4.3.2.1. Fundamental analysis—robustness. Given the simple and practical foundations of the ICC approach, it has been used in many recent studies related to empirical asset pricing (e.g., Chava and Purnanandam, 2010; Chen and Zhao, 2009; Pastor et al., 2007) and also applied in other settings where cost of capital is an important market outcome (e.g., Francis et al., 2005; Hail and Leuz, 2006). Despite the wide-spread use of the ICC estimates, studies have documented *negative* correlations between ex ante measures of ICC and ex post stock returns, suggesting that these estimates are poor measures of a firm's expected equity returns (e.g., Easton and Monahan, 2005; Guay et al., 2005), or that ex post returns are too noisy to serve as a useful benchmark of the quality of measures of expected returns (e.g., Botosan et al., 2009). Specifically, Easton and Monahan show that ICC estimates are negatively correlated with ex post observed stock returns, and they suggest that the problem arises from the quality of analysts' earnings forecasts used to calculate the ICC. Indeed, McInnis (2010) shows that it is analyst optimism that accounts for the previously documented negative relation between earnings smoothness and the ICC.

There is continued discussion on the lack of an association between measures of ICC and future stock returns. Botosan et al. (2009) are able to document a positive association between some measures of ICC and future stock returns after first decomposing stock returns into initial expectations of returns, changes in expectations about future earnings (cash flows), and changes in expectations about future discount rates. We expect this to be an active debate over the next few years because the empirical measures of earnings news and discount rate news themselves are quite noisy especially at the security level. The original decomposition of the two was intended for the aggregate market (e.g., Campbell, 1991). Extensions to the security level started with Vuolteenaho (2002), but these extensions do not yet make extensive use of accounting attributes.

A considerable portion of the recent research on estimating the ICC has therefore attempted to address criticisms that these measures are noisy and/or biased (e.g., Easton and Monahan, 2005; Easton, 2009). It is well known that there are biases and selection issues related to analyst forecasts and these biases will be reflected when used in measures of ICC. There are many studies that suggest that analysts' forecasts are biased at various time horizons (see, e.g., Dechow and Sloan, 1997; Richardson et al., 2003; Easton and Sommers, 2007). In general, analysts' medium- and long-range earnings forecasts tend to be too optimistic. Also, analysts tend to cover relatively few firms, and available forecasts tend to be for near-term earnings such as earnings for the coming quarter or fiscal year. There are also apparent biases in which firms are covered by analysts. For example, financially distressed firms are often not covered or are dropped by analysts (Diether et al., 2002).

To address some of the limitations of the ICC approach, Hou et al. (2009) outline a novel method to estimate a firm's ICC. They build on Fama and French (2000, 2008), Hou and Robinson (2006), and Hou and van Dijk (2008) and apply a cross-sectional model to forecast the earnings of individual firms. Their approach captures across-firm variation in future profitability using publicly available accounting information at the time of the forecast. Examples of the predictive variables in this earnings forecast include: dividend payout ratios, current profitability, firm size, and accruals. Hou et al. then use these earnings forecasts as inputs for a discounted residual income model to estimate ICC. An advantage of this forecasting method is that it does not rely upon analysts' forecasts to generate cost of capital estimates. An interesting aspect of this approach is that is has foundations in the fundamental analysis literature. We revisit this approach later in Section 4.3.5 on the topic of additivity and the general lack of an agreed upon set of predictive variables to forecast future earnings.

Following Easton and Monahan (2005), Hou et al. (2009) assess the reliability of their model-based ICC estimates by testing their correlation with future observed stock returns. In contrast to previous findings, Hou et al. find that their ICC estimates are positively correlated with future stock returns. They also show that the greater reliability of their forecasting-model-based estimates of ICC arises from the improved earnings forecasts generated by their cross-sectional model. Therefore, there appears to be promise in using this type of forecasting method for future research on ICC and other fundamentals-based research.

4.3.2.2. Accruals anomaly—robustness. Recent papers have examined the robustness and generalizability of the accruals anomaly. Although a vast majority of the papers that examine the accruals anomaly find that the original findings in Sloan (1996) are robust in different samples, several recent papers have directly tested the implications of potential method concerns, sample characteristics, or the choice of benchmark returns on the accruals anomaly. For example, Zach (2005) finds that excluding observations related to mergers and acquisitions, divestitures, NASDAQ-listed firms, and the use of size and book-to-market adjusted returns instead of just size-adjusted returns reduce the abnormal returns to the accrual anomaly, but that the majority of the returns are robust.

Kraft et al. (2007) find that Mishkin tests supporting the accruals anomaly are not robust to the addition of omitted variables, and that such omitted variables lead to incorrect inferences about the pricing of accruals. Since Sloan (1996), the Mishkin test is often used in the accounting anomaly literature. As applied in the accrual anomaly context, it requires simultaneously specifying a predictive regression for future earnings and a regression articulating how unexpected earnings map into future returns. These regressions are estimated jointly via an iterative process. In addition to a simple structure for the formation of stock prices, where unexpected earnings are the sole determinant, there are data requirements (i.e., knowledge of future earnings) that make this technique subject to hindsight bias.

While these criticisms are valid, it is important to remember what the Mishkin test is designed to do (see also Lewellen, this issue). It is purely a predictive regression that places some priors on the forecasting so as to allow inferences to be made about the validity of that structure. So while it is valid to criticize the data requirements for a given application of the Mishkin test, it does not invalidate the predictive ability of a given variable. For example, it is true that the Mishkin test as implemented in Sloan (1996) requires knowledge of future earnings information to calibrate the test, hence, casting doubt on the external validity of that analysis. However, a simple predictive regression of measures of accruals for future earnings and future returns is still supported in the data (e.g., Sloan, 1996). It is premature to explain away the accrual anomaly with a criticism of the Mishkin test.

Furthermore, claims in some recent papers that the accrual anomaly is sensitive to outlier returns are incorrect. Kraft et al. (2006) note that excluding less than 1% of observations based on extreme returns greatly reduces the positive returns from low accrual firms and conclude that the resulting inverted U-shaped relation between accruals and future returns is hard to reconcile with functional fixation by investors. However, such an inference is incorrect. All return realizations other than data errors are valid observations. An investor is exposed to the average return of an entire portfolio and this can be influenced substantially by extreme, but valid, return realizations. For example, if one removes the largest five monthly returns from the S&P 500 Index over the last 25 years (five months out of 25 years of data is less than 2%), then the cumulative market return falls from 449% to 283% for the period December 1987 to October 2009. Deleting extreme, but valid, return observations is inconsistent with the very forecasting exercise that an investor undertakes (e.g., Kothari et al., 2005).

A few papers examine whether the accruals anomaly is globally generalizable. The findings from these studies are somewhat mixed: LaFond (2005) and Pincus et al. (2007) document that the accruals anomaly exists outside the U.S.; Pincus et al. find that the accrual anomaly is more likely to occur in countries where: accrual accounting is used more, outside shareholder rights are weaker, concentration of share ownership is lower, and the legal system is of common-law origin. In contrast, however, Leippold and Lohre (2008) document that the "global" results are sensitive to method choices.

However, most studies that follow Sloan (1996) find that the accrual anomaly is robust in various samples, and that it is mainly attributable to investors' inability to incorporate the implications of discretion in accruals for the persistence of earnings in their forecasts of future earnings. But, as we discuss below, the anomaly has largely disappeared in recent years.

4.3.2.3. Underreaction (PEAD)—robustness. Most of the research seeking to document the robustness of the original drift result use alternative measures of earnings surprise. The original Bernard and Thomas (1989) paper uses a relatively simple standardized measure of seasonally adjusted quarterly earnings. With the advent of conference calls and extensive dissemination of financial information at the time of the earnings announcement in recent years, a simple seasonally adjusted difference in earnings may be an insufficient statistic to identify "earnings surprise." Research in the last decade has used alternative measures. For example, Doyle et al. (2006) and Livnat and Mendenhall (2006) both use earnings surprises measured with respect to prevailing consensus forecasts rather than historical earnings, and find a stronger drift using this measure. Brandt et al. (2008) show that the return drift is stronger using the stock price reaction around earnings announcements as proxy for earnings surprise. By using ex post returns as an alternative measure of earnings surprise, Brandt et al. provide some out of sample evidence in support of the original Bernard and Thomas.

Other recent papers on drift have explored whether isolating properties of earnings affect the relation. Narayanamoorthy (2006) finds that investors underestimate the implications of accounting conservatism for future earnings and shows that the returns to the PEAD strategy are greater if accounting conservatism is incorporated into the analysis. Shivakumar (2006) decomposes earnings surprises into unexpected accruals and unexpected cash flows and documents that the cash flow component is a better predictor of future stock returns, and finds that a trading strategy that uses the two components separately outperforms the one that is based on the total earnings surprise.

Perhaps the most interesting paper from the last decade related to drift in the context of robustness is Kothari et al. (2006). As discussed earlier in Section 4.2.2, they compute market level earnings change variables and show that, while these earnings changes exhibit similar time series properties to that seen at the firm level, there is no evidence to suggest that aggregate stock prices fail to understand this relation. Specifically, Kothari et al. find that the serial correlation in aggregate seasonally differenced quarterly earnings is positive for up to the next three quarters (Table 3 of Kothari et al.). Indeed, the aggregate relation is even stronger than that observed at the firm level. Most striking in their analysis is that while their firm level analysis shows the standard positive relation between seasonally differenced quarterly earnings and future stock returns, this relation is negative at the aggregate level. Kothari et al. then explore whether a Campbell (1991) decomposition of returns can explain this negative relation. They find that earnings changes have a contemporaneous and negative correlation with changes in the default spread (a candidate measure of discount rate news), and a positive relation with real growth variables such as changes in industrial production. The aggregate change in earnings could therefore reflect both earnings and discount rate news. The negative relation is concentrated in the portion of the aggregate change in earnings that is attributable to discount rate news. The implication from Kothari et al. for the firm level earnings drift anomaly is that the behavioral bias (underreaction) suggested as a support is unable to explain a similar drift for aggregate earnings.

Although the findings in Kothari et al. (2006) raise questions on the external validity of the cognitive bias explanation for the firm-level drift anomaly, it is premature to conclude that there is no out-of-sample evidence supporting the drift anomaly. Recent studies have also tested the robustness of the PEAD anomaly in other settings. For example, using a sample of U.K. firms, Liu et al. (2003) find that PEAD exists outside of the U.S. as well. Griffin et al. (2007) document that the returns to the PEAD strategy in emerging markets are similar to implementing the strategy in developed markets. Together, these analyses from non-U.S. settings help to confirm the original drift result reported in Bernard and Thomas (1989).

4.3.3. Risk

In this section, we review the treatment of risk in recent studies on accounting anomalies. A couple of general comments apply to the majority of the recent research on accounting anomalies and fundamental analysis. Very few papers published in the last decade have included the full set of return analyses described in Section 4.2.3. Most notably, very few papers look at anything beyond a set of Fama-French time series portfolio regressions and Fama-Macbeth cross-sectional characteristic regressions. The literature generally could do more to exhaust potential risk based explanations (see the list articulated in Section 4.2.3).

Second, there is some confusion in recent studies on accounting anomalies as to what risk is. We want to emphasize that if there is an observed relation between an attribute and future returns, it may be a reflection of risk. However, merely labeling this attribute as a risk factor is insufficient. The appropriate way to test an attribute is to examine whether established and theoretically based risk variables are able to explain that relation. Part of the challenge here is attributable to the lack of an agreed upon framework for capturing risk, especially for accounting related variables such as B/P, E/P, and earnings growth.

4.3.3.1. Accruals anomaly—treatment of risk. A considerable portion of recently published papers on the accrual anomaly have examined alternative risk-based explanations for the negative relation between accruals and future stock returns. Khan (2008) is perhaps the most ambitious paper in this respect. He uses an intertemporal CAPM-based four-factor model. Specifically, he estimates earnings and discount rate news betas consistent with the Campbell and Vuolteenaho (2004) (CV) framework and seeks to examine whether inclusion of these betas is able to explain the observed returns across accrual portfolios. Khan tests five different asset pricing models [single-factor CAPM, a two-factor CV model, a three-factor Fama and French (FF) model, a four-factor combined CV and FF model, and a distress risk-factor model]. Across the five models, the negative relation between accruals and future returns cannot be explained by four of the models, and can only be partially explained by the combination of the CV and FF models.

While this is suggestive of a potential risk-based explanation for accrual anomaly, Hirshleifer et al. (2006) find that it is the accrual characteristic, not the accrual factor loading, which has an association with future stock returns. As originally argued in Daniel and Titman (1997), it is important to empirically distinguish (1) the covariance between stock returns and a given attribute from (2) the returns attributable to the characteristic. Finding evidence in support of (1) is consistent with a risk based explanation for the return relation, whereas finding (2) would suggest mispricing. Specifically, Hirshleifer et al. (2006) find that high (low) accrual firms earn lower (higher) returns after controlling for the extent to which high (low) accrual firms load on a factor mimicking portfolio reflecting the accrual return. This evidence suggests that the relation between the accrual measure and future returns is due to the characteristic and not comovement, and tends to support the mispricing explanation over the risk-based explanation for the accrual anomaly.

More recently, Wu et al. (2010) articulate a risk-based explanation for the accrual anomaly. They appeal to the "q-theory" of investments that has an intuitive property of diminishing marginal returns to scale. This is a potentially compelling explanation for the observed negative relation between measures of accruals and future stock returns. It is also consistent with earlier work by Fairfield et al. (2003) and Dechow et al. (2008) who find evidence to support the idea that accruals measure changes in invested capital, and that changes in invested capital have an association with diminishing marginal returns to new investment (and related overinvestment). However, what is less clear from Wu et al., is how their empirical analysis can support a risk-based explanation from this diminishing marginal returns explanation for the accrual anomaly. First, as is standard with ex post analyses of stock returns, they conduct standard factor mimicking portfolio regressions. The dependent variable in these time series regressions is the return spread across extreme deciles of accrual portfolios; measured using the change in non-cash working capital, discretionary accruals, or a broader measure of accruals similar to that in Richardson et al. (2005). The independent variables are the standard Fama and French (1992) factors (SMB, HML and MKT) as well as a mimicking factor portfolio return that is long (short) companies that experienced high (low) levels of investment.

Wu et al. (2010) measure "investment" as the ratio of investment (sum of changes in property, plant and equipment, and changes in inventory) to lagged total assets. This new investment factor is mechanically related to accrual measures such as ΔNOA. Appendix B makes this relation clear by highlighting that ΔNOA can be rewritten as investment less changes in operating liabilities less the remaining portion of changes in operating assets that are not labeled as investment. The investment measure of Wu et al. includes many of the key components of standard accrual measures and is indeed highly correlated with the accrual measures. Across the three accrual measures examined, the average cross-sectional correlation with their investment variable is between 0.20 (discretionary accruals) to 0.66 (Richardson et al., 2005 ΔNOA measure of accruals). Thus, it is not surprising that the returns to a portfolio formed by ranking securities based on investment explains the returns to a portfolio formed by ranking securities based on accruals. This re-labeling of accruals as a risk factor does not help resolve the risk versus mispricing debate.

Wu et al. (2010, p. 190) also test the hypothesis that returns to the accrual strategy are time-varying and countercyclical. To do this, they project the accrual returns onto a measure of time varying risk premium extracted from the difference between market level implied volatilities and historical volatilities. The regression tests in Table 13 of Wu et al. support this hypothesis: their measure of time varying risk premium has a positive and significant association with accrual portfolio returns (adjusted R^2 of about 5%). Thus, they are able to reject the null hypothesis that accrual portfolio returns are not time-varying or countercyclical at conventional levels. Their evidence supports the existence of both a negative and time-varying relation between measures of accruals and future returns. They suggest that "the deterioration of the accrual anomaly in recent years might be temporary and likely to mean-revert in the near future" (p. 216). This is an alternative interpretation to the Green et al. learning story.

4.3.3.2. Underreaction (PEAD)—treatment of risk. Early work by Foster et al. (1984) and Bernard and Thomas (1989) undertake extensive analyses of possible risk-based explanations for the PEAD anomaly. Hence there has been little need for recent research to revisit the potential for risk-based explanations. A notable exception is Sadka (2006) who examines whether unexpected systematic variation in the variable component of firm liquidity is priced in PEAD portfolio returns. He decomposes firm level liquidity into a fixed and variable component, noting that the variable component most likely reflects the presence of private information (e.g., Kyle, 1985). He finds that shocks to the variable component of liquidity are priced in both momentum and PEAD portfolio returns. He interprets this evidence as being consistent with investors receiving excess PEAD returns in exchange for bearing systematic liquidity risk.

4.3.3.3. Pricing multiples and value effect—treatment of risk. A primary debate over the last two decades in this line of research is whether the positive relation between multiples such as B/P and future stock returns is generated from risk or mispricing. Going back to Fama and French (1992) and Lakonishok et al. (1994), the literature consistently shows that the book-to-market ratio (B/M) of a firm has a strong and positive correlation with future stock performance. Fama and French argue that high B/M stocks earn excess returns compared to most firms because of their greater risk, as many high B/M firms are in financial distress. More recent research by Vassalou and Xing (2004) appears to confirm that book-to-market risk essentially represents default risk in high B/M firms. On the other hand, Griffin and Lemmon (2002) show that firms with high distress risk exhibit the largest negative returns around earnings announcements. If it is the case that distress, as measured by accounting- or market-based variables, is a candidate risk factor then stocks exposed to this should have positive returns at earnings announcements. The findings that these high distress stocks experience negative future returns and that these returns are concentrated around subsequent earnings announcements are hard to attribute to a risk-based explanation.

There is a continuing debate as to the source of a risk-based explanation for variables such as B/P. The recent literature is starting to incorporate an understanding of accounting systems to help guide that empirical analysis. Penman et al. (2007) show that B/P masks a complicated relation with market leverage and then show that the positive relation between B/P and future returns can, in part, be attributable to a negative relation between market leverage and future returns, which is very hard to reconcile with a risk-based explanation. Penman and Reggiani (2010) start to link aspects of an accounting system together to articulate how a combination of B/P, E/P, and earnings growth can help observed relations with future returns. This literature, though, is far from settled.

4.3.4. Transaction costs

There tends to be very little in-depth analysis of transaction costs in recent studies on accounting anomalies and fundamental analysis. A primary reason for this is the lack of high quality trade data for researchers to quantify actual transaction costs. Instead studies have tended to either identify measures expected to correlate with actual trading costs (e.g., market capitalization, analyst following, and trading volumes) and then seek to document cross-sectional variation based on these trading cost proxies on the strength of the anomalous relation; or use trade and quote data to estimate relative and effective spreads, which tend to over-state actual transaction costs experienced by institutional investors (e.g., Stoll, 1993). Common to all of the papers incorporating some treatment of transaction costs is an attempt to assess whether the anomalous returns are within the bounds of market frictions or not. So, we also include in this subsection research related to arbitrage risk and other capital market frictions that can give rise to seemingly anomalous relations.

