance of the respondents' general characteristics in the aforementioned findings, Analysis of Variance (ANOVA) test was performed for identifying general characteristics' impacts. Table 13 presents the results. It indicates that none of the general characteristics have had a significant statistical impact on the responses. The position of the respondents, however, is the only factor that has had a significant effect on the BSC implementation hypothesis.

5. Concluding Remarks & Discussion: This study demonstrated that more than 86.8% of the respondents in the TSE, actually did hold a master or a Ph.D. degree, and fields of the studies of 75% of them were closely related to accounting and finance. Also more than 62% of them maintained more than 10 years of practical experience, and more than 89.7% of them were in the financial management and/or accounting positions. Thus, they were qualified to participate in this study.

Results of the first major and its minor hypothesis revealed that 100% of the respondents are employing "total revenues" and "operating profits", 98.5% "net profit", 95.6% "cash flows", 91%, ROI and RI, and 78% "EVA" for performance evaluations of their operations. However, as far as the hierarchical preferences is concerned, statistical frequency analysis and other information indicated that firms listed in the TSE are embarking, "net income", "operating profit", "total revenues", "ROI", "cash flows", "RI" and "EVA", accordingly.

Results of the second major and its minor hypothesis showed that only 7.35% of TSE firms are exerting BSC explicitly to some extent. In spite of this, TSE firms, on the average, are utilizing financial as well as non-financial measures for their performance evaluation systems, without any formal recourse to the BSC. The statistical analysis relating to investigated firms also indicated that, with respect to "customer perspective" of the BSC, the firms are exploiting "customer satisfaction" (100%), "market share" (100%), and number of customers complains" (92.6%), accordingly. In internal process perspective, employing "unfavorable variances from standards" (92.6%), and "percentage of sales of new products" (92.6%), are the most prevalent criteria which are being employed by the TSE firms. For "learning & growth perspective", the most dominant measures are, "employees education hours" (98.5%), "listening to employees ideas and suggestions" (85.3%), and "employees value added" (85, 3%), accordingly.

In general, results of this study are more or less consistent with other studies conducted in other countries, particularly in developing countries[12,13,8,3]. However, the difference is that TSE companies performance evaluations are not explicitly based upon the BSC and, therefore, it is not clearly following a formal system which would be based upon a designated set of missions, objectives and strategies. As a result, TSE performance evaluation systems are not directly and formally linked to their strategies.

It seems like the most reasons that TSE firms, are not adapting and implementing the BSC formally, are dovetailed to the following factors:

1. lack of some managers' familiarity with the BSC's concept and its perspectives.
2. lack of the interest on the parts of some Chief Executive Officers (CEO) with respect to implementing an advanced and contemporary performance evaluation system.
3. The existence of the public institutions and sole producers or distributors of the goods or services.
4. lack of completion in the market place for some industries and organizations.

6. Suggestions: The following suggestions are made briefly:

1. This study and other related collected information indicate that the applications of the BSC among large TSE firms are growing. Thus, it is suggested in the future, the implementation of this important and challenging technique along with its advantages and disadvantages in different industries be investigated by accounting researchers.
2. Given the importance of performance evaluation information for managers, stockholders and investors, it is suggested that the TSE or the Audit Organization of Iran promulgate the adaption of the BSC for large companies. This suggestion, of course, must be followed after an in depth analysis and a comprehensive research.
3. It is suggested that a specific organization for ranking TSE various firms' performances and assimilation of the relevant information in this area, be established in Iran.
4. It is suggested that the impacts and effects of the BSC applications in those national and international companies which have attempted to implement it be investigated, and its advantages, disadvantages at the theoretical as well as practical level be reported comprehensively. In that case, the significance, importance, and cost benefit of the BSC would be disclosed more accurately and thoroughly.

ABSTRACT

We survey recent research in accounting anomalies and fundamental analysis. We use forecasting of future earnings and returns as our organizing framework and suggest a roadmap for research aiming to document the forecasting benefits of accounting information. We combine this with opinions from the academic and practitioner communities to critically evaluate key clusters of papers about accounting anomalies and fundamental analysis disseminated over the last decade. Finally, we provide a new analysis on how an ex ante and ex post treatment of risk and transaction costs affects the accrual and PEAD anomalies, and offer suggestions for future research.

1. Introduction

In this paper, we review the literature on accounting anomalies and fundamental analysis. Given the existence of numerous excellent literature reviews of closely related topics, we have constructed our review to complement them. We focus on research studies that have publication or distribution dates after the year 2000, examine accounting-related anomalies and fundamental analysis geared toward forecasting future earnings and security returns, and examine empirical research methods.

An underlying theme of our survey is that the information contained in general purpose financial statements can help investors make better portfolio allocation decisions. To this end, an investor can use information in these statements to forecast earnings for the reporting entity, estimate the risk of these earnings, and ultimately make an assessment of the intrinsic value of the firm that can be compared to observed market prices. We use this forecasting activity as our primary

☆ We are indebted to the *CFA Institute* for their generous support in constructing and administering a questionnaire and survey of their membership. organizing principle for research on accounting anomalies and fundamental analysis.[1] While we recognize the co-existence of other accounting properties and objectives, we view forecasting as a powerful organizing concept for reviewing the recent literature.

The first part of our review tabulates the most highly cited research studies on accounting anomalies and fundamental analysis published or distributed after the year 2000. We then categorize these highly cited studies by identifying their common and overlapping citations to earlier papers in the literature. The second part of our survey presents results from a questionnaire of investment professionals and accounting academics about their opinions on accounting anomalies and fundamental analysis and how academic research has informed investment practice and to highlight some differences between that and the research conducted by investment professionals. The third part of our survey lays out a desired framework for research seeking to document the forecasting benefits of accounting information, which we then use to critically evaluate the relevant research disseminated over the last decade. In the fourth part, we present some empirical analysis on how an ex ante and ex post treatment of risk and transaction costs affects the well known accrual and PEAD anomalies. In the final part of our review, we offer suggestions for future research.

Our survey focuses on empirical research covering accounting anomalies and fundamental analysis. However, empirical research is (or should be) informed by theory, because the interpretation of empirical analysis is impossible without theoretical guidance. While we do not review in detail papers already covered in prior surveys or those papers covered in concurrent *Journal of Accounting and Economics* survey papers (see, e.g., Beyer et al., this issue; Dechow et al., this issue), we do attempt to recognize linkages between them.

Our survey, in some respects, reiterates a central theme from Kothari (2001). Specifically, academic research that seeks to explore relations between accounting attributes and future firm performance, particularly stock returns, should strive to keep market efficiency as a maintained null hypothesis. The mere finding of an association between an accounting attribute and future stock returns is not prima facie evidence of market inefficiency. As with the research reviewed in Kothari, we continue to find that researchers may be too quick to deviate from the maintained assumption of market efficiency. Furthermore, the documented deviations from market efficiency are many and varied, with little attempt to provide a framework linking them together so as to provide a compelling alternative hypothesis. We are believers in the potential for market inefficiencies; however we think that the hurdle for documenting these inefficiencies is non-trivial.

Our survey also contains a citation analysis of recently published and working papers on accounting anomalies and fundamental analysis. This citation analysis lets the "academic research market speak" on which research papers on accounting anomalies and fundamental analysis have attracted the attention of other researchers and have had a meaningful impact on the subsequent literature. While many of the most highly cited papers are from finance journals, there are some very influential papers from accounting journals that are broadly cited in both types of journals (see, e.g., Xie, 2001; Richardson et al., 2005).

We conduct a citation analysis on papers disseminated in the last decade and find four main clusters of overlapping citations common among these papers. We apply the following labels to the four clusters of research papers: *Fundamental Analysis, Accruals Anomaly* (including related investment anomalies), *Underreaction to Accounting Information* [including post-earnings announcement drift (hereafter PEAD) and other forms of momentum], and *Pricing Multiples and Value Anomaly*.

The *Fundamental Analysis* cluster cites a number of prior foundational papers including Abarbanell and Bushee (1997, 1998) and Feltham and Ohlson (1995). The citation foundation of the *Accruals Anomaly* cluster is from Sloan (1996). The *Underreaction to Accounting Information* cluster most often cites Bernard and Thomas (1989, 1990), Foster et al. (1984), and Jegadeesh and Titman (1993) as foundational papers. The *Pricing Multiples and Value Anomalies* cluster is bound together by references to the foundational papers of Basu (1977), Reinganum (1981), Ball (1992), and Fama and French (1993, 1995).

We categorize, evaluate, and discuss some of the main research advances after the year 2000 in each of the four research clusters. In addition, we identify what we believe to be essential components of "good" archival empirical research within the accounting anomalies and fundamental analysis umbrella. Those components are: (1) credible alternative hypotheses (relative to market efficiency) with sound theoretical foundations; (2) robust (in and out of sample) predictive power; (3) a sound treatment of risk; (4) a sound treatment of transaction costs (for research looking at future stock returns); (5) attempting to document additivity to pre-existing accounting attributes; and (6) incorporating non-price based tests to help strengthen inferences about risk versus mispricing. We then use these key ingredients to provide a structure for our survey.

The questionnaire we distributed to investment professionals and to accounting academics indicate some interesting similarities and differences of opinion regarding the current state of research on accounting anomalies and fundamental analysis and where that literature should proceed. While our findings suggest that many of the conventions and techniques used in academic research differ from those in the investment community, both the practitioners and academics who completed our questionnaire placed high importance for future academic research on theoretically motivated empirical tests of investor behavior; empirical tests of asset pricing, risk, and factor models; empirical research on forecasting firm and industry fundamentals; and the empirical discovery and investigation of new "anomalies" or signals.

[1] We keep the discussion of accounting anomalies and fundamental analysis distinct from each other as this is how the literature has evolved. But we note that fundamental analysis could be characterized as subsuming the accounting anomaly literature (i.e., both have the primary goal of forecasting earnings and returns).

We conduct our own empirical analyses to help illustrate some concepts and approaches to be considered and applied in future research studies. Specifically, based on the prominence of the accruals and PEAD anomalies in the recent literature and the practitioner interest in innovations related to empirical tests of investor behavior, asset pricing, and risk and factor models, we illustrate the time-series variation in the negative relations between future returns and both accruals and PEAD, and whether these relations are robust to a more comprehensive empirical treatment of risk and transaction costs, both from an ex ante and ex post perspective. Our empirical analysis shows that the negative relation between accruals and future stock returns is robust to a comprehensive treatment of risk and transaction costs, but that it has greatly attenuated in recent years (see also Green et al. (2009) for accruals anomaly only). For the relation between PEAD and future stock returns, we find that the relation is only marginally significant after accounting for transaction costs and that it has also greatly attenuated in recent years.

In addition, we provide suggestions for future research on accounting anomalies and fundamental analysis. Based on our citation analysis, literature review, practitioner/academic questionnaire, and empirical analyses, we identify six major areas of opportunity. First, there is a significant opportunity for researchers to provide greater structure to the forecasting exercise. To date, very little research combines multiple accounting attributes to forecast future earnings or returns. Second, there is a lack of research that uses macroeconomic data to forecast future earnings, risk, and value. Third, current research does not fully exploit the wealth of information contained in general purpose financial reports. Fourth, there appear to be limitations to current forecasting techniques and opportunities to overcome these limitations. Fifth, we discuss the use of accounting information by external capital providers beyond common equity holders. With the increased development of credit markets in the last decade there is now a wealth of data available on credit related instruments that can be used to help make inferences about the usefulness of accounting information for a wider set of capital providers. Sixth, we note that many capital market participants are using the same information sources to forecast future earnings and stock returns. This has lead to increased correlation in stock price movements, creating interesting market settings to explore how information is impounded into security prices.

1.1. *Relation to prior surveys*

While we are arguably the first to provide a focused survey of the vast archival empirical literature related to accounting anomalies and fundamental analysis, there are a number of prior surveys. Perhaps the paper most related to our survey is Kothari (2001) and the related Lee (2001) discussion. As the coverage of Kothari captures the broad umbrella of capital markets research in accounting, it also includes a thorough review of the academic literature related to accounting anomalies and fundamental analysis prior to 2000. Appendix A highlights key attributes of several of the more recent survey papers. A general pattern across this previous work is that the focus tends to be on older, and non-accounting related research. In particular, recent finance surveys on anomalies focus almost exclusively on behavioral finance and do not cover accounting anomalies or fundamental analysis. Classic papers such as Fama (1970), and recent papers like Keim and Ziemba (2000) and Barberis and Thaler (2003), focus on issues related to market efficiency; such as technical, fundamental and event-driven anomalies, and the now maturing field of behavioral finance. Also, because our review of accounting anomalies and fundamental analysis is related to valuation, we refer the reader to insightful reviews contained in Damodaran (2005), Ohlson (2009), and Easton (2009).

The rest of the paper proceeds as follows: Section 2 uses citation analysis to identify high impact papers from the recent literature and organizes the literature into four main research clusters. Section 3 summarizes the results of a questionnaire of investment professionals and accounting academics. Section 4 provides a synthesis of recent advances in each of the research clusters identified above. Using the relation between accruals (and SUEs) and stock returns as case studies. Section 5 presents a benchmark model for evaluating accounting anomalies employing a more-encompassing definition and treatment of risk and transaction costs. Building on the findings in Sections 2–5, we then discuss our suggestions for future research in Section 6. Section 7 summarizes and concludes.

2. Citation and cluster analysis

Our survey focuses on research studies published or circulated after the year 2000. As a starting point, we use academic citation data to identify high impact research papers on anomalies and fundamental analysis. Using citation analysis to quantify research impact has solid foundations in the accounting literature (e.g., McRae, 1974; Brown and Gardner, 1985a, 1985b; Brown and Heufner, 1994). In general, academic citation analyses use the number of citations listed on the *ISI Web of Science* and the *SSCI (Social Sciences Citation Index)*.[2] However, this citation data can paint an incomplete picture of important recent developments and innovations in an academic field. Moreover, with the advent of the internet and research sites such as the *Social Sciences Research Network (*www.ssrn.com*)* and *Research Papers in Economics (www.repec.org),* working papers are quickly and widely cited by other researchers.

[2] For example, Schwert (2007) uses *ISI Web of Science* citation data to rank papers published in the *Journal of Financial Economics* between 1974 and 2005 by the number of citations per year. Citations reported in *ISI Web of Science* are for published papers that receive citations from other published papers drawn from a set of widely-read academic journals.

Therefore, to capture a broad and timely picture of recent papers on accounting anomalies and fundamental analysis literature, we apply the methods of Keloharju (2008) and analyze citations using results returned by Google Scholar, a service that complements the citations generated by the core journals covered by *ISI Web of Science* with citations from other journals and, more importantly, from working papers. We collect the citation data by using the general citation search function of Anne-Wil Harzing's "*Publish or Perish*" program, downloadable at http://www.harzing.com/. This program uses on-line data from Google Scholar to generate the cumulative number of citations to each paper. Because the cumulative number of citations to a research study depends not only on impact, but also on the passage of time since its original circulation or publication, we follow Schwert (2007) by accounting for this "age effect" and divide the number of citations by the number of years since original circulation or publication of a paper.

We construct a list of the most highly cited recent papers by first performing a keyword search on the *ssrn.com* e-library database to identify candidate working papers and published papers related that to financial market anomalies and fundamental analysis.[3,4] We then scan the titles and abstracts of the candidate papers to determine if they (i) were posted or published after the year 2000, and (ii) focus on or have implications for empirical tests of accounting anomalies and fundamental analysis. We then obtain citation counts for these papers from Google Scholar using the "*Publish or Perish*" program. We collect citations to both working paper versions and published versions of each paper and combine duplicate entries to the same article and correct erroneous title, year, and publication year information.

2.1. Citation impact results

For the sake of brevity, the full list of the most highly cited research papers on anomalies and fundamental generated by our search of Google Scholar can be obtained from the authors directly. The ten papers with the highest average number of citations per year are:

(1) Jegadeesh and Titman (Journal of Finance, 2001), "Profitability of momentum strategies: an evaluation of alternative explanations (Jegadeesh and Titman, 2001)."
(2) Hong, Lim, and Stein (Journal of Finance, 2000), "Bad news travels slowly: size, analyst coverage, and the profitability of momentum strategies (Hong et al., 2000)."
(3) Diether, Malloy, and Scherbina (Journal of Finance, 2002), "Differences of opinion and the cross-section of stock return (Diether et al., 2002)."
(4) Zhang (Journal of Finance, 2005), "The value premium (Zhang, 2005)."

2.2. Organizing the literature: common citations to prior work

In the previous subsection, we used citation analysis of both published papers and working papers to identify which research papers on accounting anomalies and fundamental analysis have attracted the attention of other researchers and therefore have had an influence on the subsequent literature. Then we organize the literature by identifying clusters of research papers that have overlapping references to prior research studies.