The prevailing treatment of transaction costs in the academic anomaly literature involves partitioning samples based on measures of perceived trading costs (e.g., market capitalization, stock price, volumes, etc.). There are some exceptions, notably Korajczyk and Sadka (2004), who examine whether the momentum anomaly is robust to sophisticated measures of transactions costs and price pressure, Bushee and Raedy (2006), and the papers examining arbitrage risk and liquidity costs (e.g., Pontiff, 2006; Mashruwala et al., 2006; Ng et al., 2008). However, a closer inspection of these papers shows a round-trip transaction cost in excess of several percentage points. For example, Ng et al. note that the return to a zero-cost investment portfolio (using a measure of unexpected earnings scaled by market capitalization) is about 10–12% depending on the weighting method. They then claim that this return falls to around 3% after accounting for transaction costs. Ignoring the impact of portfolio turnover, this fall suggests that the round-trip transaction cost for implementing a PEAD trading strategy is in the order of 8%. These numbers seem too large for most large stocks. The typical round-trip transaction cost for institutional orders of large securities that are S&P 500 or Russell 1000 index constituents has declined from about 80 basis points in 1998 to about 30 basis points in 2009 (see, e.g., Elkins/McSherry LLC, 2009). It is important to note that this estimate is a lower bound on transaction costs, as they are estimated relative to a volume-weighted average price, understating the true market impact of a given trade. However, market impact is not enough to increase trading costs to 8%. For earlier periods (i.e., pre-1998) it is more difficult to get reliable data to estimate round-trip transaction costs for institutional trades, but stock trades of large securities were typically fixed at \$0.25 per share prior to 1975 and ticks were 1/8th of a dollar so the minimum spread was \$0.125. Assuming a stock price of \$20 per share this implies a round-trip cost of $2*[0.25+0.125/2]/20=1.5\%$. This is much larger than trading costs today but it is still far lower than estimated trading costs documented in recent studies. At a first pass, it seems hard to explain away the documented annual returns to an annually rebalanced zero-cost (equal or value weighted) investment strategy of 10% or more (e.g., Sloan, 1996) with transaction costs. We revisit this topic directly in Section 5.5.

To the defense of Ng et al. (2008), and other academic research, they do demonstrate that their measures of transaction costs (effective spreads, quoted spreads, and estimated commissions) vary strongly with the earnings surprise variable. Specifically, they find that estimated transaction costs are three times larger for firms in the extreme deciles relative to firms in the middle deciles, suggesting that transaction costs are still a relevant consideration. So even though the levels of estimated transaction costs seem too high, Ng et al.'s analysis indicates that it is necessary to take transaction costs into account when assessing the implementability of a potential trading strategy.

4.3.4.1. Accruals anomaly—transactions costs. Only a handful of papers have an in-depth analysis of the impact of transaction costs or other market frictions on the accrual anomaly. Mashruwala et al. (2006) find that the accruals anomaly is concentrated in firms with high idiosyncratic return volatility, low price, and low volume, suggesting that transaction costs may provide an obstacle to investors to trade away the accrual anomaly. Lev and Nissim (2006) find that the extreme accrual firms are small, risky, and have low profitability. Hence, they do not attract the attention of large institutional investors. Lev and Nissim find evidence that some active institutional investors trade based on the accrual anomaly, but their trading activity appears to be too small (at least in Lev and Nissim's sample period) to arbitrage away the anomaly. Collins et al. (2003) find that firms with high institutional ownership and that exceed a minimum level of holdings by active institutional investors have accruals that are less mispriced, which is suggestive of reduced anomalous pricing in the presence of sophisticated investors. This evidence is in contrast to the results of Ali et al. (2003a) discussed in Section 4.3.1.3, who find that the accrual anomaly is not weaker in the presence of increased institutional ownership. Finally, Ali et al. (2008) find that even the mutual funds that have the largest exposure to low accrual stocks have limited exposure, suggesting that few actively managed funds trade on the accrual anomaly, and, for those who can, the magnitude of the returns is not large enough to be attractive to the investor.

In summary, recent research has shown that the accrual anomaly is indeed stronger in the presence of capital market imperfections but these explanations cannot account for all of the negative relation between measures of accruals and future returns.

4.3.4.2. Underreaction (PEAD)—transactions costs. As with the recent research on accruals, there are a handful of papers assessing the ability of market frictions to explain the drift result. As discussed above, Ng et al. (2008) find that transaction costs as measured by relative and effective spreads can explain a large portion of the drift returns. Mendenhall (2004) shows cross-sectional variation in PEAD based on arbitrage risk, which is consistent with an underreaction explanation to PEAD but one that is challenging for investors to exploit due to the idiosyncratic risks involved. Reed (2007) shows that firms with larger short-sale constraints have a lower portion of their long-term price reactions to earnings announcements occurring on subsequent earnings announcement dates. This result is consistent with capital market frictions supporting the drift to the earnings-related news.

A variety of other market frictions have been explored in the context of the PEAD anomaly. Kimbrough (2005) and Levi (2008) find that firms that supplement earnings releases with additional disclosures experience less underreaction to their earnings surprises. Ke and Ramalingegowda (2005) find that transient institutional investors generate large returns from trading on the PEAD and that their trading increases the speed with which prices impound the earnings information. Ke and Ramalingegowda also document that these investors trade less in companies with higher transaction costs, which could explain why PEAD persists.

It is worth noting some potential inconsistencies across these papers. For example, the finding in Kimbrough (2005) that the drift anomaly is weaker in the presence of more detailed information about the earnings release seems at odds with Hirshleifer and Teoh (2006), who find that the drift anomaly is stronger when there is more information provided to investors from related firms announcing earnings *at the same time*.

4.3.5. Additivity

In this subsection, we attempt to link together the various streams of accounting anomaly and fundamental analysis research. This is important to do as it is useful to know whether the relation between a given accounting attribute and future earnings or stock returns is unique and incremental to previously documented attributes. We find this aspect of the current literature to be lacking and are hopeful that future research will endeavor to achieve this objective. Our discussion focuses mostly on the accrual anomaly, as the potential links between it and a vast literature on financing related anomalies is a good example of the extent of this additivity challenge.

4.3.5.1. Accruals anomaly—additivity. There are a variety of papers that have addressed the question as to whether the accrual anomaly is distinct from other anomalies. The majority of the evidence supports the view that the accruals anomaly is distinct and is incremental to other previously documented anomalies. For example: Collins and Hribar (2000) show that the accrual anomaly is distinct from the post-earnings announcement drift. Barth and Hutton (2004) show that the predictive ability of accruals for future returns is not subsumed by the predictive ability of analysts' forecast revisions, and Cheng and Thomas (2006) document that the accrual anomaly is distinct from the value-glamour anomaly.

A thorough analysis of this last overlap between the accrual and the value-glamour anomalies is contained in Desai et al. (2004) who posit that the value and accruals anomalies are related because both anomalies represent overreactions to past accounting data. In the value-glamour anomaly, investors extrapolate past growth in sales and earnings, and realize subsequently (mostly at the time of future earnings announcements) that such growth is not sustainable because growth rates mean-revert. In the case of the accruals anomaly, investors extrapolate past accruals into the future and are surprised when earnings announced subsequently are lower or higher due to reversals in accruals. Thus, both anomalies relate to errors in expectations about future earnings. Further, certain proxies for the value-glamour and accrual anomalies are closely linked. For example, sales growth, one of the proxies for value-glamour, has a positive correlation with accruals. While they are related, they are, at least empirically, additive in their ability to forecast future stock returns.

The more interesting aspect of additivity for the accrual anomaly stems from the balance sheet identity. As outlined in Section 4.3.1.3, measures of accruals like ΔNOA are closely related to measures of financing. Appendix B summarizes this relation and highlights a clear link between the accrual anomaly literature (i.e., changes in net operating assets, ΔNOA) and the vast literature in finance on anomalous relations between various measures of external financing (i.e., changes in net debt contained within net financial obligations and net external financing contained within changes in book value, $\Delta NFO+\Delta B$) and future stock returns.

Over the past decade, there have been numerous studies investigating the association between a firm's corporate asset investment and disinvestment actions and future stock returns. The findings suggest that corporate events associated with the expansion of a firm's scale and its assets (i.e., acquisitions, public equity offerings, public debt offerings, and bank loan initiations) tend to be followed by periods of abnormally low long-term stock returns. On the other hand, corporate events associated with decreases in the scale of the firm and asset contraction (i.e., spinoffs, share repurchases, debt prepayments, and other payouts) tend to be followed by periods of abnormally high long-term stock returns.[8]

In addition to these long-term event studies, other research has documented a negative relation between various forms of corporate investment and future stock returns. For example, an increase in accruals, capital investment, sales growth, and external financing all tend to be negatively related to subsequent stock returns. Recent studies include Fairfield et al. (2003), Richardson and Sloan (2003), Titman et al. (2004), and Hirshleifer et al. (2004). More recent research studies whether firm growth is fairly priced in the cross-section by introducing and fine-tuning measures of growth (see, e.g., Richardson et al. (2006a, 2006b); Anderson and Garcia-Feijoo, 2006; Cooper et al., 2008). In addition, these studies attempt to understand the underlying sources of firm-level growth effects. The refined measures of firm growth are motivated by the observation that prior studies on the effects of growth on returns use components of a firm's total investment or financing activities and often ignore the larger picture of potential total asset growth effects of comprehensive firm investment and disinvestment.

Cooper et al. (2008) use a general measure of firm asset growth that comprises the year-on-year percentage change in total assets and a panel of U.S. stock returns. They document a negative correlation between firm asset growth and subsequent firm abnormal returns. They find that asset growth remains significant in explaining future stock returns that include book-to-market ratios, firm capitalization, short- and long-horizon lagged returns, and other growth measures that include growth in sales from Lakonishok et al. (1994); growth in capital investment from Titman et al. (2004); accruals from Sloan (1996); and the cumulative accruals measure (net operating assets) from Hirshleifer et al. (2004). It is important to note the mechanical relation between the change in total assets, ΔTA, and the change in net operating assets, ΔNOA, variable described above. The results in Cooper et al. can easily be recast as an examination of ΔNOA. A change in total assets, TA, equals changes in operating assets and changes in financial assets: $\Delta TA=\Delta OA+\Delta FA$. A change in net operating assets, NOA, equals changes in operating assets less changes in operating liabilities: $\Delta NOA=\Delta OA-\Delta OL$. Thus, $\Delta TA=\Delta NOA+\Delta OL+\Delta FA$. Therefore, Cooper et al. are ignoring the offsetting relation between operating assets and operating

[8] References include acquisitions (Asquith, 1983; Agrawal et al., 1992; Loughran and Vijh, 1997; Rau and Vermaelen, 1998); public equity offerings (Ibbotson, 1975; Loughran and Ritter, 1995); public debt offerings (Spiess and Affleck-Graves, 1999); bank loan initiations (Billet et al., 2006); spinoffs (Cusatis et al., 1993; McConnell and Ovtchinnikov, 2004); share repurchases (Lakonishok and Vermaelen, 1990; Ikenberry et al., 1995); debt prepayments (Affleck-Graves and Miller, 2003); and dividend initiations (Michaely et al., 1995).

liabilities that are examined in Richardson et al. (2005) and are shown to be important in improving the forecasting ability of accruals. They are also including the changes in financial assets. As we discuss next this is a source of improvement as retained cash is reliably associated with lower future firm performance.

In an attempt to bring these literatures together, Dechow et al. (2008) show how the accrual anomaly literature is related to the various investing/financing anomalies through the balance sheet identity. While the theoretical reasons for the observed relation between these attributes and future stock returns may differ, they are very closely related. The question from a forecasting perspective is then whether they are additive in forecasting future earnings and returns. The main identity exploited in Dechow et al. is that $\Delta NOA = \Delta NFO + \Delta B$ can be extended by recognizing that the changes in book value must result from net equity issuance, $\Delta EQUITY$, and Income. With some algebraic manipulation, it is easy to show that $\Delta NOA = \Delta XFIN - \Delta FA + Income$, where $\Delta XFIN = \Delta DEBT + \Delta EQUITY$.[9] Then Dechow et al. show that the association between a broad measure of accruals (ΔNOA) and future stock returns is stronger than the relation between a measure of external financing ($\Delta XFIN$ or its constituents, $\Delta DEBT$ and $\Delta EQUITY$). Specifically, they show that the accrual measure (ΔNOA) is more effective in explaining the cross-section of returns than the net financing measure ($\Delta XFIN$), and, after first sorting on the accrual measure, the financing measure is not able to capture any return variation. An interpretation of this result is that it is the use of the external financing proceeds (i.e., ΔNOA) that predicts future returns, rather than the raising or distribution of financing (i.e., $\Delta XFIN$), as suggested by earlier studies and reviewed by Ritter (2003).

While the evidence in Dechow et al. (2008) is suggestive of the importance of a broad-based measure of accruals to forecast future earnings and returns due to the associated discretion embedded in accruals, it is important to note alternative explanations for this robust empirical relation. They state on p. 564: "An alternative interpretation is that accruals measure changes in invested capital and that changes in invested capital are associated with diminishing marginal returns to new investment (and related overinvestment). Note that these alternative interpretations are not mutually exclusive and probably coexist." Further, as we discussed in Section 4.3.3.1, Wu et al. (2010) find that the accrual anomaly may be partially consistent with time varying expected returns.

Also, we note that changes in net operating assets as a broad measure of accruals is related to the cumulative accruals measure from Hirshleifer et al. (2004). This cumulative measure (net operating assets deflated by the beginning of period total assets) can be recast as changes in net operating assets scaled by beginning of period assets and a measure of operating leverage. Specifically, using the accounting identities described above (i.e., $NOA = OA - OL$ and $TA = OA + FA$, so $NOA = TA - FA - OL$), we can re-write the Hirshleifer et al.'s measure of balance sheet bloat as follows:

$$\frac{NOA_t}{TA_{t-1}} = \frac{NOA_t - NOA_{t-1}}{TA_{t-1}} + \frac{NOA_{t-1}}{TA_{t-1}} = \frac{NOA_t - NOA_{t-1}}{TA_{t-1}} + \frac{TA_{t-1} - FA_{t-1} - OL_{t-1}}{TA_{t-1}}$$

$$\frac{NOA_t}{TA_{t-1}} = \frac{\Delta NOA_t}{TA_{t-1}} + 1 - \frac{FA_{t-1}}{TA_{t-1}} - \frac{OL_{t-1}}{TA_{t-1}} \tag{5}$$

Thus, the Hirshleifer et al. (2004) measure is an algebraic transformation of the ΔNOA measure from Richardson et al. (2005) combined with operating liability leverage and financial assets. This reconciliation is described in Richardson et al. (2006a, 2006b), who show that the predictive power of the cumulative accruals measure from Hirshleifer et al. is almost entirely attributable to the changes in net operating assets. Again, it is important for researchers to recognize accounting relations to help move the accounting anomaly and fundamental analysis literature forward.

In summary, the accrual anomaly literature has evolved over time to make clear explicit links with other anomaly papers, most noticeably those of financing and investing. Recent research (e.g., Dechow et al., 2008) suggests that the accrual anomaly actually subsumes these related anomalies. Overall, it appears that investors have difficulty interpreting the performance of firms that have significant changes in net operating assets.

4.3.5.2. Fundamental analysis—additivity. As discussed in Kothari (2001), the residual income model (Ohlson, 1995) has had a sizable impact on valuation approaches and the application of fundamental analysis in both academics and practice (see, also Claus and Thomas, 2001; Gebhardt et al., 2001; Easton et al., 2002; Baginski and Wahlen, 2003). Ohlson (2005), Ohlson and Gao (2006), Ohlson (2009), and Easton (2009) provide excellent reviews of some of the technical and analytical advances in accounting-based valuation models over the past decade. However, the question remains as to whether the recent literature has added anything new to the earlier development of the residual income model. All valuation models are theoretically the same and are merely transformations of the discounted dividend model shown in Eq. (1) with varying assumptions and data requirements (see Ohlson, 2005). However, the applicability and utility of a given valuation model depends on the plausibility of the assumptions underlying the model (e.g., the persistence of abnormal earnings) and the quality and availability of data (e.g., earnings forecasts) required by the model.

Recent advances in this area include both refinements of the valuation models and application of these models (see also Lewellen, this issue for a discussion). A particularly interesting example of a recent valuation refinement is the "OJ model" presented in Ohlson and Juettner-Nauroth (2005). This model focuses on abnormal earnings growth with no clean surplus

[9] Note that this decomposition treats deferred taxes as an operating asset or liability, but this can easily be recast to treat deferred taxes as a financial liability if the researcher so desires.

accounting, which is generally required by previous models (e.g., Ohlson, 1995). The OJ model differs from a traditional residual income model by specifying earnings per share, instead of book value per share, as the fundamental forecasting benchmark, which is far easier to implement in practice.

The proliferation of valuation models has spawned a growing debate about the superiority, applicability, and empirical properties of various models (e.g., Francis et al., 2000; Lundholm and O'Keefe, 2001; Penman, 2001; Courteau et al., 2001; Richardson and Tinaikar, 2004; Juettner-Nauroth and Skogsvik, 2005). These studies have compared the bias and accuracy of different valuation models. Not surprisingly, the various benchmarking studies conclude that different implementation techniques and the different assumptions of various valuation models lead to different abilities of the models to predict future returns.

Most studies argue that no single accounting-based valuation model has dominant empirical properties. However, the OJ model has some advantages over the traditional residual income models. Specifically, Ohlson (2005) analyses a number of situations and concludes that truncation errors of terminal streams are smaller and less frequent under the OJ model compared to a traditional residual income model that relies on book equity as a performance benchmark. These smaller terminal value errors imply that a finite-term OJ model will likely outperform a finite-term residual income model. Ohlson shows that capitalized earnings under the OJ model better capture the market value of equity than the book value of equity in a world of conservative accounting. Recent research has shown the superior ability of the OJ model to help forecast future returns. For example, Ali et al. (2003b) compare the ability of different valuation measures to predict future abnormal returns. They find that all of the valuation measures, including the OJ model, have the ability to predict future returns, and that the incremental contribution of the OJ model is significant in regressions of future returns on the value-price and *B*/*M* ratios. These findings suggest that the OJ model has some ability to predict future abnormal stock returns.

4.3.6. Non-price based tests

In this subsection, we provide a short summary of research in the last decade related to the anomaly literature that has attempted to use non-price based tests to strengthen mispricing-based explanations for relations between accounting attributes and future stock returns. We discuss these papers collectively rather than by cluster as there are not too many examples of this approach.

The primary non-priced based test is the use of analyst forecast information. Assuming that analyst earnings or price forecasts are a reasonable proxy for general market expectations, then finding an accounting attribute that is associated with future forecast errors, or that is able to forecast future revisions to those forecasts, makes it easier to classify a relation between an accounting attribute and future returns as mispricing. If analysts are unable to incorporate the attribute into their forecasts, then it might be reasonable to assume that the market also shares that inability. Bradshaw et al. (2001) find that analyst forecast optimism is greater for firms with high accruals, which is consistent with market participants not fully incorporating predictable earnings reversals associated with high accruals when forming expectations about future earnings that in turn determine prices. Bradshaw et al. (2006) find a similar relation between analyst forecast errors (short term earnings, long term earnings and target prices) and broad-based external financing measures.

While most of the non-price based tests have focused on the accrual anomaly, there is some evidence of this in the context of *B*/*P*. The early work of Fama and French (1995), examines the behavior of stock returns in relation to the value effect using non-price tests based on firms' earnings attributes. They argue that value stocks (high *B*/*M*) should have persistent, poor earnings and growth stocks (low *B*/*M*) should have persistent, strong earnings. They present empirical evidence consistent with this idea and suggest that non-price based information (i.e., earnings) can help corroborate the returns results. It is worth highlighting that the results in Lakonishok et al. (1994) and Dechow and Sloan (1997) suggest that a mispricing based explanation for the value-glamour anomaly can be corroborated by the naïve extrapolation of firm fundamentals and expectations of future growth.

In the more recent literature, there have been relatively few studies that have applied follow-up non-price tests to the value effect. One exception is Doukas et al. (2002) who examine analysts' earnings forecasts for value- and growth-stock portfolios to capture the market's expectation of future earnings. They then compare analysts' estimates with the actual earnings outcomes across value and growth stocks to determine whether the market's initial optimistic forecast bias is more pronounced for glamour stocks than value stocks. Doukas et al. find that value stocks (high *B*/*M*) display higher forecast errors and larger downward forecast revisions than glamour stocks (low *B*/*M*), indicating that investors are more optimistic about value than growth stocks. Overall, they find that investors make larger forecast errors in predicting future earnings for small-cap and value than large-cap and growth stocks.

5. Benchmark model for evaluating anomalies using ex ante treatment of risk and transaction costs: accruals and PEAD case study

Our comparison of survey responses from academics and practitioners revealed three key observations. Academic research assesses risk based on an ex post analysis of returns, rather than forecasting risk; it does not typically incorporate a firm's industry affiliation in models of expected risk; and it typically does not capture the effect of transaction costs on the implementability of a trading strategy in a sophisticated manner. We provide empirical evidence that speaks to all three of these issues in this section.

Specifically, we undertake a case study of the accruals and post earnings-announcement drift anomalies, based on how practitioners build portfolios. Our aim is to demonstrate the importance of ex ante considerations of risk and trading costs in building an implementable portfolio with a high Sharpe ratio.[10] While we focus on the accrual and PEAD anomalies, the approach outlined in this section can be extended to any accounting or non-accounting signal.

It is important to note that empirical analysis seeking to discriminate risk-based versus mispricing explanations must incorporate some variant of ex post analysis. The standard approaches are to test whether the observed attribute-return relation is robust to the inclusion of conjectured risk measures, both in time series portfolio-level tests and cross-sectional characteristic tests. As discussed in Section 4, these ex post return analyses are critically important in anomaly papers. But, our focus here is on the ex ante side of portfolio construction. Specifically, how does ex ante portfolio optimization for risk and trading costs affect one's assessment of the relation between accruals, PEAD, and returns?

This section proceeds in distinct subsections. First, we describe our accrual and earnings surprise variables and the data we use in the following empirical analysis. Second, we describe the standard mean-variance approach to portfolio construction, with particular emphasis on using a fundamental multiple factor model to forecast risk at the portfolio level (e.g., Ross, 1976). Third, we describe and use a standard model to forecast direct and indirect transaction costs. Fourth, we document that the negative relation between measures of accruals and future returns and PEAD are robust to an ex-ante and ex post consideration of risk and transaction costs for the period 1973–2000, but they have attenuated substantially in the last decade. Fifth, we provide evidence on the performance difference between a simple equal or value weighted zero-cost investment portfolio and a full characteristic portfolio resulting from optimally combining forecasts of expected returns, risk and trading costs. We illustrate that incorporating ex ante information on risk can dramatically improve investment performance ex post. For example, we compare returns between decile sorted portfolios and fully optimized portfolios, and show that the Sharpe ratio on the latter is almost twice that of the former. Finally, we conclude with some philosophical points on the risk versus mis-pricing debate.

5.1. Measures of accruals and post earnings-announcement drift

As discussed in Section 4, earnings can be additively decomposed into a cash flow and an accrual component. Previous research has shown that the accrual component is less persistent than the cash flow component and is negatively associated with future stock returns (e.g., Sloan, 1996; Richardson et al., 2005). Our aim is to assess how this negative relation is affected by a comprehensive ex ante treatment of risk and transaction costs.

We use both the narrow and broad measures of accruals from Sloan (1996) and Richardson et al. (2005). The narrow definition of accruals, ΔWC, is simply the change in non-cash working capital. The broad definition of accruals, ΔNOA, is the change in net operating assets. As described in Section 4.3.5.1., and shown in Appendix B, the balance sheet identity of *Assets* (A)=*Liabilities* (L)+*Equity* (E), can be recast into operating and financing components allowing the derivation of this broad based measure of accruals. Consistent with Richardson et al., we measure these items using balance sheet data so we can extend our sample period back further in time. We construct our sample from U.S. firms using Compustat data during the 1973–2008 period.

The precise definitions of these two accrual measures are as follows: ΔNOA is defined as the change in non-cash assets less the change in non-debt liabilities. Non-cash assets are calculated as total assets (quarterly field 'ATQ') less cash and short-term investments (quarterly field 'CHEQ'). Non-debt liabilities are calculated as total liabilities (quarterly field 'LTQ') less total debt (quarterly field 'DLTTQ' plus quarterly field 'DLCQ'). ΔWC is defined as the change in non-cash current assets less the change in non-debt current liabilities. Non-cash current assets are calculated as total current assets (quarterly field 'ACTQ') less cash and short-term investments (quarterly field 'CHEQ'). Non-debt current liabilities are calculated as total current liabilities (quarterly field 'LCTQ') less short term debt (quarterly field 'DLCQ'). We require total assets and total liabilities to be non-negative. Other variables are set equal to zero if they are missing. We deflate each of these variables by average total assets. Consistent with previous research (e.g., Richardson et al., 2005), we winsorize each deflated component of earnings at +1 and -1 in order to eliminate the influence of extreme outliers.

To generate as realistic results as possible, we compute rolling twelve month values for ΔNOA (and hence focus on quarterly balance sheet information). We wait three months before assuming that this data is available to the market. For example, if a firm has a December 31 year end, then the value for ΔNOA in July of year t+1 will reflect the four quarters up to the end of March year t. Our stock return tests use data from the CRSP monthly files, inclusive of dividends and other distributions.

To measure PEAD we follow the definition of standardized unexpected earnings (*SUE*) outlined in the work of Bernard and Thomas (1989, 1990). Specifically, we compute seasonally differenced return on average assets divided by the rolling 12 quarter standard deviation of this seasonal difference. We use income before extraordinary items (Compustat quarterly field 'IBQ') and total assets (quarterly field 'ATQ'). Since interim financial reports are only available starting in 1976, and because of the requirement of three-year data to measure PEAD, our analysis of PEAD starts in 1979.

[10] Korajczyk and Sadka (2004) and Bushee and Raedy (2006) investigate whether various anomalies are robust to assumed ex post trading costs. Korajczyk and Sadka (2004) do a limited investigation incorporating ex ante trading costs. In contrast, we examine both ex ante and ex post transactions costs, and ex ante risk.

Our model of forecasted risk (described in Section 5.2) starts in 1973. However, we present our results from the 1979 to 2008 periods to ensure an overlapping period with the PEAD and accrual anomalies. The exclusion of the first six years of data does not affect our inferences about the accrual anomaly. We also restrict our attention to the largest 1,000 securities based on market capitalization, as our forecasts of transaction costs are superior for larger firms. An added benefit of focusing on the largest securities is that potential biases related to bid-ask bounce and asynchronous trading are muted. Researchers who report results based on equal weighted returns should note that such portfolios often require extensive rebalancing costs and that the calculated returns are likely to be biased (e.g., Blume and Stambaugh, 1983; Asparouhova et al., 2010). For example, Korajczyk and Sadka (2004), note that momentum based equally weighted strategies perform the best (worst) before (after) trading costs are taken into account.

5.2. Forecasting risk

We forecast risk with the standard mean-variance framework (see, e.g., Grinold and Kahn, 2000). An investor is concerned about co-movement in the securities that she holds in her portfolio. Assuming the investor faces a quadratic utility function (standard assumption), the investor is then interested in maximizing expected returns subject to minimizing co-movement risk. We can represent this optimization problem as follows for a set of N assets:

$$\max \alpha^T h - \lambda h^T X F X^T h - \lambda h^T \Delta h, \tag{6}$$

where α is a $(N \times 1)$ vector of expected returns, h is the $(N \times 1)$ vector of portfolio holdings, X is a $(N \times K)$ matrix of exposures to common factors, F is a $(K \times K)$ matrix of variances and covariances of common factor returns, and Δ is a diagonal $(N \times N)$ matrix with the diagonal terms representing the variances of specific returns. λ is the aversion to risk. In this framework risk is F and Δ.

How do we measure risk? There is a long tradition in financial economics (e.g., Sharpe, 1964; Lintner, 1965) suggesting that assets with similar characteristics will behave in similar ways. Ross (1976) develops a linear asset pricing framework where security returns are related to the expected returns associated with a set of underlying systematic factors. These multiple common factor models are widely used to measure the risk associated with a given set of securities. The empirical challenge with this arbitrage pricing theory (APT) is how to specify the underlying systematic factors and associated security specific exposures. Fortunately, there are many who have endeavored to do this, and we can use their common factor models for our purposes here.

In the context of the standard optimization problem described above, we require a forecast of risk. Rather than estimate a complete $N \times N$ asset level variance-covariance matrix, we reduce the dimensionality of the problem by projecting total returns onto common factors, thereby decomposing total returns into a common factor component and a residual (or specific) return component. We allow common factor returns to co-vary in this framework, but not the specific returns.

A standard way to specify the common factors is via characteristic exposures.[11] The approach is as follows:

1. Specify the set of common factors. This typically includes a set of characteristics that are cross-sectionally standardized to allow direct comparison across factors (e.g., leverage, size, earnings yield, growth, value, momentum, and various macro sensitivities such as oil, metals, interest rates), and fixed effects capturing industry membership.
2. Run periodic (e.g., monthly) cross-sectional regressions where total returns are projected onto the common factors specified in stage 1.
3. Extract the regression coefficients from stage 2. These are the estimated common factor returns.
4. Compute all of the pair-wise correlations and volatilities of the common factor returns. These are estimated over rolling windows (e.g., using the last 60 months with a specified half-life). This generates the necessary inputs for the F matrix defined above.
5. The residuals from the regressions described in stage 2 are the specific returns. The specific risk is computed using time series variation in the specific returns (e.g., a rolling 24 month standard deviation of the regression residuals). This generates the diagonal elements of the Δ matrix defined above.

This exercise is repeated every period (e.g., month) to obtain a set of exposures, X, and a forecast of risk (F and Δ). It is very important to note that the basis for this risk forecast is recent realizations of firm-level stock returns. It has a built-in time-varying component. Specifically, the correlations and volatilities are not static through time. But note that they change only to the extent that realized equity returns respond to these changing state variables: this approach is not an explicit state-dependent forecasting model.

How can we assess the quality of our risk forecast? Fortunately, there is a well established literature (see e.g., Connor, 2000). A necessary condition for including a common factor is that it helps explain cross-sectional variation in returns. But a sufficient condition for including a common factor is that it improves the ability of the set of common factors to forecast risk. A standard measure for assessing the quality of common factor risk models is the 'bias test.' This test evaluates the

[11] Companies like BARRA and Axioma provide this service commercially. Alternative approaches include statistically motivated principal component analysis.

ability of the model to forecast the active risk for a portfolio over a pre-specified period. The relevant measure (bias statistic) is the time series standard deviation of the ratio of the realized portfolio return to the forecast portfolio risk. In the bias test, the null hypothesis is that the active risk forecasts are unbiased estimates of the deviation of the active returns of the test portfolios. The expected value of the bias statistic is equal to one under the null hypothesis. If the bias statistic is greater (less) than one this indicates that the active risk has been under (over) estimated. Standard tests can be applied to assess whether the observed bias statistic deviates from one. The risk model we use (BARRA USE3) has been tested extensively with this bias statistic. MSCI/BARRA and other vendors find that the out-of-sample success of forecasting portfolio level risk is quite robust. The final set of included common factors is based on the relative improvement in the bias statistic from the included variables.

5.3. Forecasting transaction costs

Transaction costs are an important factor in determining whether an anomaly is implementable. Discriminating between anomalous relations that are within or beyond transaction cost bounds is an important exercise to help sharpen inferences on the relative inefficiencies with which various attributes are priced. We are able to address this directly by focusing only on the largest securities and also incorporating forecasts of transaction costs. Our objective in this subsection is to communicate the key features of a transaction cost forecast and how this impacts the construction of a characteristic portfolio. A complete treatment of the forecasting of transaction costs is beyond the scope of our paper, and we refer interested readers to an extensive discussion of trading costs in Keim and Madhavan (1997), Korajczyk and Sadka (2004), as well as practitioner summaries contained within Madhavan (2000) and Rakhlin and Sofianos (2006).

Trading costs are typically described in terms of direct and indirect costs. Direct costs include commissions, crossing the bid-ask spread and taxes. These tend to be readily observable and are easy to incorporate into a forecasting framework. Indirect costs are the market impact costs from trading moving prices. As an order is executed, the price typically moves: buying (selling) activity is associated with increasing (decreasing) prices. These moves are costly as they reduce returns. The two most relevant factors that are able to explain this impact are volatility and trading volume (e.g., Chapter 16 of Grinold and Kahn, 2000). Impact is an increasing (decreasing) function of volatility (volume). Bid-ask spreads are ignored in the forecasting of market impact, but are included in the fixed portion of transaction costs.

The precise functional form and sensitivity to these factors is an empirical question. To calibrate such models requires access to large amounts of order and trade execution data. Unfortunately such data is typically proprietary and not generally available. We are, however, able to use the transaction cost forecasts based on a comprehensive set of institutional trades from a large institutional asset manager. The following information is key to calibrating transaction cost models: what time the order to trade is placed, the magnitude of the total trade, the direction of the trade (i.e., buy or sell), and the executed price. A challenge with using standard data such as TAQ is that it is not possible to group together trades that are deliberately broken into smaller parcels via algorithmic engines, nor is it easy to sign the direction of these trades. We have access to actual trade data, which has been used to calibrate a transaction cost forecast model (i.e., we can observe the actual impact for a large set of institutional trades and are thus able to incorporate firm specific attributes such as volume and volatility to generate a forecasting model).[12] This model is piece-wise linear, where the expected transaction costs (i.e., the cost associated with changing portfolio weight, h, from h_t to h_{t+1}) are increasing in forecast volatility and decreasing in the square root of forecast trading volume. We use this model in our analysis of the accruals anomaly and PEAD later. This forecast of trading costs is imperfect, as final trading costs are not known until the trade is actually executed. Specifically, there could be a greater impact than the one forecasted, as the executed trade accounts for more of the actual traded volume than forecast, and there is the opportunity cost of not capturing the expected return from unfilled orders. For example, for a forecast market volume of 100 shares the model may suggest a buy order of 5 shares, to optimally trade off expected returns and transaction costs, but if only 10 shares are actually traded that day then the buy order will move the price more than what was forecasted. Nonetheless, an imperfect analysis of trading costs is still a useful guide to determine the implementability of a proposed trading strategy. We use these stock specific forecasts of transaction costs both ex ante (i.e., we optimally trade-off expected returns, risk and transaction costs when constructing our characteristic portfolios) and ex post (i.e., we subtract from realized returns the actual direct costs and estimated indirect costs based on stock specific attributes).

Further, because our portfolio will hold short positions, we incorporate cross-sectional and time series variation in borrowing costs associated with achieving the desired short positions. We capture differences in borrowing costs as part of the transaction-cost forecast model. We do so by adding the prevailing borrowing cost to the expected transaction cost for trades that create short positions. In most cases the borrowing cost is a flat 0.16%, but in some cases where there is limited supply of securities to be loaned or there is a lot of demand to borrow then the borrowing cost can exceed 5%. For the earlier part of our sample borrowing costs were typically higher as well. As with previous research that uses short portfolios, our short sales are not realistic in that they do not observe the "uptick rule," which prohibit short sales when the

[12] A disadvantage of our transaction cost forecasts is that they are 'black box,' in that they are based on proprietary trading data unavailable to other researchers. In our assessment, the models are standard to what is used in industry. For the academic researcher looking to study transactions costs, the approach in Korajczk and Sadka (2004) could be adopted.

price has decreased. The returns to our short positions are therefore overstated, as they can reflect prices that are not transactable. But note that for the larger securities that we trade in our portfolio executing on an 'uptick' is typically feasible during the day by closely monitoring trading activity.

Finally, note that the forecast and actual transaction cost for a given security is dependent upon the size of the portfolio as the amount of trade in a given security is directly proportional to the size of the portfolio and stock specific attributes such as volume and volatility. We assume an initial portfolio of $400 million at the start of 1979 (pre-leverage). Similar to Korajczyk and Sadka (2004), we assume that profits are reinvested in the portfolio, so for example the Δ*NOA* characteristic portfolio grows to $6.4 billion at the end of the period. Note that this assumption means that the trading impact, and hence transactions costs, increase over time. The return for each security is reduced using the same transaction cost model described above.

5.4. Putting it all together to build a portfolio

We use the forecasts of risk and transaction costs described above to reassess the strength of the relation between accruals and PEAD and future stock returns. This reassessment allows us to make stronger inferences about the implementability of the anomalies and provide robust evidence of their existence. We also supplement our ex ante portfolio tests with standard ex post analyses of risk and transaction costs.