In order to identify clusters of papers and topics, we look for common citation patterns across research papers. We start with the sample of highly cited papers in Section 2.1 and then join all citations from these papers with other research papers. Each unique cited research paper is given an identifying code.[5] After coding each cited paper, we perform a *k*-means cluster analysis of overlapping citations from papers in our main sample. We limit the number of possible clusters to less than six to create a tractable mapping of the literature. The cluster analysis reveals four main clusters of overlapping citations to common sets of prior papers. Upon examination of the papers in the four main clusters, we assign the clusters the following labels: *Fundamental Analysis, Accrual Anomaly, Underreaction to Accounting Information, Pricing Multiples and Value Anomaly*. These four main categories largely span the literature. In addition, the four clusters include subcategories of related studies such as investment anomalies (falling within the *Accruals Anomaly* cluster), earnings drift related anomalies (e.g., PEAD), return momentum (falling within the *Underreaction to Accounting Information* cluster), and information uncertainty (as it relates to *Underreaction to Accounting Information).*[6] We use these clusters to organize Section 4 of the paper, which reviews the literature on accounting anomalies and fundamental analysis.

3. Academics' and practitioners' opinions on anomalies/fundamental analysis

In addition to our citation analysis of high impact research papers on accounting anomalies and fundamental analysis, we supplement this with a survey of the academic and practitioner communities. In this section, we highlight some of the key responses received from the academic and practitioner respondents to the questionnaire. Throughout the rest of our survey, we weave the respondents' insights into our review of the literature (Section 4), and into our suggestions for research (Section 6).

Past and future demand for research on accounting anomalies and fundamental analysis is potentially influenced by what happens in practice. Therefore, to assess the relevance of past research and help indicate directions for future research, we survey investment professionals and academics to gain a better understanding of how they view the state of the art on the fundamental analysis and anomalies research. In doing so, we document any differences in opinions on research between these two major constituents, as well as assess the awareness, demand for, and use of academic research on accounting anomalies and fundamental analysis.

3.1. Practitioner questionnaire

To survey the opinions of investment professionals on the broad topic of academic research on investment strategies, accounting anomalies and fundamental analysis, we worked in cooperation with the market research group of the *CFA Institute* to construct and administer a mini-survey of investment professionals. We constructed the survey questions in order to capture how investment professionals apply fundamental analysis and other quantitative techniques in their daily job activities and how academic research informs their practice. In addition, we included questions about the sources and uses of ''research information'' for their daily job activities. The market research team from the CFA Institute provided suggestions on the format of the questions that would maximize the likelihood and usefulness of the survey responses. We were not allowed to collect detailed demographic information from the respondents due to CFA restrictions. Furthermore, since we had to work within CFA's resource constraints, our final response rate may have been limited. Once the CFA Institute survey was distributed, we used a similar format for the academic survey.

[5] This coding process was partially automated and, as a result, was subject to some errors as some papers in our sample cite the working paper version of a study, while other papers include a more up-to-date citation of the published version of the same study. In addition, there are also possible transcription errors by both authors of the papers and by us in tabulating references to create the citation database.

[6] Again, for the sake of brevity, the full tabulation of papers within each cluster is available from the authors upon request.

The practitioner survey was administered and distributed by the CFA Institute via e-mail on January 26, 2009. A reminder e-mail was sent to non-respondents February 10, 2009 and the survey closed on February 12, 2009. The population from which the sample was drawn consisted of all active members of the *CFA Institute*, excluding those without a valid e-mail address and those that requested not to be sent e-mails or surveys. The sample was generated using a stratified random sampling technique; this produced a representative sample of 6,000 members to receive the survey based on key demographics (in this case, region and years holding the CFA charter). There are, of course, limitations to our sampling procedure. For example, it is possible that we ended up sampling multiple individuals from the same entity, thereby violating the assumption of independence across responses. Alternatively, we could have identified a non-representative set of the investor community. We tried to mitigate these eventualities by working with the CFA Institute research team, but ultimately we were unable to quantify these potential concerns due to our inability to access data on participant demographics. We obtained 201 usable responses, giving an overall response rate of 3.4%. While this response rate may seem low at first glance, it is useful to compare it to the 8.5% response rate in Graham and Harvey (2001), which had the benefit of targeted mailing and repeated follow-ups.

3.2. Academic questionnaire

In order to benchmark and contrast the practitioners' opinions, we sent the questionnaire described in Section 3.1. to academics who work and teach in the field of financial analysis. The sample of academics was identified by randomly selecting 40 active researchers whose names appear in the academic references listed at the end of this paper and 40 accounting academics who teach financial statement analysis (FSA) classes to MBA students. The sample of FSA teachers was identified from a Google search using the combined search terms: "MBA," "Financial Statement Analysis, and "Syllabus."[7] The e-mail questionnaire was sent out to the sample of academics in May and June of 2009. The cutoff for the academics' responses was June 30, 2009. As of that date, 63 out of 80 (79%) of the academics in the sample responded to the survey questions. The number of academic respondents for each question is listed in Table 1. The high response rate likely resulted from the fact that the e-mailed survey directly identified the purpose of the survey (i.e., for the upcoming *Journal of Accounting and Economics Conference)* as well as the likely familiarity of the respondents with the names of the accounting academics who conducted the survey.

3.3. Analysis of responses to survey questions

Table 1 provides a summary tabulation of the responses to each of the survey questions. The samples consist of 201 practitioner responses to the questionnaire and 63 academic responses to the questionnaire. The test of difference across the sample mean for each answer is calculated using a chi-square test of populations of unequal size and unequal variance. The *p*-values are adjusted using Cochran–Cox's approximation of the degrees of freedom for unmatched samples.

While there are many consistent responses across the sample of practitioners and academics, we highlight some of the key differences. For example, Question 1 of the survey asked "Which risk model is most appropriate for risk calibration of an equity trading strategy?" There is a large gap between the opinions of academics and practitioners. While 55% of academics recommend some variation of the Fama-French 3-factor model, only 29% of practitioners recommended this approach. The largest fraction of practitioners (35%) recommended the use of a CAPM model with industry and size adjustments, while only 7% of academics recommended this approach. This observation suggests a striking difference between how academics and practitioners assess risk.

We revisit this issue directly in more detail in Section 5, but for now we note that a key source of this difference stems from one's perspective in thinking about risk. Academic research seeks to test the nature of the relation between a given attribute such as accruals and future returns. To the extent that the documented association is a manifestation of risk, then standard ex post analyses such as the Fama and French time-series factor-mimicking portfolio regressions are appropriate techniques to help distinguish risk and mispricing explanations for an observed relation between an attribute and future returns. Therefore, the academic responses indicating the Fama-French approach as the model of choice is not surprising. However, to the extent that one is interested in constructing a portfolio that optimally trades off expected returns and expected risk, one may wish to look at more than the three mimicking factors that are included in the standard Fama and French testing procedure. The practitioner responses suggest that industry membership is an important consideration for risk. Given that a significant portion of cross-sectional variation in returns can be attributable to industry membership, and the desire of equity investment managers to minimize tracking error relative to index benchmarks, it is not too surprising to see this difference in opinion on the importance of industry membership in the context of risk.

Another area with a major difference of opinion arises in Question 4 of the survey that focuses on which techniques were used and generated successful outcomes for equity trading strategies. The most striking feature of the responses is the concentration of academics along the 'neutral' dimension. This is perhaps a reflection of the difference in beliefs in

[7] Additional factors influencing the selection of the sample of FSA teachers includes: (a) the availability of the FSA teacher's valid e-mail address as generated from the Google search criteria, and (b) the ranking of the FSA teacher's website/web presence as generated by Google (we sequentially gathered e-mail addresses based on the appearance of web hits generated from the original Google search criteria).

market efficiency across academics and practitioners, and is perhaps not surprising given the self-selection to respective professions. We also note that there are large differences of opinion on the success of various strategies over the past decade. While 61% of practitioner respondents claimed that earnings or cash flow momentum was successful, only 22% of

Table 1
Summary of results of questionnaire/survey of investment professionals' and academics' opinions on academic research on fundamental analysis and equity market anomalies.

The samples consist of 201 practitioner responses to the questionnaire and 63 academic responses to the questionnaire. The differences across the sample mean for each answer are calculated using a chi-square test of populations of unequal size and unequal variance. The *p*-values are adjusted using Cochran–Cox's approximation of the degrees of freedom for the unmatched samples.

Q1: Which risk model is most appropriate for risk calibration of an equity trading strategy?

	Practitioner opinions (%)	*Academic opinions* (%)
CAPM with size and industry adjustments	35	*7***
Fama-French 3-factor model (market, size, book value/market value)	24	*22*
Multifactor model	11	*4***
Other model	11	*15*

* Indicates difference in means across practitioner and academic sample answers are significant at 5% level.
** Indicates difference in means across practitioner and academic sample answers are significant at 1% level.

academic respondents believed that this type of strategy was successful. Similarly, 57% of practitioner respondents claimed that growth strategies were successful, while only 22% of academic respondents believed that growth strategies were successful, and 56% of practitioners and 52% of academics claimed that value strategies were successful. On the other hand, 74% of academic respondents believed that accounting quality was a successful strategy over the past decade, a percentage that far exceeds the 41% of practitioner respondents who believe that this signal was successful over the same period. These differences of opinions point to possible differences in how expected returns and risks are measured, and how trade impact and transactions costs are quantified and accounted for in trading models.