Specifically, we use the forecasts of risk and transaction costs to solve a more general objective function of expected return maximization subject to a risk penalty and a trading cost penalty. We estimate the solution to this extended objective function numerically. We solve the objective function every month, for the 1979–2008 period. The solution to the optimization problem is subject to additional constraints. The relevant constraints that we examine are: the target risk of the final portfolio is 10% (annualized); the sum of the positions in the final portfolio is zero (fully invested); and the portfolio weights can be positive and negative, but no position can be greater than 5% of the over-all portfolio. There is no restriction on the leverage of the final portfolio. We define leverage to be the average of the sum of the long and short positions, respectively (i.e., a value of one means a self-financed zero ex ante beta portfolio). Across the time period examined, the leverage of the characteristic portfolio incorporating expectations on transaction costs is on average about 3.7 with an inter-quartile range of 3.3–4.2. This means that, on average, for a $100 investment, you have a $370 exposure on the long and short side of the portfolio.[13] McGuire et al. (2005) using Bank of International Settlement data, suggest that equity long/short hedge fund leverage was above 5 in the latter part of the 1990s and decreased to about 3 during 2000–2005. While the average leverage for our characteristic portfolio (3.5) fits within this range, it is important to note that risks associated with periods of deleveraging will not be reflected in the portfolio returns that we document. For example, forced selling of positions can be triggered by margin calls which could in turn feed into larger than expected market impact costs.

The 10% target risk constraint is worth further discussion. The optimization problem described above is solved numerically to identify a vector of portfolio weights. In expectation, the annualized volatility of the returns to this vector of portfolio weights is 10%. In other words, if our risk model is "good" then we should observe an ex post volatility of about 10% for the portfolio. For our empirical analysis the portfolio has a realized annual volatility of 9.7%, which suggests that our risk model is "good".

We present the results of our analyses graphically (Fig. 1a and b) and with standard statistical tests (Tables 2 and 3). The return to the portfolio for a given month is computed as the sum of the product of the active weight and the total return for each position at the start of that month. We use total returns because this is a fully invested long/short portfolio.

Fig. 1a (b) reports the natural logarithm of the cumulative returns to both the Δ*NOA* and *SUE* characteristic portfolios using realized returns without (with) a correction for ex post transaction costs. The bold (dashed) line in Fig. 1 shows the cumulative return of the Δ*NOA* (*SUE*) characteristic portfolio. The key inferences we make from Fig. 1a are as follows: a portfolio that is optimized for ex ante risk and transaction costs shows a relation between measures of accruals and drift and future stock returns, and these relations have attenuated substantially in recent years. It is important to note from Fig. 1b that the returns of the Δ*NOA* characteristic portfolio appear robust to ex post treatment of transaction costs. The returns to the *SUE* characteristic portfolio in contrast are much smaller than that for the Δ*NOA* characteristic portfolio, and they attenuate much earlier in the sample period.

[13] A simple example can illustrate how leverage is achieved in the portfolio. An investor gives $100 to an asset manager. Consistent with the optimization constraints used in our empirical analysis, assume that the asset manager has agreed to provide a target risk level of 10% (annualized) for this investment. In a given month, it may be the case that to achieve this level of risk the asset manager needs a portfolio with 3.7 times leverage (i.e., $370 long and $370 short). To do this, the asset manager will borrow $370 worth of securities from a prime broker and use the proceeds from the sale of these securities to purchase the $370 of long positions. In return for providing the equity lending facility, the prime broker will charge a lending fee (i.e., 'borrow cost' as described in the text). As Saffi and Sigurdsson (2007) note, the typical wholesale lending fee is about 10 basis points for the largest securities in the US in recent years (see Table 1 of Saffi and Sigurdsson (2007)). In our example, the explicit financing charge for this levered portfolio is $0.10\% \times \$370$ short (i.e., $0.37). These stock specific borrow costs are included in our portfolio simulations. There is no explicit margin interest for this levered portfolio as the long positions and the invested capital serve as collateral for the prime broker lending the securities. It is important to note that the selection of the risk level is somewhat arbitrary, but 10% is fairly standard for equity long/short portfolios. It may be possible to construct a portfolio with lower risk targets and hence lower leverage and generate higher risk adjusted returns.

b

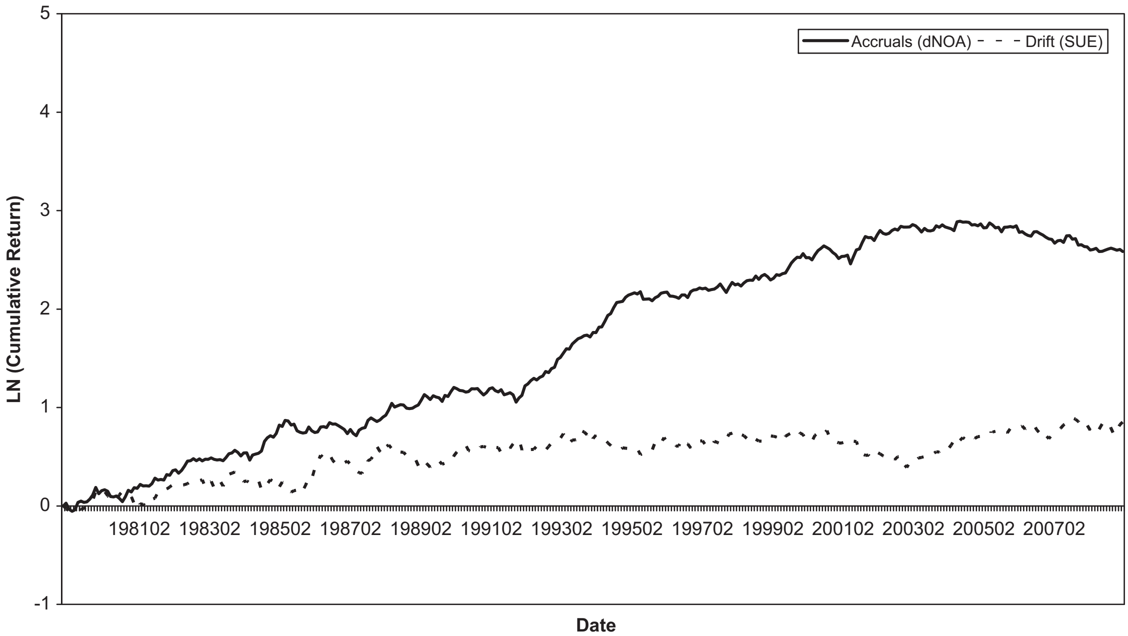

Fig. 1. (a) Cumulative log total returns to a Δ*NOA* (bold line) and *SUE* (dashed line) characteristic portfolio for U.S. data (1979–2008). Portfolios are formed using ex ante risk and transaction cost information. Each portfolio is (i) rebalanced monthly from the largest 1,000 US securities based on market capitalization, (ii) constructed to achieve a target annualized risk level of 10%, and (iii) subject to constraints that keep portfolio leverage less than five times, and individual security positions less than 5%. Returns are *before* actual transaction costs. (b) Cumulative log total returns to a Δ*NOA* (bold line) and *SUE* (dashed line) characteristic portfolio for U.S. data (1979–2008). Portfolios are formed using ex ante risk and transaction cost information. Each portfolio is (i) rebalanced monthly from the largest 1,000 US securities based on market capitalization, (ii) constructed to achieve a target annualized risk level of 10%, and (iii) subject to constraints that keep portfolio leverage less than five times, and individual security positions less than 5%. Returns are *after* actual transaction costs. Actual transaction costs are inferred using a simulated portfolio of $400 million at the start of 2009 and assumes that the forecasted transaction cost function reflects realized trading costs.

Table 2 reports formal statistical tests of the declining returns to the Δ*NOA* and *SUE* characteristic portfolios through time. Specifically, to test the significance of this temporal decline we conduct an ex post analysis of the returns to the Δ*NOA* and *SUE* characteristic portfolios using the standard Fama-French approach. To accommodate a test of the temporal decline

t-Statistics are reported in parentheses beneath regression coefficients. *p*-Values reported beneath *F*-statistics.
$R^{\Delta NOA}$ is the monthly return to the ΔNOA characteristic portfolio. ΔNOA is measured as defined in Section 5.1.
R^{SUE} is the monthly return to the post earnings announcement drift (PEAD) characteristic portfolio. *SUE* is measured as the ratio of seasonally differenced quarterly operating income deflated by average assets, to the standard deviation of this seasonally differenced profitability measure using the trailing 12 quarters.
We rebalance portfolios every month using ΔNOA or *SUE* information at the start of the month and returns for that month. The investment universe is the largest 1,000 securities based on market capitalization at the start of the month. Portfolios are rebalanced monthly to achieve a target annualized risk of 10%. Portfolios are fully invested with individual positions limited to be no more than 5% of the total portfolio.
R^{MKT} is the monthly excess (to risk free rate) market return.
SMB is the monthly mimicking factor portfolio return to the size factor. Data obtained from Ken French's website.
HML is the monthly mimicking factor portfolio return to the value factor. Data obtained from Ken French's website.
YR_{7982} is an indicator variable equal to one for months that fall within 1979 and 1982.
YR_{8387} is an indicator variable equal to one for months that fall within 1983 and 1987.
YR_{8892} is an indicator variable equal to one for months that fall within 1988 and 1992.
YR_{9397} is an indicator variable equal to one for months that fall within 1993 and 1997.
YR_{9802} is an indicator variable equal to one for months that fall within 1998 and 2002.
YR_{0308} is an indicator variable equal to one for months that fall within 2003 and 2008.
358 monthly observations from 1979 to 2008 are used for this time series regression. Each portfolio is formed for the same initial universe (the largest 1,000 US securities by market capitalization at the start of each month).

aspect we use multiple intercepts. We split the 30-year sample period into six periods, and include six time-fixed effects. Table 2 presents these results. First, the standard factors (*MKT*, *SMB*, *HML*) are unable to explain the returns to either the ΔNOA or *SUE* characteristic portfolio returns. Second, the strength of the negative (positive) relation between ΔNOA and future returns has weakened, especially in the most recent period (see also Green et al., 2009). It is interesting to note that while we are able to reject the null hypothesis of equal returns to ΔNOA across the six time periods, we are unable to do so at conventional levels for *SUE*. Our results in Table 2 indicate that PEAD got weaker until 2002; however, this trend did not continue in the 2003–2009 period. Closer inspection of the results (unreported) show that the most recent three-year period has generated insignificant returns for both ΔNOA and *SUE*, but that the 2003–2005 period produced a marginally positive return for *SUE* but not for ΔNOA.

To help get a sense for whether the returns to the ΔNOA and *SUE* characteristic portfolio are robust to an analysis of actual transaction costs, we include additional columns that are based on stock specific transaction costs. As described above, actual transaction costs are based on the trading impact, which is partly a function of portfolio size. We assume an initial portfolio of $400 million at the start of 1979 (pre-leverage) and assume that profits are reinvested in the portfolio, so for example the ΔNOA characteristic portfolio grows to $6.4 billion at the end of the period. Note that this assumption means that the trading impact, and hence transactions costs, increase over time. The return for each security is reduced using the same transaction cost model described in subsection 5.3, which is a direct function of portfolio size. Given that we start the initial portfolio at $400 million in 1979, we are subtracting larger transaction costs in the more recent time period. The returns after transaction costs in Table 2 provide even stronger evidence that the returns to the ΔNOA and *SUE* characteristic portfolios have attenuated in recent years.[14]

[14] In unreported tests we have replicated the analysis in Table 2 using equal-weighted, value-weighted and linear weight portfolios. Across all regression specifications, we find that the average return for the ΔNOA and *SUE* characteristic portfolios is not significantly different from zero in recent years, suggesting that the increased market impact associated with the growing size of the optimal portfolios reported in Table 2 is not driving the attenuation in returns.

Table 3
Ex post return analysis (Fama-French) of accrual anomaly.

Panel A: ΔNOA returns
$R_t^{\Delta NOA} = \alpha + \beta^{MKT} R_t^{MKT} + \beta^{SMB} SMB_t + \beta^{HML} HML_t + \varepsilon_t$

$R^{\Delta NOA}$ is the monthly return to the respective ΔNOA portfolio. ΔNOA is measured as defined in Section 5.1.
R^{SUE} is the monthly return to the respective post earnings announcement drift (PEAD) portfolio. *SUE* is measured as the ratio of seasonally differenced quarterly operating income deflated by average assets, to the standard deviation of this seasonally differenced profitability measure using the trailing 12 quarters.
For the before and after transaction cost portfolios, we rebalance portfolios every month using ΔNOA or *SUE* information at the start of the month and returns for that month. The investment universe is the largest 1,000 securities based on market capitalization at the start of the month. Portfolios are rebalanced monthly to achieve a target annualized risk of 10%. Portfolios are fully invested with individual positions limited to be no more than 5% of the total portfolio. Both the before and after transaction cost portfolios are identical, the difference is the inclusion of actual trading costs from the latter.
The linear weight portfolio contains every security with weights directly proportional to the magnitude of the respective measure. These portfolios are evaluated only on a before transaction cost basis.
The equal and value weighted extreme decile portfolios contain only those securities in the top and bottom 10% of each monthly cross-section based on the respective measure. These portfolios differ only in terms of the weights assigned to the constituents of the extreme deciles. These portfolios are evaluated only on a before transaction cost basis.
R^{MKT} is the monthly excess (to risk free rate) market return.
SMB is the monthly mimicking factor portfolio return to the size factor. Data obtained from Ken French's website.
HML is the monthly mimicking factor portfolio return to the value factor. Data obtained from Ken French's website.
The Sharpe ratio is calculated as the ratio of the annualized return (as measured by the intercept) relative to the annualized standard deviation. As Lewellen (2010) notes this is a simple transformation of the Fama-Macbeth test statistic and is computed as $\sqrt{12}/\sqrt{358}$ multiplied by the respective Fama-Macbeth test statistic, where 358 reflects the number of months used in the Fama-Macbeth regression.
Our ΔNOA characteristic portfolio is formed with a 10% annualized risk target.
358 monthly observations from 1979 to 2008 are used for this time series regression. Each portfolio is formed the same initial universe (the largest 1,000 US securities by market capitalization at the start of each month).

There are many reasons as to why the relation between anomaly variables and future returns has attenuated over time. The explanation we find most appealing is "adaptive" market efficiency (e.g., Grossman and Stiglitz, 1980), where capital market participants learn about the relevance of information for security prices, and prices adjust accordingly. Additional empirical analysis such as the following could strengthen this claim: tracking time series variation in buy- and sell-driven volume at the time that financial statement information is released to the market (increases in sell-driven volume contemporaneous with increases in ΔNOA in more recent years is consistent with the market responding more quickly to this information); tracking aggregate capital flows associated with investors who are known to exploit these types of anomalies (returns to these anomalies should decrease as such flows increase); and exploiting cross country variation in the strength of the relation between measures of accruals and future returns and the covariates described above. Green et al. (2009) also note the attenuation of the relation between a measure of current accruals (e.g., the change in non-cash working capital construct in Sloan, 1996) and future stock returns. They find this attenuation to be coincident with an increase in capital allocation to that strategy, a finding that they argue is consistent with adaptive market efficiency. As noted above there are additional analyses to strengthen this assertion, and we leave this more comprehensive analysis to future research. Further, it is important to note the possibility that time varying expected returns could explain the attenuation in the return profile of the Δ*NOA* and *SUE* characteristic portfolios (e.g., Chen et al., 1986; Wu et al., 2010).

In summary, we find that the negative relation between accruals (and drift) and future returns is evident in portfolios that are constructed to optimally trade off expected returns and risk; is robust to a more comprehensive, ex ante and ex post, treatment of transaction costs; and there is a substantial deterioration in this relation in the last five years which is consistent with an adaptively efficient market (e.g., Grossman and Stiglitz, 1980; Lo, 2004).

5.5. *Is all this extra effort worth it?*

Up to this point, we have replicated the negative relation between accruals and future returns and PEAD with a portfolio that is optimized over forecasts of risk and transaction costs. These risk forecasts and transaction cost forecasts are used in practice, and it is important that academics understand them and why they matter. The academic hurdle of abnormal performance is often higher than that in practice because academics do not optimize (much) on risk. In contrast, in practice, the optimization approach chooses low risk, low transaction cost stocks from among those with similar alphas. Academics often ignore this last step except in some approaches like a weighted least squares regression where weighting is on the basis of volatility. On the other hand, practitioners must weigh the benefits of the additional complexity from including forecasts of risk and transaction costs against the costs of such effort.[15] In this subsection, we illustrate the benefit from improved forecasts of risk in the context of examining the Δ*NOA* and *SUE* characteristic portfolios.

The typical academic anomaly paper sorts each cross-section into deciles or quintiles based on the variable of interest (e.g., accruals) and takes a long (short) position in the extreme deciles. The equal- or value-weighted difference of these extremes is termed as a zero-cost investment strategy. In contrast, the approach described in Section 5.4 takes the sorting variable (accruals) and combines it with forecasts of risk and transaction costs to derive an optimized set of portfolio weights. We term the resulting portfolio the "optimized portfolio" for our discussion here. So we are comparing the zero-cost investment strategy with the optimized portfolio.

Table 3 shows the ability of the standard Fama-French factors (*MKT*, *HML* and *SMB*) to explain five sets of portfolio returns for both the Δ*NOA* and *SUE* measures: (1) optimized portfolios not accounting for actual transaction costs; (2) optimized portfolios accounting for actual transaction costs; (3) portfolios whose weights are directly proportional to the relevant measure (e.g., every security is included in the portfolio with its weight determined solely by the magnitude of the Δ*NOA* or *SUE* measure; (4) equal-weighted returns of a zero-cost investment portfolio that is long (short) the bottom (top) 10% of firms based on the relevant measure; and (5) value-weighted returns of a zero-cost investment portfolio that is long (short) the bottom (top) 10% based on the relevant measure.[16]

There is a very noticeable difference in the risk profiles across these sets of returns. In all cases the ability of the standard Fama-French factors to explain the returns are similar (i.e., all have very low R^2), and most portfolio returns have statistically significant intercepts suggesting an anomalous return relation. It is important to note that the statistical significance is much weaker for the latter three simpler portfolio construction approaches. This is particularly true for the Δ*NOA* portfolio returns. Annualized Sharpe ratios from the 358 months of data support this inference: the Sharpe ratio for the optimized portfolio before (after) transaction costs is 1.51 (0.78) and that for the various before transaction cost simpler approaches are about 0.55.[17] While this difference in Sharpe ratio is impressive, it is not that surprising as the risk forecast is calibrated to do precisely the following: build a portfolio that not only captures one's expected return but also minimizes risk at the portfolio level. The simpler approaches, including the linear-weight portfolio, do not make any explicit attempt to control for cross-sectional differences in expected risk.

Perhaps a reason why this optimized portfolio-level analysis has not been performed in the past is a lack of ready access to standard common factor models. Future research could either seek to build/refine such common factor models from first principles as described in Section 5.4., or could directly use common factor models from providers such as BARRA and Axioma. By using optimized portfolios it will be easier for researchers to make stronger inferences about the implementability of anomalous return patterns. Of course, such an analysis should also try to incorporate an ex post analysis of transaction costs as discussed above in Section 5.4. While this ex post treatment of transaction costs can never be complete, it is important for researchers to understand the impact of portfolio turnover and security characteristics, to be sure that the anomalous returns are at least plausibly greater than expected transaction costs.

[15] Obviously, investors' utility functions would incorporate these costs and benefits. Moreover, Grinold and Kahn (2000) show how utility functions are monotonically related to statistics such as the Sharpe ratio (or information ratio).

[16] We did not have an easy way to modify the transaction costs for the linear, equal and value weighted portfolios primarily due to the file structure on the optimization software we were using. This is a limitation from the analysis, but the point of the empirical exercise is served via the before and after transaction cases with the fully optimized portfolios. The reduction in Sharpe ratios would be similar for the other three cases as they exhibit similar levels of portfolio turnover.

[17] One approach to testing the relative attractiveness of the two series of portfolio returns is to treat them as asset returns and run standard tests for identifying efficient portfolio weights (e.g., Britten-Jones, 1999). This test simply regresses a vector of 1 s against the time series of the relevant asset returns and the coefficients from the regression provide the optimal in-sample weight to achieve the best (i.e., closest to an arbitrage opportunity) returns for an investor. Comparing the returns to the before transaction cost optimized Δ*NOA* characteristic portfolio and the three simpler Δ*NOA* portfolios suggests that the optimal weight on the optimized portfolio is greater than 80% (and significantly different) in all three cases.

For future research looking to study anomalous relations and attempt to assess whether documented returns exceed plausible transaction costs, we would recommend the approach in Korajczk and Sadka (2004). In addition researchers could try weighted least squares regressions in addition to standard OLS regression. The weights in these cross-sectional regressions could be inversely related to volatility (risk and transaction costs are an increasing function of volatility) and/or positively related volume (transaction costs are inversely related to volume). These approaches will only give approximate solutions to the more general optimization as (i) they do not solve for the precise form of the weighting function, and (ii) they are not attempting to explicitly trade off returns, risk and transaction costs.

5.6. Discussion and caveats

Our goal in this section was to illustrate the effect of a more comprehensive treatment of forecasting risk and transaction costs. A primary motivation for this analysis is to help shed light on the risk versus mispricing debate that permeates a significant fraction of the academic literature devoted to 'anomalies.' Specifically, the association between a given attribute and future stock returns is always subject to the two competing explanations of risk and mispricing. Under the risk explanation, the relation between the attribute and future stock returns is explained by a risk premium for firms with that attribute. Under the mispricing explanation, the relation between the attribute and future stock returns is caused by capital market participants failing to incorporate the impact of the attribute for future prices (typically through changes in expectations about future earnings for the types of attributes that we discuss in this survey). Absent an agreed upon asset pricing model, it is difficult to distinguish between the two explanations. In summary, our analyses in Tables 2 and 3 suggest large returns that are difficult to explain using existing asset pricing models. The magnitude of these returns, while still statistically significant, has diminished substantially in economic magnitude in recent years.

For those who are still unconvinced about the risk/mispricing debate and argue that measures of accruals reflect differences in discount rates or time varying expected returns (e.g., Wu et al., 2010), there is a natural experiment ahead: as time moves forward will the negative relation between accruals and future stock returns re-appear? If it does not, then the claim that 'accruals' is a (time varying) risk factor is not valid. If it does, then the claim that it is a risk factor may be valid. To the extent that capital flows determine prices and there is time series variation in flows following certain attributes, then time series variation in associations between attributes and future returns could be attributable to these flows. To help disentangle these explanations, future research could measure aggregate flows and differentiate these flows from time varying risk characteristics (e.g., macro-economic state variables).

6. Suggestions for future research

In this section, we bring together the streams of research discussed in prior sections, the feedback from the academic and practitioner questionnaire, and our own insights to make suggestions for future research on the use of accounting information in forecasting both future firm fundamentals and future returns.

We first emphasize that research into accounting anomalies and fundamental analysis is far from dead. The analyses reported in Section 5 suggest that some well known anomalous relations have waned over time. This does not mean that the forecasting role of accounting information has disappeared. Indeed, as a profession, we may have barely touched the surface of this topic. To help illustrate the potential benefit from improved forecasts of future earnings, consider the returns to a perfect forecast earnings strategy. Even with perfect foresight of future fundamentals, there is still a large portion of return variation that is not known (e.g., Easton et al., 1992 show, at annual horizons, that earnings is only able to explain less than 10% of the variation in stock returns).

Perfect foresight in fundamentals has, unsurprisingly, very impressive returns. Specifically, for the 1998–2008 period, a portfolio that took long (short) positions based on future changes in earnings would have generated (on a pre-transaction cost basis) a Sharpe ratio of 3.56. This is substantially larger than the 1.51 Sharpe ratio for the pre-transaction cost ΔNOA optimized portfolio described in Section 5.5. This suggests a potential benefit from improved forecasts. Clearly, this is a high hurdle, but one that has considerable potential reward. It is, of course, an open empirical question as to the possible improvement from current forecasts embedded in price. It is conceivable that we are already forecasting earnings as well as possible. If so, there are no potential rewards to better forecasts, as we are already forecasting as well as possible. While it is certainly possible we have the best forecasts at present, future research can and should attempt to refute this assertion.

In the following subsections, we organize our suggestions of future research into areas where we see the greatest opportunity for interesting future work on forecasting firm earnings and returns. We try not to simply add to the laundry list of accounting attributes examined in the past. Rather, we encourage researchers to exploit the breadth of data about firms that are available to them as they start to build the framework alluded to above. Our suggestions for future research primarily stem from the perspective of an equity investor.

6.1. Improved forecasting frameworks

A striking feature of the current state of accounting anomalies and fundamental analysis is how knowledge of the accounting system itself is not fully exploited to link accounting information to stock prices and returns. Eq. (1) introduced in Section 4 is clearly a sound theoretical support for research into accounting anomalies and fundamental analysis, but it is tautological. Recent papers such as Fama and French (2006, 2008) and Penman and Zhang (2006) recognize this tautology and attempt to bring a number of forecasting variables together, and try to do so in a logically consistent manner. Future research needs to start from a sound appreciation of the accounting system that generates the primary inputs for forecasting (i.e., book value and earnings) and the process by which security prices are determined. There has been an enormous amount of work on the latter point as evidenced by the numerous papers on empirical asset pricing. However, what is missing is an appreciation of the accounting system that creates many of the inputs to those asset pricing models (e.g., B/P, investment growth, and profitability).

We believe there is a significant opportunity at present for accounting researchers to benefit from their knowledge of accounting systems to identify key interrelations between accounting data, start to build a cohesive forecasting framework, and to combine this accounting knowledge with work in the empirical asset pricing literature. While some recent research has started to do this (e.g., Penman and Reggiani, 2010), there is still a considerable amount of work to be done in this regard.

Ohlson (1995) is perhaps the most relevant framework for empirical research in accounting anomalies and fundamental analysis to start from. Recent research by Chee et al. (2010) attempts to enrich equation (1) above with known properties of the accounting system. Chee et al. use the linear information dynamics in Ohlson to additively decompose the ex post stock returns over a rolling five year period into a fundamental and speculative component. The fundamental component of stock returns is justified by the realized fundamentals over the five-year period (i.e., cum-dividend residual earnings), and the forecast of the persistence of this five-year residual income. This decomposition exploits the fact that earnings are more persistent when they are aggregated over longer horizons (e.g., Easton et al., 1992). Chee et al. find that the speculative component of returns exhibits the strongest mean reversion. They show that when returns over the last five years are not the result of past cumulative cum-dividend earnings and/or that past cumulative cum-dividend earnings is not expected to be persistent, then past stock returns are more likely to mean revert. We view Chee et al. as a good example of how research in accounting anomalies and fundamental analysis can better exploit knowledge of the accounting system to help generate superior forecasts of future earnings and returns. The framework in Chee et al. has extensions that include improved measures of expected returns and improved forecasts of persistence in residual income.

6.2. Using macroeconomic information

The majority of the surveyed literature examines the ability of accounting attributes in primary financial statements to help predict measures of future firm profitability and future stock returns. In the set of papers identified in our review, there is little use of macroeconomic information. However, there are a few exceptions, such as Basu et al. (2010) who find that analysts do not correctly account for inflation in their forecasts. More generally, incorporating macroeconomic information directly into the forecasting framework is likely to be a fruitful area for future research.

There is a wealth of macroeconomic information that can be used as part of the exercise to build forecasts of future firm fundamentals. Examples include industrial production, inflation expectations, aggregate risk premia, term structure, commodity prices, currency movements, etc. Given the large set of candidate macroeconomic information that can be used, the associated risk of in-sample data over-fitting is large. Furthermore, these macro variables are interdependent and one needs to impose some structure on this exercise to ensure that the problem is tractable, yet still retains sufficient interdependencies to be useful for forecasting. To date, academic research has tended to use macroeconomic information primarily in the context of ex post analysis of returns (e.g., Chen et al., 1986). We would like to see more use of this kind of information, ex ante, to help condition the relevant set of forecasting variables for future earnings and returns. We would expect the selection of the macro variables to be based on sound economic reasoning. A simple framework could work as follows: identification of income sensitivity to various macroeconomic state variables (e.g., interest rates, consumer sentiment, currency movements), and then incorporation of a forecast of the relevant macroeconomic state variables into forecasts of company-level earnings and possibly returns. For example, the knowledge that the income of Hennes and Mauritz (a Swedish-based retailer) has a significantly negative sensitivity to movements in the U.S. dollar, primarily due to contractual commitments in U.S. dollars, can be used in combination with information on how the U.S. dollar has (or even is likely to) moved in relation to H&M's reporting currency to forecast future earnings. Specifically, changes in exchange rates lead to a direct translational impact on reported earnings as well as an arguably longer term transactional effect where end consumers alter their consumption patterns in response to currency movements. Together these effects affect reported earnings. While this approach certainly brings additional complexity to the forecasting exercise, it is an open empirical question as to whether it helps generate superior forecasts of firm earnings and firm value.

6.3. Using accounting information beyond what Is contained in the primary financial statements

The vast majority of the research examining accounting information in the context of security pricing emphasizes the primary financial statements. This is not an arbitrary research design choice. The primary financial statements provide an articulated view of the firm's ability to generate future earnings and associated free cash flow to capital providers. But there is clearly a large amount of contextual information beyond that contained in the primary financial statements, which is still relevant for forecasting future earnings and returns. There are numerous industry specific metrics that are relevant for forecasting future earnings. Examples include same-store sales metrics for retailers, load factors for airlines, capacity utilization for manufacturers, etc. Such metrics are often available in financial reports and other times will be collected by other third party data providers. Academic research in accounting and finance has typically not made use of this information explicitly or to help condition standard models of earnings persistence. When teaching financial statement analysis, we typically seek to understand the relevant key success and risk factors for relatively homogenous firms (e.g., industries). We conjecture that if we incorporate this improved understanding in our research, it will result in superior forecasts of earnings and stock returns. A good example of research that makes thoughtful use of this kind of information is Amir and Lev (1996), who examine industry-specific metrics to help forecast profitability in a technology-intensive industry.

Another source of additional information is the notes to the financial statements. Examples include the ongoing debate on the differential value relevance of information disclosed in the financial statements relative to that disclosed in the footnotes and the more general value relevance study of pension related items, fair value disclosures for banks, etc. These papers (e.g., Davis-Friday et al., 1999) mostly document contemporaneous relations between footnote items from general purpose financial reports and stock returns. Our focus is on the ability to forecast future earnings and stock returns.

Recent research that uses additional information to forecast earnings and stock returns include the use of valuation assumptions related to the expensing of stock options and option exercise decisions (e.g., Bartov and Mohanram, 2004; Bartov et al., 2007). Another example is Li (2008) who computes measures of 'readability' of the annual report and documents that firms with easier to read financial reports have more persistent earnings. Several recent papers also examine footnote disclosures of fair-value, level 1, 2, and 3, financial assets to condition measures of book value for the purposes of equity valuation (e.g., Goh et al., 2009). Likewise, some recent research has explored the information contained in detailed pension and tax footnotes to help improve forecasts of future earnings and stock returns (e.g., Franzoni and Marin (2006) for pension funding status; Hanlon (2005); Thomas and Zhang (2008) for tax footnote related information).

There is much information contained in the general purpose financial reports and it is becoming increasingly easy for users to access this information through the tagging of tables and text that accompany the primary financial statements. The development and U.S. adoption of eXtensible Business Reporting Language (XBRL) and the increasing sophistication of natural language processing machinery (e.g., Manning and Schutze, 1999) means that users now have substantially more information in machine readable form to conduct large-scale archival analyses for the usefulness of that information for forecasting purposes. The set of information contained in financial reports is too detailed to list, but we expect to see research efforts utilizing this information to be worthwhile.

6.4. Using information from (and for) credit markets

Accounting information is useful to all investors, not just equity investors. For example, creditors are interested in protecting their principal and ensuring the ability of the firm to service their interest obligations, and outstanding debt. An example of the potential use of accounting information from the perspective of a creditor is in the context of default. Accounting information can be used on a standalone basis (e.g., Altman *Z*-Score (1968) and Ohlson *O*-Score (1980) type discriminant models) or in conjunction with structural models (e.g., Moody's/KMV Expected Default Frequency, EDF) to build forecasts of expected default. These default forecasts can in turn be used to assess the relative quality of prices in credit markets. The potential for extending the use of accounting information for forecasting aspects of future firm performance and the related pricing of securities is significant. A primary reason for this is the recent development of credit-default-swap (CDS) contracts and the significant increase in the CDS market for publicly traded companies.

Perhaps one of the most exciting aspects of credit market data is that researchers can track prices of multiple securities for a given firm, and each of these securities differs in its earnings (cash flow) participation. This richness in capital structure creates unique opportunities to combine information across segmented capital markets (the marginal investor is likely to be different across these markets) for the purposes of forecasting, to examine whether the entire capital structure is efficiently priced, and to examine different aspects of the accounting information that are relevant across the capital structure. Financial economics theory suggests that there exist certain agency costs associated with having both equity and debt financing in the capital structure. These theories, such as debt over-hang, over-investment, asset substitution, have implications for future firm profitability, and are now testable with the rich credit market data, which is only recently available.

6.5. Lessons from the 'crowded' market of August 2007

One of the key challenges in making suggestions for future research is that it is difficult to extend a relatively mature field. The case of identifying accounting variables that help predict future earnings and stock returns is no exception. Markets are competitive and incentives are such that inefficiencies should be quickly spotted and exploited. On average this is true. Indeed, the set of information on which investors base their decisions is increasingly similar. The market experience in August 2007 highlights this issue. The summer of 2007 was the start of unprecedented market volatility. As discussed in Lo and Khandani (2007), a large multi-strategy investment vehicle allegedly had to deleverage in the first week of August 2007. The more liquid securities in this multi-strategy investment portfolio were equity instruments that were then liquidated. This price pressure caused a significant feedback loop in the market. Systematic (or 'quant') investors discovered that they were holding correlated portfolios and additional investors were forced into closing out positions due to their leveraged portfolios and the need to meet margin calls. This natural experiment presents an opportunity to assess the relative 'uniqueness' of a given investment strategy. Future research could make use of this setting to help document whether a given accounting attribute used for forecasting is 'novel.' Specifically, if the characteristic portfolio of a given attribute does not experience a drop in the middle of August 2007, then it is less likely that this is a commonly used forecasting attribute. This is useful to know as it helps enrich our understanding of what is new and additive in forecasting future earnings and returns. Of course, the usefulness of this approach is limited as investors change their practices over time and thus the price pattern in August 2007 is no longer representative of the new conventional thinking. But it is, at least, a barometer for the uniqueness of the forecasting insight.

More generally, the event of August 2007 created awareness of additional dimensions that could and should be part of empirical research efforts examining accounting attributes and future returns. First, research could exploit information on trading volume to complement returns-based analyses. For example, tracking abnormal volume around the dates at which accounting information arrives at the market can help isolate how aggressively a given accounting attribute is traded upon. This empirical exercise has become easier for securities listed on the NYSE as that exchange now provides signed volume information, allowing for more precise inferences about trading aggressiveness on the direction of the accounting information. Second, the speed with which accounting information is incorporated into stock prices is typically given only a cursory treatment in academic research. This would necessitate looking at daily, weekly, or monthly returns and documenting the return relation for a given horizon (e.g., one or two weeks ahead). This type of analysis can help researchers understand time series changes in price discovery. Third, it is interesting to assess the influence of aggregate capital flows on the relation between a given accounting attribute and future returns. While we can debate the precise amount of capital necessary to ensure complete price discovery, it seems unambiguous that as more capital seeks to trade on a given attribute, then the relation between that attribute and future returns will diminish. Recent research by Green et al. (2009) is starting to examine these relations. As discussed in Section 5.5., they find that the relation between measures of accruals and future returns attenuated as significant amounts of capital were invested into quantitatively oriented strategies that focus on exploiting accounting information. This type of analysis can readily be extended to other accounting attributes and to other markets to help sharpen our understanding of price discovery.

6.6. Using alternative archival research techniques

The most common statistical technique used in the surveyed archival research papers is cross-sectional and/or panel linear regressions. The general linear model seems reasonable as a first approximation. But there are a variety of other approaches that could be used to help improve our ability to forecast future fundamentals and stock returns. In this subsection we make a few suggestions for future research along with some recent examples.

There is a substantial literature examining structural relationships within social networks. The field of social network analysis has its roots in sociology, social psychology, and anthropology with the development of graph theory and sociograms to capture the relationships between members of a network (e.g., Moreno, 1934). This research area has only recently received attention in the accounting and finance literatures (see, e.g., the analysis in Kuhnen, 2009), on the impact of mutual fund linkages and mutual fund performance). The techniques developed in social network analysis can be applied to any setting where there are relations between agents in the same network and there is reason to believe that these links impact their decision making (e.g., firms in the same industry). The structural linkages between firms implied by these networks could improve the forecasts of future firm profitability. Cohen and Frazzini's (2008) analysis of the links between customers and suppliers from supplemental financial statement disclosures is an example of how to use information about structural linkages between firms to generate improved forecasts of future firm performance. Cohen and Frazzini show that identification of customer-supplier relationships from required footnote disclosures about material customers is effective at capturing economically meaningful links. Specifically, they show a strong lead-lag relation between the fundamentals and stock returns of customers and suppliers: supplier's fundamentals and stock returns move, with a lag, to that of their key customers. A related body of literature is the intra-industry information transfer research, which documented spillover effects from one firm onto another (e.g., Baginski, 1987).