The responses to Question 6 are particularly germane to our topic of review: fundamental analysis. We observe significant differences between academics and practitioners about the type of valuation model they use. 71% of academics note they use some version of residual income valuation and only 16% of practitioners use this type of valuation model. Instead, we see 74% (52%) of practitioners using simple earnings (book) multiples. These contrast with only 54% (38%) of academics respectively. This is suggestive of simplistic heuristics being used in practice but can also indicate that the quality of inputs necessary to use residual income valuation approaches (most notably forecasts of future earnings and earnings growth) is currently too low to be fully harnessed in practice. We come back to this issue in Section 4 when discussing the state of the current literature on accounting anomalies and fundamental analysis.

In terms of what academics and practitioners would like to see from future research we do observe some similarities. Notably the responses to Question 9 suggest that empirical research on forecasting firm and industry fundamentals is viewed to be important [59% (75%) of practitioners (academics) view this as important], empirical discovery of new variables to assist in forecasting earnings or returns is viewed to be important [55% (55%) of practitioners (academics) view investigation of new anomalies as important]. But we continue to see some striking differences, especially on the need for theory, where academics find it more important than practitioners. We see that academics view the need for theory as very important, as evidenced by the greater weight of responses on tests of investor behavior [62% (92%) of practitioners (academics) view this as important], theoretical models of investor behavior [51% (68%) of practitioners (academics) view this as important], and theoretical models of trading strategies [27% (48%) of practitioners (academics) view this as important]. While these responses do not help us shed light as to what that 'theory' would be, it is useful to note that this is of general concern to the literature that we review. As we detail further in Section 4, we feel that it is paramount for all research in accounting anomalies and fundamental analysis to rest on sound and testable hypotheses.

Also, we note that there is considerable agreement on where the current state of research is lacking. Question 10 asks respondents to comment on whether various aspects of the current research have the correct emphasis. Similar to the responses for Question 9, we find that academics view the current research as having too little emphasis on theoretical foundations [18% (56%) of practitioners (academics) view this as insufficiently emphasized]. However, both academics and practitioners, find that current research does not adequately reflect transaction costs: 68% (46%) of academic (practitioner) respondents believe that there is too little emphasis on the potential market impact of executing a trading strategy, and 59% (50%) of academic (practitioner) respondents believe that there is too little emphasis on the impact of real world trading costs for a strategy. We revisit the topic of transaction costs, both from an ex ante and ex post perspective, in Sections 4 and 5 of this study. For now, we note that a key limitation is access to high-quality trade data that would allow researchers to calibrate meaningful models of market impact, and hence incorporate that into the empirical analysis. We are fortunate enough to have access to such data which we explore in Section 5.

4. Survey of recent research papers

In this section, we summarize a framework for research on fundamental analysis and accounting anomalies. We outline why forecasting is an important activity for current and potential investors in a firm. The decision-making usefulness of financial information is ultimately tied to its ability to generate reliable and accurate forecasts of a firm's future earnings and associated risks, which in turn helps investors make optimal investment decisions. Consistent with this investor perspective, an important objective of empirical archival research is to understand the properties of financial accounting information and how this information might help generate better forecasts of those investment inputs. In so doing, research can then help shed light on other fundamental questions such as market efficiency and more generally the price discovery process.

We also offer a series of broad observations and recommendations about the desirable elements of well-executed archival empirical research on fundamental analysis and accounting anomalies. The main desirable elements are credible alternative hypotheses with solid foundations, robust (in and out of sample) predictive power, a sound treatment of risk and transaction costs, evidence that an 'anomalous' relation is incremental to relations that have been previously documented in the literature, and the inclusion of supplemental non-price tests (in addition to price- and returns-based tests) to strengthen inferences about market efficiency. Section 4.2 expands on these observations and recommendations.

Next, we use these observations and recommendations to place the literature into context and offer our critique. Rather than compile an exhaustive summary of each and every paper that has been written over the last decade on these topics, we discuss some general themes that emerge along with our critique on what we see the research lacking.

4.1. Forecasting framework

To help place some structure on the forecasting that is at the heart of the research in accounting anomalies and fundamental analysis, it is useful to start with the traditional dividend discount model. Most, if not all, of the papers we survey start with this model and combine it with the additional assumption of clean surplus accounting (i.e., net dividends, D, is equal to income, Y, less the change in book value, BV). As Ohlson (1995), Kothari (2001) and others have shown, this model gives price as a function of earnings, expected returns, and change in book value:

$$P_t = \sum_{\tau=1}^{\infty} E(D_{t+\tau})/(1+r)^{\tau} = \sum_{\tau=1}^{\infty} E(Y_{t+\tau} - \Delta BV_{t+\tau})/(1+r)^{\tau} \tag{1}$$

Eq. (1) is a simple transformation stating that price is a function of forecasted (expected) returns (r), and forecasted (expected) future financial statement variables (Y and BV). This framework shows that it is important to forecast returns, earnings and asset growth. This framework, similar to the Fama and French (2006) framework, suggests that expected (and hence realized returns) should be positively related to expected profitability and negatively related to asset (or book) growth, and much empirical evidence supports this basic prediction.

The framework offers several key insights. First, given price and forecasts of accounting information (i.e., income and growth in book values), one can estimate the expected rate of return. This is the literature on implied cost of capital, which we discuss later. Importantly, this approach assumes both market efficiency and accuracy in the forecasts of accounting information. As we note later, deviations from these assumptions cast doubt on the quality of estimates of implied cost of capital. Second, given forecasts of expected returns and accounting information, one can estimate an intrinsic value (V) as is done in the fundamental analysis literature. In contrast to the implied cost of capital literature, this approach entertains the possibility of inefficient prices to the extent that the estimated intrinsic value is then compared with price (e.g., V/P). Third, if one is able to predict future accounting information and show that these forecasts are different from those embedded in price, it is possible to use this framework to forecast excess returns. This is the accounting anomalies literature. If investors' expectations of future earnings are higher (lower) than actual future earnings, current prices will be too high (low), and future returns will be low (high).

A central feature of the literature that we survey is how investors use accounting information to forecast the level and risk of a firm's dividends and then discount the dividends to estimate the value of claims to a firm. If the estimated value and the observed market value of these claims diverge, then an investor must decide if anticipated gains, net of current and forecasted future transactions costs, are sufficient to generate a profitable investment opportunity.

While the framework described above is a convenient way to link the various papers that we survey, it does not offer much insight from the perspective of how accounting information can help forecast the level and riskiness of firm earnings. We return to this in Section 4.3.1 below.

4.2. Desirable elements of fundamental analysis and accounting anomalies research

In this subsection we describe desirable features of a well-executed archival empirical research study on fundamental analysis and accounting anomalies. In our view, the most important features are a credible alternative hypothesis, robust predictive power, a sound treatment of risk and transaction costs, ensuring incremental forecasting additivity of newly discovered attributes, and the inclusion of supplemental non-price tests to strengthen inferences. We use these six elements as a foundation for discussing recent literature.

4.2.1. Credible alternative hypotheses

Research examining the usefulness of accounting information to forecast future firm performance should strive to articulate credible hypotheses based on solid foundations (such as economic, psychological, and institutional foundations). As argued in Kothari (2001) it is reasonable to maintain a null hypothesis of efficient security prices. Empirical capital markets based research then needs to offer credible alternative hypothesis to this null hypothesis of efficient capital markets. In other words, why will a given piece of accounting information help forecast future earnings and stock returns? This is especially important for research examining the association between accounting attributes and future returns. Why do stock prices fail to incorporate information in a timely and unbiased manner?

As discussed in the context of Eq. (1), it is important to note that the forecasting exercise need not imply market inefficiency (e.g., Fama and French, 2006). Documentation of a given accounting attribute that helps forecast levels of future earnings will help form forecasts of expected returns. This forecasting says nothing about market efficiency or inefficiency. For example, the differential persistence of earnings components that is at the heart of the accruals anomaly (e.g., Sloan, 1996), need not imply anything about market efficiency. It is possible that using earnings components rather than aggregate earnings generates a superior forecast of future earnings, but that the market understands this relation and correctly prices this differential persistence.