One aspect of these networks that is often over-looked in previous accounting and finance research is their density. As an example, Fig. 2 gives a graphical representation of the links between directors of public companies listed on the Australian Stock Exchange. Fig. 3 shows the linkages between Japanese firms in 2008 based on cross-holdings between companies: this is clearly a very dense network. We show these two graphs as examples of the types of links that exist between firms (e.g., over-lapping directors and cross-equity holdings), and to help visualize the richness of measures that can be extracted. There are many other ways in which firms can be linked and there are many measures that can be extracted from such graphs. It is not only the links between individual firms that matter for the purposes of capturing spillover effects, but also the overall inter-connectedness of the network (see, e.g., Scott, 2000).

The majority of empirical research on accounting anomalies and fundamental analysis assumes that the underlying data generating process is the same for all firms. This need not be true. For example, the persistence of abnormal earnings

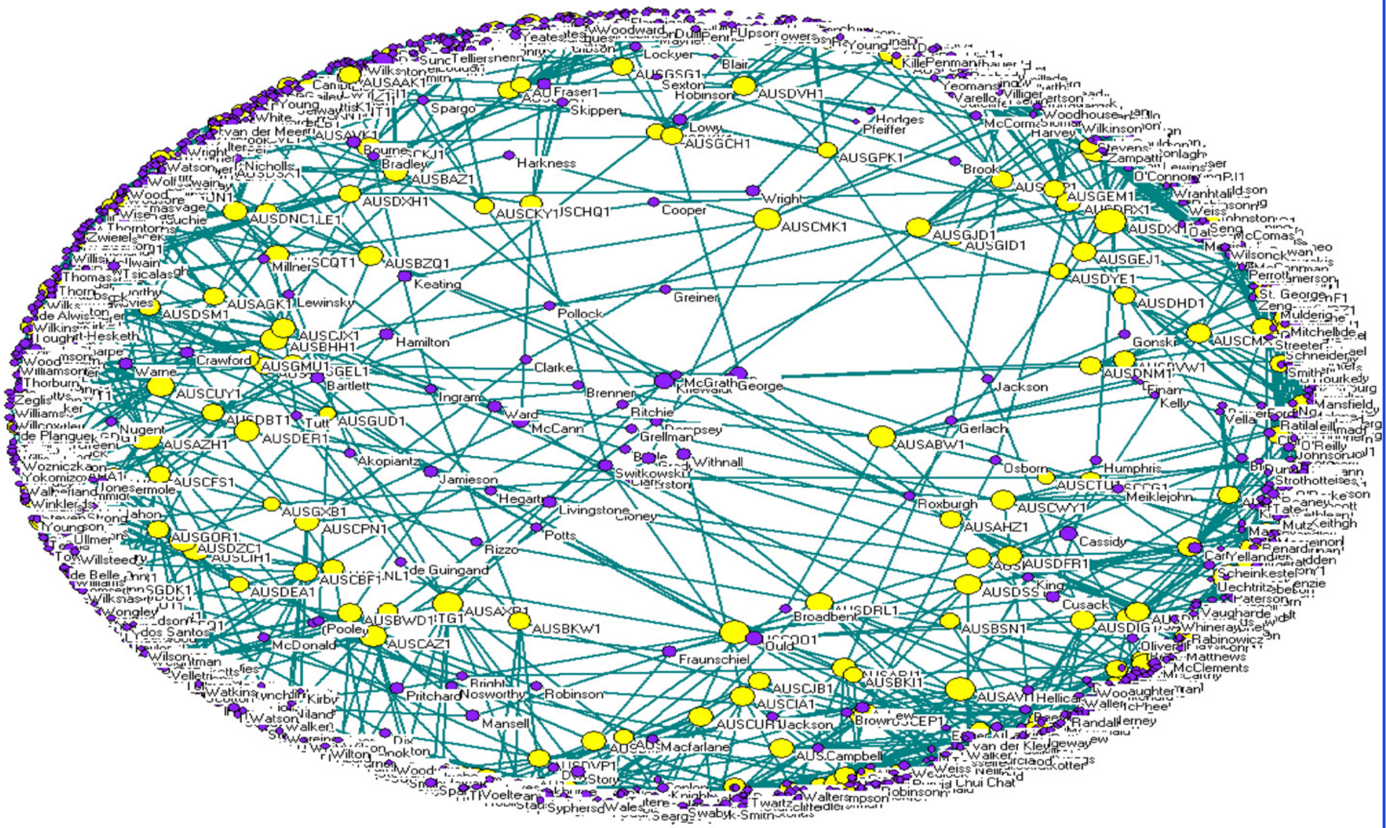

Fig. 2. Graphical representation of linkages between board director members in Australia (ASX 200 companies).

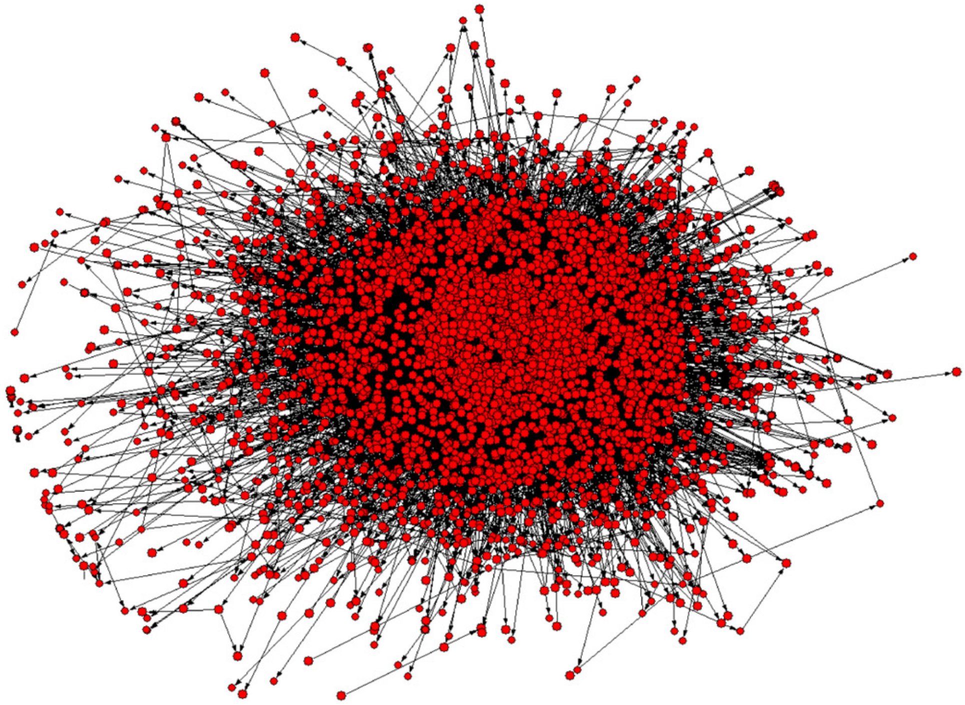

Fig. 3. Graphical representation of linkages between Japanese firms as of 2008 based on cross-equity ownership.

may not vary solely based on industry membership: it may vary on other difficult to observe characteristics. The traditional research paper would suggest candidate conditioning variables and then progressively add interaction effects to test for their significance. Alternative approaches to adding progressively more interaction variables include Bayesian hierarchical linear modeling, where the strength of an attribute on future earnings or stock returns is directly a function of firm characteristics; and the cluster-wise regression and recursive partitioning, where the researcher allows the relation between an attribute and future earnings and/or returns to be non-linear and to have complicated interaction effects. Research in areas other than fundamental analysis has made some use of these techniques (see e.g., Bushee and Goodman, 2007; Larcker and Richardson, 2004; Larcker et al., 2007). Valid criticisms of these approaches are that they are less theoretically motivated and are at risk of in-sample data fitting. However, this latter concern can be mitigated through the use of out-of-sample cross validation techniques, which researchers can then use to build superior forecasting models.

7. Conclusion

In this survey, we highlight recent advances in accounting anomalies and fundamental analysis. A key theme to our survey is that information contained in general purpose financial reports helps facilitate better decision making about the allocation of scarce economic resources from an investor's perspective. We focus our attention on research whose primary aim is to forecast earnings and stock returns.

In conclusion, we offer a few philosophical comments about the entire literature we review. The debate about market efficiency, which underpins a large portion of the literature on the use of accounting information for security pricing, has moderated substantially over the years. Grossman and Stiglitz (1980) make the pertinent observation that security prices need to become efficient and this can only happen if capital market participants actively trade on useful information driving security prices toward a 'true' price. In this sense the capital market is adaptive in its efficiency (see e.g., Lee (2001) and Lo (2004) on market efficiency from an evolutionary perspective). The analysis that we provide in Section 5 speaks to this issue directly: markets adapt over time and what was once mispriced now appears to be correctly priced. This field of research is coming full circle: by documenting robust relations between a given accounting attribute and future stock returns; the research process helps improve market efficiency.

Much prior research has attempted to 'explain away' anomalous return patterns by showing that the association between a given attribute and future stock returns is concentrated in a subset of firms. These subsets tend to contain smaller, less liquid securities where transaction costs and/or idiosyncratic risk are greater (e.g., Fama and French, 2008). This is a useful and informative literature, but there is a risk of misinterpreting the results. Market (in)efficiency is clearly related to these partitioning variables. When securities are more liquid and information is more readily available, we would expect security prices to be more efficient. Thus, finding that a relation between an attribute and future stock returns is concentrated in a subset of less liquid securities is not prima facie evidence in support of market efficiency. It may well still be possible to successfully exploit an anomaly in this subset of securities, and, in Grossman-Stiglitz terms, receive an adequate compensation for that effort, but of course, only to the extent that the additional transaction costs incurred from trading in smaller, less liquid securities is compensated by higher levels of returns.

With the wealth of information available to investors today, and the computational power available for empirical archival analysis, there is a risk of information overload, which could exacerbate frictions in the market and impede the price discovery process. There has been considerable research on information over-load and the impact that this could have on the price discovery process (see e.g., Daniel, Hirshleifer and Teoh (2002), and Libby et al. (2002) for surveys of this literature). Going forward, we expect the quantity of information, as well as the ease with which researchers can access it (i.e., machine readability), to increase. The joint impact of increased information, and an increasing ease for investors to process and manipulate this information, on the ability of investors to forecast earnings and stock returns will continue to be a productive research field.

Our ability to conduct archival analysis has increased through time both in terms of research design and in terms of computing power to manipulate large data sets. This increased ability creates a significant 'inefficiency bias' in research that uses long time series of data. The further one goes back in time to examine associations between an attribute and future stock returns, the greater this risk. In some sense, it is relatively 'easy' to find an 'anomaly' in the 1960s, 1970s, and even in the 1980s. It is much harder to do so in the last ten years. Part of this is attributable to advances in computing ability, but part is surely attributable to the increase in capital invested on the basis of many of the insights discussed in this review.

A common thread that we weaved throughout our survey is the ability of accounting information to help forecast future earnings and future stock returns. This is a necessary condition for the usefulness of the research effort (i.e., are we able to improve our forecasts?). It is a separate question as to whether security prices reflect that information on a timely basis. For example, the question of whether an attribute is associated with future stock returns is the focus of much of the literature that we have surveyed. We would like to re-emphasize that this understates the potential usefulness of this field of research. Given the multiple other users of general purpose financial reports (e.g., customers, suppliers, competitors, management, etc.) that make financial decisions, analysis to improve forecasting models of future earnings is invaluable regardless of the answer to the risk vs. mispricing debate.

Finally, we believe that the accounting anomaly and fundamental analysis literatures have provided considerable influence to academics, standard setters, and practitioners by demonstrating the usefulness of accounting information to forecast future earnings and stock returns. This is an area that is at the core of the accounting profession. We are hopeful that future research will benefit from the suggestions offered in this paper and capitalize on the wealth of accounting information that is available for forecasting future earnings and stock returns. We would like to remind researchers of the opportunities to be gained from improved forecasts of future earnings. It is still the case that perfect foresight of future earnings would generate a very profitable investment strategy. So, while it may be the case that forecasting has become an increasingly competitive activity, the rewards from undertaking this activity are potentially still substantial.

Appendix A. Summary of related survey papers

See Table A1.

Appendix B. Linkages between measures of accruals, investing and financing

Sloan (1996)

$$Accruals = (\Delta Current\ Assets - \Delta Cash) - (\Delta Current\ Liabilities - \Delta Short\ Term\ Debt - \Delta Taxes\ Payable) - Depreciation$$

Richardson, Sloan, Soliman and Richardson (2005)

$$\Delta Assets = \Delta Liabilities + \Delta Book$$

$$\Delta Operating\ Assets + \Delta Financial\ Assets = \Delta Operating\ Liabilities + \Delta FinancialLiabilities + \Delta Book$$

Abstract

The primary goal of this study is to provide a theoretical model that shows explicit solutions for equilibrium prices and derives the equilibrium required return for the firm's stock price. In other words, this theoretical study provides a direct link between accounting information, related to the firm's reports, and the cost of capital within an equilibrium setting. Accounting information is judged to be of high value because it affects the market's ability to direct firms' capital allocation choices. The findings showed that an increase in expected cash flows, coming from improvements in the quality of accounting information, leads to a reduction in the firm's cost of capital.

Keywords: Theoretical Model, Accounting Information, Cost of Capital, Stock Returns

1. Introduction and Literature

One of the key decisions a firm has to reach is the fundamental determination of its cost of capital. This has a substantial impact on both the composition of the firm's operations and its profitability, since shocks onto anticipated cash flows are reflected in the firm's cost of capital. Many studies have spent tons of ink coming up with proposals leading to a lower cost of capital. [1] argue that it is the environment of a firm, which is described by many parameters, such as accounting standards, market microstructure and information coming from the firm's reports, that really influences the accounting type of information that determines the firm's cost of capital and, consequently, its stock price.

Accounting information reduces information asymmetries, which lead to adverse selection in transaction activities in the stock market ([2]) as well as to enhanced liquidity, which lowers the discounts at which firms must issue capital ([3]). [4] argue that accounting information tends to compensate shareholders through stock returns by reducing their exposure to investment risks. Research in asset-pricing models has not, so far, modelled explicitly the accounting information environment in determining the firm's required return, though [5] argue that more factors other than market risk could be equally responsible for determining a firm's financial aggregates, such as stock returns. Neglecting such a factor, however, places the concept of market efficiency in serious dispute, a fact that played a prominent role in the recent global financial crisis. According to [6], although theoretical arguments support the view that new accounting information leads to changes not only in firm's stock prices, but also in the traded volume due to the enhanced effect of informed traders, the empirical evidence does not seem supportive to the above argument. [6] finds that excess returns do change upon the arrival of new accounting information, but only if the new information set can impact the trading activity, the firm's ownership characteristics, and the family-firm status.

This study is an extension of two empirical works by [7,8] that investigate empirically the impact of accounting information on the firm's cost of capital and, then, on firm's stock returns. Their result present that certain accounting information variables, directly related to the firm's operation and originated from the firm's financial reports, exert a true impact on the cost of capital and, thus, on firm's stock returns. While the empirical analysis provides some important results in the relevant literature, a theoretical model is needed to support those empirical findings. Thus, the primary goal, and the novelty as well, of this study is to provide a theoretical model that shows explicit solutions for equilibrium prices and also derives the equilibrium required return for the firm's stock. In other words, it attempts to investigate the link between accounting information and the firm's cost of capital. To the extent that accounting information affects expected cash flows, it also affects the firm's costs of capital. Therefore, this theoretical study will provide a direct link between accounting information related to the firm's reports and the cost of capital (so as between the cost of capital and firm's stock returns) within an equilibrium setting. Accounting information is judged to be of high value because it affects the market's ability to direct firms' capital allocation choices. Moreover, higher accounting information improves the coordination between firms and investors with respect to capital investment decisions, resulting in an increase in expected cash flows without a commensurate increase in the firm's covariance with the market, which is expected to have a negative effect on the firm's cost of capital.

At this point we will attempt to connect the derived equilibrium stock price to the pieces of accounting information used in the empirical studies by [7,8] and to justify their empirical findings. At this point, we explicitly mention that emphasis is given on the disclosure of public information. [9] investigate the separation between public and private information and their role for the firm's cost of capital. They find that private information increases the risk to uninformed investors of holding the firm's stock, once informed investors are more capable of shifting their portfolio weights to incorporate new information. They also determine how in equilibrium the quantity and quality of information affects asset prices, leading to cross-sectional differences in firm's required returns. In such a framework, an individual firm can influence its cost of capital by choosing features like its accounting treatments and market microstructure. Their explicit suggestion is that more information is better than no information at all.

Overall, a firm's information structure affects its stock return. This dictates that a firm's cost of capital is influenced by information, providing an important linkage between asset pricing and the information structure of corporate securities.

Certain studies have attempted in the past to determine the role of accounting information. Empirical studies in the issue suggest that accounting information is negatively associated with the firm's cost of capital ([10-12]).

One main stream of related literature exemplifies the role of incomplete information. [13] investigates how the uncertainty, surrounding the presence of certain assets, influences capital market equilibrium conditions. Here the term incomplete is defined in a sense that not all potential investors know about every asset. His results display that in equilibrium the value of the firm is always lower under incomplete information conditions, while better information reduces the rate of return demanded by investors by improving risk sharing. The same results are also displayed by [14] through a reduction in estimation risk. However, [15] dispute the mechanism of estimation risk on the grounds that the effect of the investor base is susceptible to arbitrage, while there is much debate about the diversifiability and pricing of such risk, while [11] find a negative impact running from accounting information and the cost of capital. They find, however, that the association turns positive if higher levels of accounting information are caused by higher stock price volatility. [16] explore the relationship between the role of strategic disclosures and the cost of equity capital. Based on theoretical arguments, the association is expected to be negative, though the empirical analysis is mixed. Their empirical findings, however, confirm the above mentioned negative relationship due to the fact that their innovative model considers explicitly the role of timely strategic disclosure drawing on standardised Regulatory News Service (RNS) headings. [17] investigate how new accounting information, concerning the firm's leverage level, influences firm's stock prices. They find that the impact of such information is an increasing function of debt levels.

An alternative stream of research gives emphasis on the role of information disclosure by firms. Accounting information is the key turning private into public information. This is the framework in which our study belongs. [18], through an equilibrium model, shows that information production is costly, implying the need for each investor to expend resources to collect the needed information. [3] analyze how disclosure affects the willingness of market makers to provide liquidity by investing in a particular stock. They also show that disclosure changes the risks to market makers, which in turn induces entry or exit by dealers. [1,19] show that disclosure is affected by insiders and strategic issues, while [20] use a structural microstructure model, which provides estimates information-based trading for a large cross section of stocks. [21] reaches the same conclusions only if the accounting practices, *i.e.* those that contribute to accounting information, are characterized as aggressive. [22] investigate the influence of accounting information on individual giving decisions through its impact on market liquidity and the cost of capital for business entities. However, their experimental empirical results display a minimal of such impact. Finally, [23] find that higher levels of accounting information and disclosure due to the adoption of IAS lead to higher excess returns, results that are consistent with the negative impact accounting information exerts on the cost of capital.