A researcher must be able to articulate clearly why it is that a given variable is associated with future returns. Because our focus is on accounting anomalies, we focus on the association coming from one's ability to forecast future fundamentals (e.g., profitability). Therefore, a research study should attempt to highlight the friction through which market prices do not incorporate this fundamental information in a timely fashion. Kothari (2001, p. 173) also makes a similar plea to researchers when he says "… [accounting] research has to move beyond reporting descriptive statistics and evidence of the success of trading strategies into proposing theories and presenting empirical tests of the hypotheses derived from the theories." While we are not suggesting that all forecasting research lacks a sound theoretical foundation, we suggest that researchers articulate a good reason why a given accounting attribute is likely to be useful in generating a superior forecast. In particular, when forecasting future stock returns, there is a high hurdle to be met to explain why stock prices in a highly competitive capital market are not efficient and why a given accounting attribute seems to be ignored by a myriad of individuals who have strong financial incentives to exploit any and all useful forecasting information.

The pursuit for a credible alternative hypothesis is not new. Indeed, Foster et al. (1984) and Bernard and Thomas (1989), two of the most widely cited papers that examine anomalous relations between accounting attributes and future returns, struggle with the reasons for a delayed price response. Kothari (2001) notes potential inconsistencies across research papers on this point. In some cases, there are accounting attributes for which the market under-reacts to the release of that information (e.g., earnings surprises). In other cases there are accounting attributes for which the market over-reacts to the release of that information (e.g., earnings components such as accruals). It is worth re-iterating the importance of well specified, ex ante, predictions on relations between accounting attributes and future returns (or future earnings). Bernard and Thomas (1989, 1990) are a classic example of research that recognizes this importance. They establish a temporal pattern between adjacent earnings surprises and show that the market reaction to the initial surprise is consistent with the market failing to understand the expected pattern of future earnings surprises. Richardson et al. (2005) is another example. They predict that the least reliable components of earnings will be associated with reduced persistence, and provide empirical support for this conjecture. The negative relation between measures of accruals and future returns is then consistent with the capital market ignoring this differential persistence when setting prices. Specifically, stock prices behave as though capital market participants assume earnings components are equally persistent, thereby ignoring the ex ante differential persistence in earnings components when prices are initially set.

4.2.2. Robust predictive power

After articulating a credible alternative hypothesis, a researcher can then seek to document whether the data confirms the conjectured relation. For example, is the attribute (or characteristic) examined robustly related to future returns? Therefore, it is desirable to utilize the longest time series and broadest cross-section of data available. In addition, out-of-sample tests are necessary to strengthen the inferences that can be made about the usefulness of a given accounting attribute to forecast either future earnings or future stock returns. If there are relevant institutional factors or other characteristics that vary through time or across firms, then variation in these influential factors should be tested and variation in the observed outcomes can also be used to strengthen inferences. Tests of predictive ability of a given attribute need to be conducted in a 'fair' manner. The researcher should ensure that all data is available at the time the 'back test' is run (e.g., observations should be ranked based on information that would be available to all investors before they would make investment decisions, and the researcher should allow a 'waiting period' after the end of a fiscal period to be sure that financial statement data was available to investors), and that there are no survivorship issues with the sample.

A good recent example of assessing the robustness of a given relation is Kothari et al. (2006). While not "out of sample" in the sense of testing a given hypothesis in a different time period or geographic region, Kothari et al. test whether a given hypothesis, underreaction to information, holds across different sets of information. Specifically, they take the firm level post earnings announcement drift result documented in Bernard and Thomas (1990) and test whether similar 'anomalous' drift-related price behavior is evident at the aggregate market level. They compute market-level, earnings-change variables and show that while these earnings changes exhibit similar time series properties to those seen at the firm level, there is not any evidence to suggest that aggregate stock prices fail to understand this relation (if anything the relation is of the opposite sign, i.e., when the market experiences a positive aggregate earnings surprise returns are lower in the future). This 'no result' does raise the question on the external validity of the firm level post earnings announcement drift anomaly. But we would emphasize that there are many other papers that show that firm level post earnings announcement drift persisted into the 1990s (after the publication of Bernard and Thomas, 1989) and is evident in other countries.

4.2.3. Risk

Researchers seeking to document a relation between an accounting attribute and future returns, and to attribute these anomalous future returns to inefficient processing of this accounting information by market participants, must take care to ensure that a risk-based explanation is not also consistent with the empirical relation. This is the standard joint hypothesis criticism (Fama, 1970). We encourage researchers to give primacy to the risk-based alternative explanation. Fortunately, there are a variety of empirical tests available to researchers to help distinguish between an efficient risk-based explanation and a market-inefficiency explanation. We stress that the two explanations need not be mutually exclusive, and it is indeed very hard to completely rule out a risk-based explanation as a given attribute can always be 'labeled' as a candidate risk factor (see, e.g., the discussion in Fama and French, 2006; Hirshleifer et al., 2006).

Assessing risk is done with a variety of ex post analyses. These include: cross-sectional regressions of characteristic portfolio returns on candidate risk measures in the Fama and MacBeth (1973) style; time-series regressions of zero-cost characteristic portfolios on candidate mimicking factor portfolio returns in the Fama and French (1993) style; time-series regressions of characteristic portfolio returns on macro state variables in the Chen et al. (1986) style; attempts to track abnormal returns before and after the sorting period to allow for time varying beta to explain the abnormal returns (e.g., Foster et al., 1984); showing that the returns of a zero-cost characteristic portfolio are positive in up and down markets, as a risk explanation would not be consistent with a stable return stream across different macroeconomic environments (e.g., Bernard and Thomas, 1990); and examining the extent to which the future returns are concentrated around subsequent earnings announcements (e.g., Bernard and Thomas, 1989), since returns concentrated in a couple of days around future earnings announcements are harder to attribute to time varying risk explanations, as one would need sharp changes in risk over these relatively short windows.

4.2.4. Transaction costs

Researchers who make inferences from documented associations between an accounting attribute and future returns also need to address trading costs. Specifically, it is important to show that the documented relation cannot be readily explained away by trading costs or other market frictions. This is very important as an inference of market efficiency is quite different if the return magnitude is within the bounds of expected trading costs or not. If it is not, and can be reliably shown to be so, then this would provide more compelling evidence against efficient prices.

The literature takes several approaches to examine the importance of trading costs to support documented associations between accounting attributes and future returns. These tests comprise the following: (i) partitioning the sample on market capitalization, analyst following, trading volume, institutional ownership, idiosyncratic risk (and other variables expected to be associated with trading costs) and examining the strength of the return relation across groups (if the return relation is only in the set of smallest stocks with no analyst coverage, or with little trading volume, then the 'anomaly' is probably not 'implementable' and hence within the bounds of efficient prices), (ii) benchmarking the returns on simple round-trip transaction-cost estimates and combining this round-trip trading cost with the turnover of the proposed strategy to assess if the returns are still significantly different from zero after accounting for the total trading costs, and (iii) examining the symmetry of the return pattern (if it is all driven on the short side of the strategy then it is harder to get over the transaction-cost hurdle, as the borrow cost (or stock lending fee) that needs to be paid to support a short position on a security can be large, especially for smaller, less liquid securities).

It is important to consider what is included in trading costs. It is not only direct costs (e.g., taxes, commissions and crossing the bid-offer spread), but also indirect costs from trading activity impacting prices. Fortunately, there exist benchmark empirical estimates to help with this calibration. For example, using aggregate trading and commission data, Stoll (1993) suggests that the round-trip transaction cost for investing in a large cap common share was about 1%. In the last decade, this round-trip cost has fallen to about 0.3% for the constituents of indexes like the SP 500 and the Russell 1000 (see, e.g., Elkins/McSherry LLC, 2009).

4.2.5. Additivity

One striking aspect of the literature that we survey below is the large and growing set of accounting attributes that have been examined. Given the commonality of business models and the articulation inherent in financial statements, the dimensionality of the relevant attributes for forecasting is not very large and these attributes are certainly correlated. We encourage researchers to carefully consider the previously documented attributes and describe how the new attribute differs (both conceptually and empirically) from what has already been documented in the literature.

Perhaps the most striking example here is the various measures of accruals and external financing. These measures are related in deterministic ways: growth in the balance sheet (measures of accruals) must be financed from somewhere (e.g., measures of external financing). We will discuss this deterministic relation in more detail in Section 4.3.5.1, but we want to highlight the point here that it is important for research to start articulating true incremental contribution to the myriad of existing variables that have been examined previously. Subrahmanyam (2010) notes more than fifty variables that have been examined as potential candidates to explain the cross-section of returns. His summary captures all potential determinants of returns, including changes in expectations about discount rates, which arguably fall outside the scope of our review, but it emphasizes the haphazard nature of this line of research.

To date very few papers have made a serious attempt to bring some structure to the anomaly literature. Fama and French (2006) discussed earlier in this section, and Penman and Zhang (2006) are the most obvious examples. Penman and Zhang first build a theoretically motivated comprehensive forecast of future earnings using previously documented variables. They then use this forecast to split observed earnings multiples into a justified and abnormal component, and show that the relation between earnings multiples and future returns is concentrated in the abnormal component. While we may debate the interpretation of their results (i.e., is the result that the relation between earnings multiples and future returns is concentrated in the 'abnormal' component indicative of mispricing or not?), the paper is worthy in its attempt to provide structure to the earnings forecasting exercise. Irrespective of the nature of the commonality between accounting attributes, future research should strive to impose structure on the growth of the anomaly literature.

4.2.6. Non-price based tests

As discussed in Section 4.2.3, it is often difficult to empirically differentiate between risk-based and market-inefficiency explanations for an accounting anomaly. This is particularly true if one relies exclusively on price- or returns-based tests. While there are a variety of standard ex post analyses that can help rule out a risk-based explanation, researchers can supplement these price- and returns-based tests with non-price tests to further discriminate between risk-based and market-inefficiency explanations for anomalous returns. For example, to the extent that we can observe or infer the actions of particular capital market participants (e.g., sell-side analysts) and their actions are a reasonable proxy for the overall behavior of capital market participants, then this can help give insights into possible "irrational" behavior by market participants. For example, researchers can use sell-side analysts' earnings and price forecasts to examine the extent to which these forecasts are inefficient with respect to the relevant accounting attribute. The benchmark test here is to document whether future analyst forecast errors or revisions can be explained by that accounting attribute. An example of this approach is Bradshaw et al. (2001), who show that analyst forecast errors are more optimistic for firms with high levels of accruals relative to low levels of accruals. This is consistent with analysts failing to incorporate the differential mean reversion of income implied by cross-sectional variation in accruals.

4.3. Using our framework to survey recent research

In this subsection, we summarize and critique key studies that have been circulated since the year 2000 that examine the usefulness of accounting information to forecast future firm performance. We use our six recommendations for archival empirical research studies (credible hypotheses, robust predictive power, sound treatment of risk, sound treatment of transaction costs, incremental additivity, and the inclusion of non-price tests) to serve as our discussion framework. Our citation analysis in Section 3 generates four main clusters of research topics: *Fundamental Analysis, Accruals Anomaly, Underreaction to Accounting Information*, and the *Pricing Multiples/Value Anomaly*. Therefore, we discuss each of our recommendations as they relate to recent research papers in each of these clusters. For some of our recommendations, we group our discussion of fundamental analysis and pricing-multiple papers together.

Given the breadth of the recent literature on fundamental analysis and accounting anomalies, we do not discuss in detail every paper circulated since the year 2000. We are selective in our review of the literature over the past decade that best reflects how research in accounting anomalies and fundamental analysis has developed credible hypotheses, demonstrated robust predictive power, conducted rigorous testing of risk and transaction costs, explored incremental additivity and sought to buttress returns based tests with non-price tests.

4.3.1. Does recent research test credible hypotheses?

4.3.1.1. Fundamental analysis—credible hypotheses. Penman (2009) defines fundamental analysis as "the analysis of information that focuses on valuation." As noted by Kothari (2001), an important motivation for fundamental analysis research and its use in practice is to identify mispriced securities relative to their intrinsic value for investment purposes. Hence, the majority of the fundamental analysis research in accounting seeks to come up with better forecasts of earnings or stock returns to assist in the valuation or identification of mispriced securities. As discussed in Section 4.1, there is a considerable overlap between research on fundamental analysis and accounting anomalies. Fundamental analysis is of interest to believers and non-believers of market efficiency, as it can help us understand the determinants of value to assist in informed investment decisions and the valuation of non-publicly traded assets for which market inefficiency is not a concern.

Eq. (1) is the lens through which all of the literature on fundamental analysis can be evaluated. While it does provide some structure for examining how variables relate to each other, and how variables relate to future profitability, asset growth and returns, it fails to capture the role of an accounting system. Specifically, what is missing from that framework is an explicit statement that financial statement information is produced by an accounting system and that the accounting system may reflect the underlying asset risk of a business. Arguably, an appreciation of how the accounting system reflects risk will lead to a superior understanding of how accounting information can in turn be used to measure and forecast risk. For example, the current accounting system underlying US GAAP and IFRS rests largely on conservative accounting principles. This conservatism generally means that revenues are often deferred until the receipt of revenue is almost certain. Many costs are expensed as soon as they are incurred rather than being capitalized and expensed over many periods (e.g., advertising and research and development expenditures). A result of this accounting system is that book values tend to be less than market values. This wedge between book and market values, the B/P ratio, could be related to the risk of a firm's operations, and hence reflect expected returns. For example, the types of activities that require significant capital and R&D related expenditures to develop are often risky in nature, and this risk is reflected in the conservative accounting principles that govern GAAP.

A good example of how incorporating an understanding of the accounting system can help articulate relations between returns, multiples, and earnings growth can be found in Penman and Reggiani (2010). Starting with the empirical observations that E/P and B/P are associated with future returns and the residual income framework, they show that expected returns are a linear combination of E/P, B/P, and earnings growth. The key to the framework in Penman and Reggiani is that earnings growth and expected returns are not independent as is often assumed in Eq. (1).

For example, consider two firms preparing financial statements under the same accounting system that are facing the same cost of capital with the only difference being that one firm is increasing its investment activity. It is easy to show that the B/P and E/P for the growing firm will be lower. A cursory examination of the multiples suggests that this firm is less risky. But its earnings growth is at risk and once this is recognized there is no difference in expected returns across the two firms.

However, Fama and French (2006), assert that it is possible to isolate determinants of expected returns by varying one of their three components (*B*/*P*, expected asset growth, or expected future earnings), while holding the other two variables fixed. This comparative static approach is limited, as it fails to capture the intended interactions of a well articulated accounting system. For example, growth can affect both reported earnings and book values. As Penman and Zhang (2002) note, biased accounting systems that fail to recognize assets such as advertising and research and development will lead to lower current book values and higher future accounting rates of return. Thus, growth will affect *B*/*P* and expectations of future profitability simultaneously. These linkages get even more complicated when assessing the cross-sectional relation between expected returns, *E*/*P*, *B*/*P*, and earnings growth as is standard in the literature we review, because the components are correlated with each other and are correlated with other potentially relevant variables. Further, there is likely a positive relation between earnings growth and expected returns as captured in Eq. (1). Due to the conservative nature of the accounting system, only relatively certain transactions are reflected in current earnings leaving a lot of uncertain transactions to be recognized later in future periods when they are realized. This creates a natural positive relation between earnings growth and expected returns. The point we want to emphasize here is that there is a great opportunity for future research to explicitly incorporate information from the design of accounting systems into measuring and forecasting risk.

In recent years, fundamental analysis research has generally focused on forecasting earnings, forecasting stock returns, or estimating a firm's cost of capital. Prior to 2000, there was a flurry of research that used accounting variables (and ratios of these variables) to predict future returns (see, e.g., Ou and Penman, 1989; Lev and Thiagarajan, 1993; Abarbanell and Bushee, 1997). In general, these studies either explicitly or implicitly took the idea that if the market does not efficiently price expected earnings and financial statement information, then better forecasts of earnings will predict future returns. This earlier work was certainly subject to the criticism of a ''kitchen sink'' approach to the forecasting exercise. A number of correlated variables were included in predictive regressions for future earnings or future returns leading to concerns of in-sample identification of predictive variables. We emphasize that although the general approach of using accounting information to forecast future earnings is a sound exercise, the selection of explanatory variables should be guided by theory.

More recent fundamentals-based return studies have sought to bring this line of research closer to a credible alternative hypothesis. Several papers in the last decade have focused their analysis on subsets of securities where mispricing is expected to be the greatest.

Piotroski (2000) focuses on neglected high *B*/*P* securities and applies standard financial statement analysis to this subset of stocks and finds surprisingly strong predictive power for future returns. Beneish et al. (2001) apply a two-stage approach to financial statement analysis, first using market based signals to identify likely extreme performers, and then applying fundamental signals to differentiate between winners and losers among the firms identified as likely extreme performers in the first stage. Baker and Wurgler (2006) use a variety of measures of investor sentiment (e.g., share turnover, the closed-end fund discount, and first-day IPO returns) and show that stocks that are difficult to arbitrage exhibit large reversals in months following periods of high aggregate investor sentiment. Zhang (2006) shows that stocks with greater information uncertainty exhibit stronger statistical evidence of mispricing in terms of return predictability based on cross-sectional regressions with an ex ante book-to-market ranking. Finally, Nagel (2005) shows that mispricing is greatest for stocks where institutional ownership is lowest by using institutional ownership as a proxy for the extent to which short-selling constraints bind, and relying on the assumption that short-selling is cheaper for institutional investors. A considerable fraction of recent research in fundamental analysis that links accounting attributes to future returns has started to focus their design on securities where the frictions that would support an ''anomalous'' relation are expected to be the greatest.