Finally, there are liquidity-based models that indirectly link accounting information and firm's expected stock returns. [24] make use of a model in which investors with different expecting holding periods prefer to trade assets with different relative spreads since they demand compensation for those spreads. As a result, expected stock returns are increasing with spreads. [9] show a model in which investors demand lower stock returns if such stocks have greater public and less private information.

The remainder of this paper is organized as follows. Section 2 presents the theoretical model and provides certain comparative static's. Finally, Section 3 concludes the paper.

2. The Model

2.1. The Firm's Environment

The equilibrium model we employ is a variation of [18]'s model and captures the interaction between firms and investors in equity markets as well as the fundamental role of accounting information in improving the efficiency of firms' investment decisions. In such a way, reporting accounting information has real effects that determine the firms' cost of capital. Poor accounting information leads to misaligned investments, which rational investors anticipate and price in equilibrium by discounting firms' expected cash flows at a higher rate of return.

Our model deals with an economy with M_j firms, $j = 1, 2, \cdots, M$ and a risk-free rate. Let c_j and P_j be the uncertain cash flows of firm j and the market equilibrium price of firm j, respectively. We define the firm's j cost of capital as the rate of return R_j obtained from equating the price of firm j to its expected cash flows:

$$p_j = E(c_j)/(1+R_j) \quad \text{or} \quad R_j = E(c_j)/P_j - 1$$

Next, we assume that n_j shows a measure of accounting information which is disclosed by firm j to the firm's investors and the market. Our goal, as it was set above, is to determine whether an increase or decrease in firm's j accounting information leads to a corresponding decrease or increase in the firm's j cost of capital.

In the following step, we introduce a perfectly competitive market for firm's j stocks comprised of N_i investors, $i = 1, 2, \cdots, N$. Our investors are risk-averse. Without the hypothesis of risk aversion, the cost of capital turns out to be zero. Let also introduce an investor's utility function, represented by $U(c)$, where c denotes an amount of cash. Each investor has a negative exponential utility function, yielding:

$$U(c) = \alpha\left(1 - \exp\left[-c/\alpha\right]\right)$$

where α > 0 and describes the investor's tolerance for risk. This particular utility function has the characteristic that as risk tolerance becomes unbounded, the utility function converges asymptotically to risk neutrality, *i.e.* lim $U(c) = c$.

$$\alpha \to \infty$$

In a perfectly competitive market the market price for firm j we define the vector $D_i = \{D_{i1}, \cdots, D_{iM}\}$ as the 1xM vector of investor's demand for ownership in M firms. In other words, D_{ij} displays investor's i demand for firm j expressed as a percentage of the total firms. If now $D_i^* = \{D_{i1}^*, \cdots, D_{iM}^*\}$ displays the vector of endowed ownership in firms, *i.e.* D_{ij}^* displays the investor's i endowment in firm j expressed as a percentage of the total firms. Next, we define $P = \{P_1, \cdots, P_M\}$ the vector of firm prices, *i.e.* P_j displays the price of firm j. Finally, let B_i and B_i^* be investor i's demand for a risk-free bond and his endowment in bonds, respectively. The problem we are called to solve yields:

$$\max E\left[\alpha\left(1 - \exp\left[-1/\alpha\left(D_i\{c_1, \cdots, c_M\}' + B_i\right)\right]\right)\right] \quad (1)$$

w.t.r.t. D_i, B_i

or (see Equation (2))

w.t.r.t. D_i, B_i

where V is an MxM covariance matrix with the t-thy term defined as: $Cov(c_s, c_t)$ and D_i and B_i are the control variables of the system, subject to the following budget constraint:

$$D_i P' + B_i = D_i^* P' + B_i^*$$

The first order condition with respect to the variable D_i yields:

$$0 = E(c_j) - P_j - 1/\alpha \sum_{s=1}^{M} D_{is} Cov(c_j, c_s) \quad (3)$$

Since in the aggregate investors have claims to the cash flows of the entire firm, for each s it must be the case that:

$$\sum_{i=1}^{N} D_{is} = 1$$

Therefore, summing both sides of (3) with respect to i yields:

$$0 = N\left[E(c_j) - P_j\right] - 1/\alpha \sum_{i=1}^{N}\sum_{s=1}^{M} D_{is} Cov(c_j, c_s)$$

$$\max \alpha\left(1 - \exp\left[-1/\alpha\left(D_i\{E(c_1) - P_1, E(c_2) - P_2, \cdots, E(c_M) - P_M\}' + D_i^* P' + B_i^*\right) + 1/2\ 1/\alpha^2\ D_i V D_i'\right]\right) \quad (2)$$

or

$$0 = N\left[E\left(c_j\right) - P_j\right] - 1/\alpha \sum_{s=1}^{M} Cov\left(c_j, c_s\right)$$

The last expression implies that the stock price for firm j is defined as:

$$P_j = E\left(c_j\right) - 1/N\alpha \sum_{s=1}^{M} Cov\left(c_j, c_s\right) \quad (4)$$

According to (4), the price for firm j is equivalent to the one derived from the Capital Asset Pricing Model (CAPM). According to [25] and assuming that the risk free rate is zero, the CAPM is a market equilibrium pricing equation that yields the following association between firm's stock price and firm's cash flows:

$$P_j = E\left(c_j\right) - \left[\left(E\left(c_0\right) - P_0\right)/\sigma_0^2\right] Cov\left(c_j, c_0\right)$$

where c_0 represents the sum of cash flows coming from all firms in the economy, *i.e.* the market portfolio, σ_0^2 represents the variance of the sum of all cash flows, while P_0 is the sum of the stock price of all firms. Equation (4) and the above expression together yield:

$$P_0 = E\left(c_0\right) - 1/N\alpha\ \sigma_0^2$$

which, in turn, implies:

$$\left[E\left(c_0\right) - P_0\right]/\sigma_0^2 = 1/N\alpha$$

The above expression constitutes the price of covariance (or non-diversifiable) risk in the economy. According to the above setting, the price of firm j turns to be:

$$P_j = E\left(c_j\right) - 1/N\alpha\ Cov\left(c_j, c_0\right) \quad (5)$$

Equation (5) is equivalent to Fama's CAPM model as a market equilibrium pricing equation.

2.2. Cost of Capital

In this section we will attempt to figure out what factors can influence the firm's j cost of capital. Our analysis is totally based on Equation (5) that describes the evolution of the firm's j price of stock. To this end, we assume that firm's j cash flows are described by:

$c_j = a_j + b_j\theta + d_j\pi_j$

where θ denotes a random variable with mean zero and finite precision of q, π is also a random variable with mean zero and finite precision of h_j, a is an intercept term, b and d are coefficients associated with the variables θ and π, respectively. We also assume that the π_j's are uncorrelated across firms. In addition, we assume that firm's j cash flows have an element of common variation across firms through θ and an element of idiosyncratic variation through π_j. This issue captures that industry- or economy-wide events affect the cash flows of virtually all firms, while firm-specific or idiosyncratic events only affect the cash flows of firm j. The latter events are considered diversifiable and not priced through a CAPM framework. Within such a setting we get:

$$\begin{aligned} Cov\left(c_j, c_0\right) &= Cov\left(c_j, \sum_{s=1}^{M} c_s\right) \\ &= b_j \sum_{s=1}^{M} b_s E\left(\theta^2\right) + d_j^2 E\left(\pi_j^2\right) \\ &= b_j \sum_{s=1}^{M} b_s\, 1/q + d_j^2\, 1/h_j \end{aligned}$$

The term $b_j \sum_{s=1}^{M} b_s\, 1/q$ is considered to be the element of common variation in firm's j cash flows with the market, while the term $d_j^2\, 1/h_j$ is considered to be the element of idiosyncratic variation. If we substitute the whole expression into Equation (5), it yields:

$$P_j = E\left(c_j\right) - 1/N\alpha\, b_j \sum_{s=1}^{M} b_s\, 1/q + d_j^2\, 1/h_j$$

while the expression for R_j yields as the Equation (6).

According to Equation (6), there are certain factors leading to the reduction of the firm's cost of capital:

- The decline of the variance in the idiosyncratic variation in firm's cash flows, $1/h_j$,
- The decline of the variance in the common variation in firm's cash flows with the market, $1/q$,
- The increase in the shareholder's base of the economy or alternatively the increase in the number of investors who participate in the market, N,
- The increase in the risk tolerance of the market, α, and most crucially,
- The increase in the firm's j expected cash flows.

For satisfying the goal of this research paper, we focus on the last factor. More specifically, we saw that an increase in expected cash flows affected the firm's cost of capital R_j. This occurs because as long as expected cash flows increase, the price P_j at which the market values the firm's stocks increases at a different rate. In other words, the effect on R_j depends on how fast stock prices increase relative to expected cash flows, which, in turn, depends on the remaining parameters of the relevant expression, *i.e.* the covariance of the cash flows with the market or the degree of risk aversion.

$$R_j = E\left(c_j\right)/P_j - 1 = 1/N\alpha\left[b_j \sum_{s=1}^{M} b_s\, 1/q + d_j^2\, 1/h_j\right] \Bigg/ \left[E\left(c_j\right) - b_j \sum_{s=1}^{M} b_s\, 1/q + d_j^2\, 1/h_j\right] \quad (6)$$

Our next step involves us to determine when and how an increase or decrease in firm's accounting information leads to a corresponding decrease or increase in the firm's cost of capital. From the above we yield that an increase in firm's accounting information reduces either the variance in the idiosyncratic variation in firm's cash flows or investor's anticipations about that variance; in both cases the cost of capital decreases. In other words, an increase in disclosure of accounting information leads to lower investor's uncertainty about the parameters that matter for a secure pricing of the firm. Thus, in order to be consistent with the approach followed in [8], we must identify how the variables used there to proxy accounting information are related to the firm's cost of capital. In particular:

Cost of capital and leverage = according to pecking order behaviour, there exists a negative relationship between a firm's financial leverage and its cash flows. In particular, firms with higher internally generated cash flows require less debt. Firms with productive investment opportunities rely first on available cash flows to meet these financing needs. When such cash flows are depleted, the firm issues debt. This setting implies that debt acts as a residual of cash flows. Cross-sectional leverage studies that focus on the above mentioned contemporaneous relationship find extremely high support for such behaviour ([26-29]). Once we get a negative association between leverage and cash flows, Equation (6) predicts that there also exists a negative relationship between cash flows and cost of capital and thus we get a positive association between leverage and cost of capital as [8] find.

Cost of capital and interest coverage = [30-32] focus on the 'balance-sheet effects' of cash flow shocks and argue that investment projects do not absorb a firm's entire cash-flow shock and that several competing allocations, such as cash saving and debt reduction, expand or contract a firm's potential for investment expenses. They display that high interest coverage indicates an inability to obtain debt financing, signalling relatively severe financial constraints. As a result, high interest coverage motivates firms to look for alternative financial sources. Depending on the availability of such alternative sources, the association between cash flows and interest coverage is blurred, while [33,34] argue that lower expected cash flows imply that firms have used those cash flows to finance their investment projects and are not motivated to turn to debt issues, thus, experiencing lower interest coverage. But, through Equation (6), lower cash flows are associated with a higher cost of capital, implying that interest coverage and cost of capital are both negatively associated, as [8] find.

Cost of capital and book values = the association between cash flows and book values depends heavily on the size of firms. In particular, [35,36] argue that there exists a positive association between cash flows and book values for small firms, while the opposite is true for large firms.

Cost of capital and price-earnings ratio = in case when the price-earnings ratio is positively driven by the future growth of firm's opportunities ([37,38]), then higher expected growth implies higher price-earnings ratios and higher expected cash flows, which, through Equation (6), lead to lower cost of capital, giving result to a negative association between price-earnings ratios and cost of capital as [8] find.

Cost of capital and betas = certain empirical studies have focused on how cash flows affect the firm's level of systematic risk or beta. In studies by [39,40], a negative relationship is found. The rationale stems from how variances in dividends affect the timing of a firm's cash flows and, therefore, the level of systematic risk obtained by firm's potential investors, which, in turn, will affect the firm's cost of capital. Recently, [41] show that even by separating the motivation for paying a dividend from the immediate impact the dividend itself has on the firm, there is a clear negative relationship between cash flows and the systematic risk of the firm. Thus, this negative relationship, through Equation (6), implies that there also exists a positive relationship between betas and the cost of capital as [8] show.

2.3. Earnings Quality and the Cost of Capital

Finally, in this section we will extend the above model to account for the role of earnings quality. [42] documents a negative relationship between accruals and financial aggregates, such as stock returns. [43] investigate whether a higher level of quality for audit disclosures is used as a signalling mechanism about the future course of stock prices. Their results display that such higher quality levels of accounting disclosures have a substantial impact on firms' expected earnings and, thus, on their stock market returns. This empirical evidence provides strong support to the signalling value of audit quality levels. [44] also confirm that lower quality accounting information about certain accounting variables, such as accruals and earnings, undermines market efficiency and generates asset pricing anomalies. [45] investigate whether improvements in accounting information through a higher quality of announcements regarding accruals can be affected following regulatory interventions targeting the enhancement of accounting information for the case of the UK. They find that such an improvement does exist following the adoption of the FRS3 regulatory framework.

Thus, to display how earnings quality can affect the firm's expected cash flows, we will present a case where each firm j reports on its investment opportunities to the market. We also assume that investors provide managers with incentives to maximize the firm's market value. Therefore, managers select projects that maximize the market price, given the firm's report to the market. In other words, the quality of earnings affects investment choice, which, in turn, affects expected cash flows.

The effect of higher earnings quality is to improve the investment efficiency of the firm, without altering the firm's covariance with the market. The idea is that the firm's technology determines the covariance of the firm's cash flows with the market. Earnings quality simply affects the efficiency with which the investment project is implemented. In other words, what we want to show is that even when earnings quality is firm specific and has no effect on the covariance of the firm's cash flows, is expected to affect the cost of capital through its impact on expected cash flows.

In this setting, we assume that the firm's j cash flows arise from a process in which an investment of an amount k_j results in cash flow of $c_j = b_j\theta + k_j\pi_i - 1/2\,k_j^2$, where θ and π_j are independent, normally distributed random variables with a mean 0 and precisions of q and h_j, respectively, while b_j is a positive, fixed coefficient. k_j is firm's j investment choice. The term $-1/2\,k_j^2$ captures that there are diminishing returns to investment ([46]). We also assume that the π_j's are uncorrelated across firms.

We define π_j as firm's j earnings per unit of investment. It is an unknown variable to the market. However, each firm provides the market with a report, say r_j, of its earnings per unit of investment with some noise. That is:

$$r_j = \pi_j - \varepsilon_j$$

where the noise ε_j has a normal distribution with mean 0 and precision n_j. Once again, noises across firms are assumed to be uncorrelated.

Let now $P_j\left(r_j\right)$ represent the price of firm j conditional on a report about earnings: $P_j = E\left[P_j\left(r_j\right)\right]$. From Equation (6) we express $P_j\left(r_j\right)$ as:

$$\begin{aligned} P_j\left(r_j\right) &= E\left(c_j \middle| r_j\right) - b_j b_0\,1/\alpha q \\ &= k_j E\left(\pi_j \middle| r_j\right) - 1/2k_j^2 - b_j b_0\,1/\alpha q \\ &= k_j n_j \Big/ \left(h_j + n_j\right) r_j - 1/2\,k_j^2 - b_j b_0\,1/\alpha q \end{aligned}$$

Next, we assume that firm's j investment choice is to maximize the firm's market price conditional on an earnings report. This particular assumption implies that the manager's information about π plays no role; what really matters is the report to the market. More specifically, firms' investment opportunities are not observable to investors and not contractible. Thus, to overcome possible agency problems, stockholders provide incentives to maximize market values. Stock-based compensation is very common in practice and is widely suggested as a way to align the interests of managers and stockholders ([47]). To this end, we assume that incentives are a monotonically increasing function of the firm's market price.

Let now assume that kk_j represents the investment choice that maximizes market prices conditional on the firm's report. The first order condition of maximizing $P_j\left(r_j\right)$ with respect to k_j yields:

$$kk_j = n_j \Big/ \left(h_j + n_j\right) r_j$$

If we substitute the expression for kk_j back into the expression for $P_j\left(r_j\right)$ yields:

$$P_j = E\left[P_j\left(r_j\right)\right] = 1/2\,n_j \Big/ \left[\left(h_j + n_j\right) h_j\right] - b_j b_0\,1/\alpha q$$

Next, let $c_j(r_j)$ represent the firm's j cash flows conditional on the firm's earnings report and an investment choice kk_j, where $E\left(c_j\right) = E\left[c_j\left(r_j\right)\right]$. Then:

$$c_j\left(r_j\right) = kk_j\, n_j \Big/ \left(h_j + n_j\right) r_j - 1/2\,kk_j^2$$

As a result:

$$E\left(c_j\right) = E\left[c_j\left(r_j\right)\right] = 1/2\,n_j \Big/ \left[\left(h_j + n_j\right) h_j\right]$$

In the last step, the expression for the firm's stock price and its expected cash flows implies the following for the firm's cost of capital:

$$R_j = b_j b_0\,1/\alpha q \Big/ \left[1/2\,n_j \Big/ \left\{\left(h_j + n_j\right) h_j\right\} - b_j b_0\,1/\alpha q\right] \quad (7)$$

Next, through expression (7) we will determine how changes in earnings quality are associated with changes in R_j, which is, of course, our last goal here. We consider an increase in earnings quality of firm j, *i.e.* an increase in n_j. By taking the derivative of R_j with respect to n_j from expression (7) we yield:

$$d\left(R_j\right) \big/ \mathrm{d}n_j =$$
$$-\left[2h_j^2 b_j b_0\,1/\alpha q\right] \Big/ \left[n_j - 2h_j\left(h_j + n_j\right) b_j b_0\,1/\alpha q\right]^2 < 0$$

According to the above derivative, an increase in earnings quality leads to the reduction of cost of capital, which verifies the findings by Apergis *et al.* (2010b). In other words, an increase in earnings quality increases investment alignment, which, in turn, increases expected cash flows, while has no effect on the covariance of these cash flows with the market. Thus, the market equilibrium price of those cash flows rises faster than the expectation of those cash flows, and the cost of capital declines.

3. Conclusions

This theoretical study developed a simple equilibrium model to analyze the association between accounting information and firm's cost of capital and to verify or not previous empirical findings by the authors. We characterize asset prices in a market equilibrium setting with risk-averse investors. The findings showed that, even in a CAPM world, an increase in expected cash flows, coming from improvements in the quality of accounting information, leads to a reduction in the firm's cost of capital. Overall, the study provides a direct link between accounting information and the cost of capital that does rely on the fact that accounting information along with improvements in its quality has real effects on capital allocation that governs firm's cost of capital.