These papers are certainly not without criticism, as Guay (2000) summarizes in his discussion of Piotroski (2000). A primary concern is the external validity of the documented results. Specifically, there are a large number of accounting attributes to select from and in various combinations. The standard criticism here is in-sample fitting, or rather, computing test statistics without correcting for the appropriate degrees of freedom. The majority of empirical research in fundamental analysis can be subjected to this criticism as the entire data set is typically examined. To ensure external validity of the results one must use a hold out sample. We come back to this topic in Section 4.3.2 when we talk about robustness, but at this juncture we can state that the F-Score metric originally proposed by Piotroski has held up since the publication of that paper, mitigating criticisms of in-sample fitting (e.g., Mohanram, 2005).

4.3.1.2. Determining the implied cost of capital using fundamentals—credible hypotheses. A large stream of academic research that is closely related to traditional fundamental analysis investigates the measurement of the implied cost of capital (ICC). While there are certainly errors in the measurement of ICC, the quality of this measurement has improved in recent years.

Prior to the recent development of the ICC, most studies have tended to rely on realized stock returns as a proxy for ex ante expected stock returns because they are not directly observable. However, these estimates are problematic because realized returns are noisy (see, e.g., Elton, 1999). To address some of the limitations of asset-pricing methods used to determine a firm's cost of capital, recent accounting and finance studies propose an alternative approach to estimate expected returns: the implied or imputed equity cost of capital (e.g., Claus and Thomas, 2001; Gebhardt et al., 2001; Botosan et al., 2009; Pastor et al., 2007; Easton, 2009). The implied equity cost of capital for a company is the internal rate of return (IRR) that equates the company's stock price to the present value of all expected earnings available to equity-holders. In other words, it is the rate that the market uses to discount the expected earnings of the company as in Eq. (1).

This ICC approach relies heavily on forecasting a firm's future earnings, and much of the work uses analysts' forecasts of future earnings as the key forecasting variable. A key challenge with this approach is the forecasting horizon. Explicit forecasts are typically only available for the next five years and the precision of those forecasts decreases as the horizon lengthens. These constraints necessitate some assumptions about how to calculate terminal values. And given that equity is typically a long duration asset; calculations of expected returns can be very sensitive to these assumptions. A major advantage of the ICC approach to risk measurement is that it does not have to rely on noisy realized returns or on a specific asset-pricing model other than a discounted future-cash-flows model. Therefore, the ICC approach applies standard fundamental valuation techniques and uses observed market prices and forecasts of earnings to derive the market's assessment of the equity risk (cost of capital) of a firm. For the firm as a whole, under the assumption of market efficiency and if one has accurate forecasts of future earnings, one can invert Eq. (1) to solve for r (e.g., Claus and Thomas, 2001; Gebhardt et al., 2001; Easton, 2009).

This approach is based on a sound theoretical foundation, but it is open to multiple interpretations. Hence, we caution against the blind use of these measures of ICC. For example, an estimate of ICC from Eq. (1) can be interpreted as the price one might pay for a given amount of risk and earnings growth. That is, allowing for inefficient prices, the estimate of expected returns extracted from Eq. (1) could merely reflect the extent of that inefficiency. As stated in the introduction, it is reasonable to start with the null hypothesis of market efficiency, but care should be taken when interpreting results that are based on that assumption. Furthermore, the quality of the cost of capital estimate extracted is only as good as the forecasts of earnings and earnings growth rates.

4.3.1.3. Accruals anomaly—credible hypotheses. The accruals anomaly originally documented by Sloan (1996) suggests that firms with high (low) reported accruals in a fiscal period tend to have abnormally low (high) future earnings and stock returns. Sloan's original paper hypothesizes that investors naively fixate on bottom line income and they do not appear to understand that earnings are composed of both operating cash flows and (non-cash) accruals, and that the cash flow and accrual components of earnings have different abilities to predict future earnings. In particular, accruals tend to reverse in future periods, and investors do not appear to understand this time-series property when they develop their forecasts of future earnings and therefore set current stock prices.

Sloan (1996) defines accruals by using changes in balance sheet items, and measures accruals as changes in non-cash working capital minus depreciation expense scaled by average total assets. The precise definition of this accrual measure is as follows:

$$\begin{aligned} Accruals = {} & [(\Delta CurrentAssets - \Delta Cash) - (\Delta CurrentLiabilities - \Delta ShortTermDebt \\ & - \Delta TaxesPayable) - Depreciation]/AverageTotalAssets. \end{aligned} \tag{2}$$

All components of accruals above correspond to the following Compustat data items: (1) current assets (annual field 'ATC' and quarterly field 'ATCQ'); (2) cash and short-term investments (annual field 'CHE' and quarterly field 'CHEQ'); (3) current liabilities (annual field 'LCT' and quarterly field 'LCTQ'); (4) short term debt (annual field 'DLC' and quarterly field 'DLCQ'); (5) taxes payable (annual field 'TXP' and quarterly field 'TXPQ'); (6) depreciation (annual field 'DP' and quarterly field 'DPQ'); and (7) total assets (annual field 'AT' and quarterly field 'ATQ').

A more general definition of accruals is introduced in Richardson et al. (2005). They separate operating from financing activities, and recast the standard balance sheet identity of assets (A) equal to liabilities (L) plus book value of equity (B). Specifically, assets have an operating component (operating assets, OA) and a financing component (financial assets, FA), and liabilities have an operating component (operating liabilities, OL) and financing component (financial liabilities, FL). Re-arranging the basic accounting identity obtains the following:

$$NOA = NFO + B \tag{3}$$

This recognizes that net operating assets (operating assets less operating liabilities) are equal to net financial obligations (measured as short-term debt plus long debt less financial assets) plus book value of equity. This relation also holds for changes:

$$\Delta NOA = \Delta NFO + \Delta B \tag{4}$$

The left-hand side of Eq. (4) is the broad measure of accruals. It captures the current accruals reflected in the original Sloan (1996) measure such as changes in inventory, accounts receivables, and accounts payable. But it also includes many non-current accruals such as intangibles, property, plant and equipment, and deferred employment obligations. Table 1 in RSST outlines all of the various components of the ΔNOA accrual measure. Appendix B summarizes how the original accrual measure from Sloan (1996) is related to the broader definition of accruals in RSST. The main differences are that the Sloan measure ignores non-current accruals, excludes taxes payable, and treats depreciation expense as a current accrual.

The accruals anomaly can be viewed using Eq. (1) as follows: investors attempt to forecast a firm's earnings using both cash flow and accrual information, but they do not properly weight the information. Therefore, they have a biased forecast of future earnings, and the current price is then incorrect. The evidence presented in Sloan (1996) is consistent with the hypothesis that investors do not properly weight earnings components in generating their forecasts. Much of the follow-up work on Sloan (1996) refines the forecasting of future earnings, risk, and returns.

The hypotheses for this area of research are based on priors that certain components of income are expected to be less persistent. Researchers have used these priors to refine research designs over the last decade and focused testing on types of accruals that are most consistent with them. This research has generally found that the various accrual components of income are indeed less persistent than the cash flow component.

The hypothesis development for returns forecasting uses the evidence from the earnings forecasting hypotheses and then combines it with additional assertions about capital market imperfections that can support stock prices that do not completely impound information in a timely manner. This is the most challenging aspect of accounting anomaly and fundamental analysis literature. Kothari (2001, pp. 191–192) comments on this very point. In terms of the accrual anomaly literature, though, there is a well specified prior as to the direction of the expected mispricing. A reasonable null hypothesis is that the market is efficient and investors price components of earnings consistent with their differential ability to forecast future earnings. Hence the alternative hypothesis is that investors assume earnings components are equally persistent, which can then be tested by looking for evidence of differential pricing implications across earnings components. The research has generally found that the accrual component of earnings has a negative association with future returns, consistent with this alternative hypothesis. Of course, there is a remaining question as to why this relation would ever exist (assuming for now that it is not a reflection of risk). One possibility is behavioral biases discussed in, e.g., Hirshleifer (2001) and Subrahmanyam (2007).

The accrual anomaly related papers published in the last decade have sought to extend the original hypothesis in Sloan (1996) that naïve investor fixation on bottom line earnings is the source of the negative relation between accruals and future earnings and returns. First, many papers have exploited measures of investor sophistication or settings where fixation is less likely to occur and use this to sharpen empirical tests of Sloan's original hypothesis. Examples of this approach include the following: Ali et al. (2000) find that abnormal returns are not lower for firms that are followed by "sophisticated investors" (e.g., the largest firms, those with high analyst following and high institutional ownership). Sophisticated investors should be able to understand the properties of accruals, therefore providing evidence inconsistent with the naïve investor fixation hypothesis. Zach (2005) finds that there is little evidence of accruals actually reversing, and suggests that a simple naïve fixation story is hard to reconcile with the results. Kothari et al. (2007) find that overvalued firms have incentives to remain overvalued, but undervalued firms have no incentives to prolong their undervaluation. These incentives generate an asymmetric relation between measures of accruals and past and future returns. They argue this relation is more consistent with an agency theory of overvalued equity rather than a naïve investor fixation explanation for the accrual anomaly. Conversely, the recent work of Hirshleifer et al. (2004) suggests that the limited attention of investors who focus on accounting profitability without taking into consideration the other factors in forecasting future cash profitability can explain the mispricing of net operating assets scaled by total assets, which is consistent with the investor fixation hypothesis.

Second, some of the recent papers examining the accrual anomaly have sought to attribute the relation to a combination of earnings management and accounting distortions. These papers tend to show that the negative relation between accruals and either future earnings or future returns is strongest for accruals that can be characterized as reflecting either earnings management or accounting distortions. Note that the evidence from these papers on the association between different types of accruals and future stock returns is still consistent with a type of investor fixation or limited attention. These papers seek to identify components of accruals with greater issues of reliability that would lead them to have a lower association with future earnings. For example, Xie (2001) argues that the anomaly is attributable to the mispricing of discretionary accruals as a consequence of overestimating the persistence of the discretionary accruals. Chan et al. (2006) essentially replicate Sloan (1996) and show from a variety of analyses that most of the evidence supporting a negative relation between accruals and future returns is consistent with accruals capturing the earnings management activities of the management. Beneish and Vargus (2002) document that the lower persistence of income increasing accruals is concentrated when there is insider selling, suggestive of an earnings management-based explanation for the accrual anomaly. Richardson et al. (2005) extend the original Sloan (1996) measure and argue that investors fail to appreciate the least reliable accruals where there is likely to be the greatest amount of distortion and earnings management.

Third, some other recent papers have explored whether diminishing marginal returns to new investment can explain the negative relation between accruals and future earnings. Fairfield et al. (2003) argue that the lower persistence of accruals may be attributable to the effect of growth on profitability. They document that accruals co-vary more with invested capital, the denominator used in the computation of profitability, than cash flow. As such, Fairfield et al. examine how growth in the net operating assets has an association with future earnings. Consistent with their hypothesis of diminishing marginal returns to new investment, they find that firms that have grown the most experience lower levels of future profitability.

In follow-up work, Richardson et al. (2006a) show that by decomposing the change in net operating assets (the broad measure of accruals described above) into a sales growth component and a change in asset turnover component, the negative relation between accruals and future earnings is concentrated in the change in asset turnover component. Asset turnover (the ratio of sales to assets) measures both efficiency and the majority of accounting distortions present in the balance sheet. To the extent that the firm has not expensed assets as it should have, or has capitalized assets it should not have, the ratio of sales to assets will reflect this choice. Specifically, firms that have the largest decrease in asset turnover are those that have the greatest concentration of asset related accounting distortions. This is confirmed by their later empirical analysis that shows a relation between changes in asset turnover and severe cases of earnings management that result in SEC enforcement actions. Although researchers can make subjective ex ante classifications as to the quality of earnings (e.g., Richardson et al., 2005), it is useful to confirm those subjective choices with an objective ex post classification. Specifically, research in the last decade has shown that firms with high accruals tend to be subject to more SEC enforcement actions, class action lawsuits, and fewer qualified audit opinions (see, e.g., Bradshaw et al., 2001 and the summary in Wu et al., 2010). This association between the measures of accruals and ex post accounting problems is consistent with managerial manipulation of financial statement data that investors do not understand.

In summary, these studies show how the accruals anomaly literature has evolved over the past decade. Overall, each paper has attempted to provide insights into the problems that investors have in using current accounting information to correctly forecast future earnings and returns. The primary explanation for the negative relation between accruals and future stock returns (holding aside the issue of risk) is that capital market participants fail to correctly use accrual information in their forecasts of future earnings.

4.3.1.4. Underreaction (PEAD)—credible hypotheses. The first documented major accounting-based market anomaly is known as post-earnings announcement drift (PEAD) (see, e.g., Bernard and Thomas, 1989). The main feature of the PEAD anomaly is that investors appear to underreact to earnings news and a firm's stock price "drifts" in the direction of the earnings news after an earnings announcement. The PEAD anomaly can also be summarized as follows: investors attempt to forecast a firm's earnings using innovations to current reported earnings, but they underestimate the implications that current earnings have for future earnings. This underreaction generates anomalous returns because prices do not reflect all of the information contained in current earnings changes. Recent studies attempt to explain why the anomaly occurs and why it has persisted. In addition, the literature has expanded to consider underreaction to other corporate information and its relation to momentum in stock returns. We focus the review in this section only on the PEAD literature, but readers should note that our discussion also applies to other research studying the underreaction to other sources of accounting information (e.g., option expense disclosures, pension footnotes, new product releases, and a variety of corporate actions).

A general problem for "drift" related research is whether to expect an under- or overreaction to a relevant event. The prevailing prediction is underreaction to an event, but a prediction for overreaction is also possible. As Kothari (2001, p. 191) states "currently the null of market efficiency is rejected regardless of whether positive or negative abnormal returns (i.e., under- or overreaction) are observed." It is therefore plausible for the market to overreact or underreact to a given piece of information, and absent a compelling reason for underreaction, the alternative hypothesis is not well specified. That said, most of the recent research has sought to isolate settings where underreaction is most likely to occur. This approach is similar to what we discussed earlier for the accrual anomaly literature.

Some examples of drift research in the last decade include the following: Bartov et al. (2000) find that institutional ownership (as a proxy for investor sophistication) has a negative association with the magnitude of the abnormal returns after earnings announcements, which suggests that it is the trading by unsophisticated investors, who do not appear to realize the implications of current earnings for forecasts of future earnings and stock returns, that is generating the drift. Battalio and Mendenhall (2005) find that investors executing small trades seem to respond to a less sophisticated signal that does not fully impound the implication of current earnings changes for future earnings, also consistent with the suggestion that small investors underlie the PEAD. Shivakumar (2006) also finds that small traders appear to underreact to earnings surprises relative to larger traders, again suggesting that small (and likely less informed) traders are a driver of the PEAD phenomenon. In contrast, Hirshleifer et al. (2008) present findings that the returns to the PEAD strategy cannot be explained by the trading activity of individual investors. While this set of papers generally suggests that smaller and less informed traders are responsible for the drift to earnings surprises, this still leaves open the question as to why larger, more informed, traders do not fully exploit this relation. We revisit this topic in Section 5 where we document a substantial decline in the PEAD over the last decade.

One concern about the studies listed above is that the quality of the proxies used to capture investor sophistication, such as trade size and institutional ownership, is questionable. This is especially the case for trade size. Over the last decade, there has been an increasing use of algorithmic trading by various institutional investors. This method results in trade sizes getting increasingly smaller (see, e.g., Elkins/McSherry LLC, 2009). It is therefore more difficult to attribute small trades to less sophisticated individuals. This change in market microstructure and the trading behavior of large institutions over the last decade also has implications for any empirical measure that uses trade size as a key input (e.g., measures of informed trading as in Easley and O'Hara, 1987). It is also useful to contrast the results across the drift and accrual anomaly literatures on the dimension of investor sophistication. In the previous section, we noted that research has found that the accrual anomaly is not weaker in the presence of larger institutional investors, but we see some evidence that the drift anomaly is. The relative consistency of explanations across anomalous variables is something to which future research should pay more attention.

In a similar vein to investor sophistication, some of the recent research related to drift has explored whether limited attention and other investor cognitive biases give rise to the drift. DellaVigna and Pollet (2006) assume that investors are distracted more at the end of the week, and find that earnings announcements that take place on Fridays have more drift than earnings announcements that occur on other weekdays. Liang (2003) finds investors' overconfidence about their private information and the reliability of earnings results in the underreaction to current earnings innovations and a slow revision of investors' forecasts of future performance, which in turn leads to PEAD. Hirshleifer and Teoh (2006) find that drift to earnings surprises is greater when there is a larger number of related companies also announcing earnings at the same time, consistent with the limited ability of investors to process large amounts of information.

In addition, a paper by Chordia and Shivakumar (2005) suggests that the illusions of inflation can create the observed drift after earnings surprises are announced. This hypothesis suggests that investors do not incorporate the effect of inflation in their forecasts of future earnings growth rates. Specifically, they find that the sensitivity of earnings growth to inflation monotonically increases across earnings surprise portfolios, and that controlling for the predictive ability of inflation reduces the predictive ability of earnings surprises for future returns. This is a novel extension of the drift literature but it is an explanation that could also hold for other earnings based anomalies. Future research can assess whether illusion of inflation can explain additional anomalous associations between earnings attributes and future stock returns.

4.3.2. Robust results