Market Efficiency and the Post-Earnings Announcement Drift*

DENNIS Y. CHUNG, *Simon Fraser University*

KAREL HRAZDIL, *Simon Fraser University*

1. Introduction

The literature on post-earnings announcement drift (PEAD) provides extensive evidence that firms with better (worse) than expected earnings experience significantly positive (negative) abnormal stock-price performance during weeks or even months following the earnings announcements (e.g., Ball and Brown 1968; Bernard and Thomas 1989; Freeman and Tse 1989). Fama (1998: 286) refers to the predictability of returns after earnings announcements as the ''granddaddy of all underreaction events'' resulting from investors' underestimation to value relevant earnings information. The underreaction explanation, however, raises the question of why arbitrageurs do not take advantage of the mispricing opportunities thereby eliminating the drift and reinforcing market efficiency.

In support of the underreaction story, previous studies have examined specific factors that affect arbitrage activities and provided bases for making inferences about market efficiency, that is, transaction costs (Ng, Rusticus, and Verdi 2008), investor sophistication (Bartov, Radhakrishnan, and Krinsky 2000), liquidity risk (Sadka 2006), and arbitrage risk (Mendenhall 2004).[1] However, these individual factors are unlikely to broadly capture the overall degree of frictions in the market. The key contribution of our study is the use of an innovative and more comprehensive measure of limits to arbitrage in the context of PEAD. We analyze how previously documented specific determinants of the drift relate to the overall degree of market frictions and examine whether the existence and persistence of the PEAD are directly associated with the extent to which information is efficiently impounded in prices.

We view the market from a microstructure perspective and use the short-horizon return predictability approach of Chordia, Roll, and Subrahmanyam 2008 (hereafter CRS) to measure market efficiency. CRS conclude that short-horizon return predictability from historical order flows is an inverse indicator of market efficiency. Because information is impounded in stock prices through trades (Kyle 1985), the CRS estimation of return predictability is a more direct approach for assessing the efficiency of market makers, specialists, and arbitrageurs in processing current earnings information. Using a sample from the 500 largest New York Stock Exchange (NYSE) firms, CRS examine two exogenous events that have decreased minimum bid-ask spreads and test the corresponding impact of changes in liquidity on return predictability over time. CRS are among the first to confirm

1. For instance, Bartov et al. (2000) demonstrate that traditional proxies for transaction costs as well as firm size add little incremental power in explaining the PEAD when institutional holdings are considered. Their results suggest a connection between the existence of PEAD and the trading activities of unsophisticated investors. Mendenhall (2004) supports the underreaction explanation by reporting evidence that the magnitude of PEAD is significantly associated with arbitrage risk after controlling for a wide range of explanatory variables used in prior research.

Contemporary Accounting Research Vol. 28 No. 3 (Fall 2011) pp. 926–956 © CAAA

that liquidity stimulates arbitrage activity, which, in turn, enhances the degree of intraday market efficiency, as evidenced by a reduction in short-horizon return predictability. Overall, the short-horizon return predictability characterizes the information environment and reflects the extent to which information is impounded in prices. Consistent with CRS, we refer to the inverse of short-horizon return predictability from order flows as market efficiency.[2] This innovative approach based on market microstructure allows us to study the nature of the information environment in which the PEAD originates.[3]

We first contribute to the literature on order flows and short-horizon return predictability in connection with the measurement of market efficiency. CRS argue that liquidity is a reason to expect improvement in market efficiency. Chung and Hrazdil (2010a, b) validate the lack of short-horizon return predictability as an indication of market efficiency for all NYSE and NASDAQ Stock Market (NASDAQ) firms and examine the dynamics between liquidity and market efficiency during informational periods (after controlling for various proxies for trading activity and information asymmetry). We extend CRS and Chung and Hrazdil (2010a, b) and provide further empirical evidence that short-horizon return predictability captures other factors, such as volatility, information asymmetry, investor sophistication, volume, size, and trading costs that affect arbitrage activities and the extent to which information is impounded in prices. These results support our motivation to use short-horizon return predictability as a broader measure of market efficiency in the context of PEAD.

We utilize the CRS estimate of short-horizon return predictability as an inverse measure of market efficiency and our prediction is that the abnormal returns subsequent to earnings announcements are negatively associated with market efficiency. To test this prediction, we first document a significant difference in post-announcement returns for firms in the highest and lowest unexpected earnings deciles. We further document a reversed U-shaped pattern in market efficiency across firms with increasing earnings surprises. In other words, firms with the extreme earnings surprises that experience most significant drifts are least efficient in incorporating information into prices. Consistent with Ng et al. 2008 we also document that, while the average transaction costs of all firms are relatively low, the transaction costs of the shares of the firms in the extreme earnings surprises portfolios are high.

In the multivariate regression setting, we present evidence that it is the market efficiency variable that is significantly and negatively associated with the long-window post-announcement abnormal returns. After controlling for a wide range of explanatory variables that are associated with barriers to arbitrage, we find that firms in the highest market efficiency decile experience, on average, a 2.5 percent smaller difference in PEAD between extreme unexpected earnings deciles than firms in the lowest efficiency decile. One interpretation of this result is that the market efficiency measure is an important proxy for the extent of arbitrage activities that are instrumental in making prices converge to fundamental value and that the importance of this market efficiency measure is not subsumed by any proxy for barriers to arbitrage used in prior literature.

2. The short-horizon return predictability effectively captures the degree of market inefficiency (frictions). However, for consistency of interpretation with prior studies (i.e., Boehmer and Kelley 2009; Chung and Hrazdil 2010a; Visaltanachoti and Yang 2010), we refer to the lack of short-horizon return predictability as an estimate of the extent to which information is efficiently impounded in prices (i.e., market efficiency).
3. Research utilizing this methodology is also beginning to appear in the literature. For instance, Aktas, de Bodt, and Van Oppens (2008) use the order imbalance and return predictability relation to examine the effects of insider trading on market efficiency. Others, such as Visaltanachoti and Yang 2010, analyze the speed of convergence to market efficiency for foreign stocks listed on the NYSE. Further review of the market efficiency estimations is provided in the next section.

We further contribute to the recent literature that examines the effects of transaction costs on the PEAD. Ng et al. (2008) find evidence that firms with higher transaction costs also provide the higher abnormal returns under the PEAD trading strategy and conclude that transaction costs can provide an explanation not only for the persistence but also for the existence of PEAD. In a related study, Chordia, Goyal, Sadka, Sadka, and Shivakumar (2009) report that transaction costs account for 70–100 percent of the paper profits from a long-short strategy designed to exploit the earnings momentum anomaly. CRS's estimate of short-horizon return predictability incorporates other factors that affect arbitrage activities and provides the basis for us to extend our analysis to the PEAD trading strategy with the market efficiency focus.

Using portfolio analyses, we follow prior literature (e.g., Korajczyk and Sadka 2004) and use relative bid-ask spreads as direct estimates of the transaction costs of making roundtrip marginal trades. We also apply the estimation approach developed by Lesmond, Ogden, and Trzcinka 1999 to derive an alternate and more comprehensive estimate of transaction costs (including price impact and opportunity costs). Consistent with prior literature, we find that taking into account these transaction costs significantly reduces the profitability of trading on the PEAD portfolios. We further confirm that transaction costs are responsible for the existence of the drift; however, this applies only to stocks for which information is efficiently impounded in prices. In other words, for firms in the highest market efficiency decile arbitrage activities help reduce the effect of underreaction to earnings news; all transaction-cost-adjusted estimated profits are statistically insignificant and sometimes negative across different periods. On the other hand, we extend prior literature by documenting increasing drift for stocks with overall high barriers to arbitrage (even after we incorporate the effect of transaction costs). These profits reach several percentage points and remain statistically significant. Thus, it is not just transaction costs that are responsible for the magnitude and existence of the PEAD; rather, there are other factors (that the market efficiency measure captures more fully) that prevent arbitrageurs from eliminating the drift.

Our findings support the theory that the PEAD results from investors' underreaction to earnings news, which raises the question of why informed investors do not fully price the news in quarterly earnings announcements and take advantage of the mispricing. Our results can be interpreted along the lines of Hou and Moskowitz 2005 who find that price response delay to information is a powerful predictor of cross-sectional average returns. Under the assumption that the short-horizon return predictability is a valid proxy for inefficient environment with high barriers to arbitrage and the consequent extent to which information is impounded in prices, our results show that this measure performs better than proxies used in prior literature in predicting and explaining stock returns after earnings announcements.

The rest of this paper is organized as follows. We summarize the PEAD along with the liquidity literature and propose our empirical predictions in section 2. Section 3 develops measures for market efficiency, defines remaining variables, outlines the sample selection procedure, and describes the data. We discuss the main empirical results and cover robustness tests in section 4. The final section concludes and offers opportunities for future research.

2. Background and hypothesis development

Potential explanations for the drift

In the most-often-cited evidence in favor of the underreaction explanation, Bernard and Thomas (1990) were able to predict, for up to four quarters ahead, the future abnormal reaction to earnings announcements based on the current and historical time-series patterns of earnings. The presence of significant autocorrelation patterns for seasonally differenced earnings suggests that investors underreact to value relevant earnings information and significantly underestimate (or are unaware of) the current earnings and their implications for future earnings. The existence of predictable abnormal returns over a prolonged period is inconsistent with the semi-strong form of market efficiency with respect to earnings information.

Among the earlier studies that have examined price continuation in the direction of earnings surprises are Ball and Brown 1968, who documented the return predictability for up to two months after the annual earnings announcements, and Foster, Olsen, and Shevlin 1984, who confirmed the existence of 60 trading days of return predictability using quarterly earnings announcements. This PEAD anomaly survived countless batteries of tests over the past 40 years by being exposed to various risk-based asset pricing models, different exchanges and countries, and numerous estimation models for quarterly earnings expectations.

The underlying reason for the PEAD anomaly has not been uniformly supported, given the evidence for several competing theories. Some market efficiency proponents argue that the PEAD stems from systematic misrepresentation of abnormal returns after the earnings announcements. For example, Ball, Kothari, and Watts (1993) argue and provide evidence that systematic risk is positively related to the earnings news, and therefore expected returns are likely misestimated following earnings surprises. Others point to methodological shortcomings such as actual versus assumed earnings announcement dates, calendar versus fiscal quarter classification, or specific earnings methodology that existing studies use to estimate unexpected earnings (e.g., Jacob, Lys, and Sabino 2000; Kim and Kim 2003). Finally, limits to arbitrage have been supported as an important factor driving the existence and persistence of PEAD. These studies argue that PEAD continues to be observable because of frictions in the market that impede an informed investor to arbitrage away the market underreaction to earnings news. For example, Bhushan (1994) concludes that the PEAD is inversely related to both direct (share price) and indirect (dollar trading volume) costs of trading and these relations subsume the previously documented inverse relation between the drift and firm size. Mendenhall (2004) finds that the drift is strongly related to the arbitrage risk measure developed by Wurgler and Zhuravskaya 2002. Bartov et al. (2000) argue that trading activity of sophisticated investors quickly corrects the mispricing that arises from the trades of unsophisticated investors. Others, such as Ng et al. 2008 and Chordia et al. 2009, document that the drift is most pronounced in highly illiquid stocks, with high trading and market impact costs.

Given that the profitability of the PEAD strategy is strongly related to transactions costs, others propose that, if unexpected variations in liquidity have a systematic component, then the PEAD could be viewed as compensation for liquidity risk provided it is sensitive to unexpected changes in systematic liquidity. For instance, Sadka and Sadka (2004) find that systematic liquidity risk is an important determinant in explaining the cross-sectional variation of expected returns among unexpected earnings-sorted portfolios. They conclude that it is not the liquidity spread that explains the drift; rather the substantial part of the PEAD can be viewed as compensation for risk associated with shocks to the information environment in the economy (systematic liquidity). Others such as Sadka 2006 decompose firm-level liquidity into variable (typically associated with private information) and fixed price effects and conclude that a significant part of the PEAD returns can be viewed as compensation for the unexpected variations in the aggregate ratio of informed traders to noise traders.

In our paper, we utilize the short-horizon return predictability approach developed by CRS to estimate the firm-specific levels of market frictions prior to earnings announcements and examine their association with the consequent post-earnings announcement abnormal returns. We are not the first to relate proxies for efficient processing of information in quarterly earnings to the PEAD. For instance, Bartov et al. (2000) investigate whether drift is a manifestation of inefficient processing of quarterly earnings by examining the relation between drift and investor sophistication.[4] Other studies, such as Hou and Moskowitz 2005, go one step further and assess the impact of aggregate market frictions for cross-sectional return predictability using a parsimonious measure based on the price delay in response to information.[5] Given the recent advances in the microstructure literature on short-horizon return predictability, we are first to utilize high-frequency data in a direct approach to assess the efficiency of market makers, traders, and arbitrageurs in their processing of current earnings information. With this approach, we can better interpret market efficiency in the context of PEAD.

Market efficiency: Return predictability from historical order flows

Research on market microstructure gives us a basis to explore the price formation process and study how information is incorporated into security prices. O'Hara (1997: 1) suggests that, "as microstructure research is set in the markets for financial assets, this enhances our ability to understand both the returns to financial assets and the process by which markets become efficient." Recent empirical studies in the market microstructure literature also show increasing interest in the relation between order flows and stock returns (e.g., Chordia, Roll, and Subrahmanyam 2005, 2008; Chordia and Subrahmanyam 2004; Chung and Hrazdil 2010a, b). These studies generally analyze the determinants and properties of market-wide order imbalances in connection with future short-horizon returns and provide evidence that return predictability from past order imbalances is eliminated through the trading activities of specialists and arbitrageurs (floor traders), who have the advantage of immediately observing order flows.

Recent research on order flow and return predictability has expanded its scope and made connections to the concepts of liquidity and market efficiency. CRS are among the first to analyze return predictability in connection with liquidity and interpret their findings from a market efficiency perspective. CRS suggest two possibilities of how liquidity can be related to short-horizon return predictability. First, due to limited risk-bearing capacity and/or facing inventory financial constraints, if market makers cannot absorb the impact of price pressures from imbalances in buy and sell orders, temporary price deviations arise which induce return predictability and create arbitrage profit potential. Higher liquidity resulting from exogenous decreases in bid-ask spreads allows the market makers to reduce their excess inventories, facilitates arbitrage, and encourages trading on private information, which leads to lower return predictability and higher market efficiency. In this case, liquidity is positively associated with market efficiency. Second, if market makers fail to utilize the information in order flows and eliminate return predictability, other market participants have incentives to gather new information about order flows and trade on such information. While the consequent increased adverse selection faced by market makers lowers liquidity, the market is more efficient as more information is incorporated in

4. Bartov et al. (2000) find that the degree of inefficient pricing of abnormal returns subsequent to quarterly earnings announcements is negatively correlated with the proportion of a firm's stock held by institutions. Their results suggest that trading activities of institutional investors improve on the earnings-processing problems that cause PEAD and increase the degree to which earnings information is efficiently priced.

5. Hou and Moskowitz (2005) find that firms with delayed price response to information are small, volatile, and neglected by most market participants; these are also firms that experience high PEAD. Hou and Moskowitz use weekly returns data instead of high-frequency data in their study to estimate price delay because of their concern about potentially confounding microstructure influences such as bid-ask bounce and nonsynchronous trading. They point out that using high frequencies data may provide more precision and perhaps more dispersion in the price delay measure.

prices (Barberis, Shleifer, and Vishny 1998). In this case, liquidity is negatively associated with market efficiency. A third possibility also exists, as CRS point out: if market makers can fully absorb the price pressure from imbalances in buy and sell orders and utilize all information in the order flows, then there should be no relation between liquidity and market efficiency. CRS are among the first to confirm that improved liquidity associated with exogenous decrease in bid-ask spreads stimulates arbitrage activity, which reduces short-horizon return predictability, an inverse indicator of market efficiency. The results by CRS therefore effectively reject the other competing explanations that liquidity would be accompanied by greater return predictability (based on Barberis et al. 1998) and that liquidity would bear no relation to market efficiency.

In addition to liquidity, Chung and Hrazdil (2010a, b) further validate the short-horizon return predictability as a proxy for market efficiency and analyze several of its determinants: size, volume, trading frequency, and information asymmetry (proxied by the high adverse selection component of the bid-ask spread). They not only document a positive association between a continuous measure of liquidity and market efficiency but also show that this effect is amplified during periods that contain new information. Their results are consistent with the theoretical framework that public information about future returns is contained in past order flows and that it may take some time for prices to reflect fully the new information that is available in the market (Chordia et al. 2005). During periods with a high level of new information (e.g., around earnings announcements), the market tends to be less efficient in incorporating the information into prices, suggesting that stock prices incorporate information slowly, which in turn leads to trends in returns over short horizons (i.e., consistent with the underreaction hypothesis). Overall, Chung and Hrazdil (2010a, b) find that, over the period January 1, 1993 to June 30, 2004, their explanatory variables account for about 50 percent of the variation in return predictability for NYSE firms and about 30 percent of the variation for NASDAQ firms.

Apart from liquidity and information asymmetry effects, the financial literature has identified additional proxies for information flow, arbitrage risk, investor sophistication, volume, size, and trading costs that are expected to influence arbitrage trading activity, which in turn affects market efficiency (e.g., Ross 1989; Bhushan 1994; Bartov et al. 2000; Mendenhall 2004; Hou and Moskowitz 2005; Pontiff 2006; Ng et al. 2008). Consistent with the arguments developed in these studies, we posit that short-horizon return predictability captures the impact of volatility, number of analysts following, institutional ownership, information asymmetry, and various transaction costs that impact on the extent to which information is impounded in prices. Provided that these variables are associated with market efficiency, the CRS measure of short-horizon return predictability becomes a useful measure as it aims to capture parsimoniously the aggregate impact of all potential frictions that operate during the price formation process in the trading of a stock.

In this paper, we rely on the CRS measure and use it as a direct proxy to broadly capture the overall degree of frictions in the market. We apply this measure of market efficiency to the information environment in which the PEAD originates. Unlike Lee 1992, who only examines intraday order imbalances around earnings announcements, we analyze this aggregate measure of market frictions and its direct relation to the PEAD.[6] Consistent with CRS, we derive this measure as the negative of the adjusted R^2 from the predictive regressions of five-minute returns on lagged order imbalances and lagged order imbalances interacted with a dummy variable for illiquidity regimes. Accordingly, we

6. Lee (1992) provides a detailed intra-day analysis of returns and directional volumes around earnings announcements during 1988 for 230 firms listed on NYSE; we provide a more comprehensive analysis linking the return predictability from order flows to the PEAD anomaly.

hypothesize a negative association between the market efficiency measure and abnormal returns subsequent to earnings announcements (PEAD), which would indicate a faster incorporation of earnings information into prices. More formally, our hypothesis can be stated as:

HYPOTHESIS: *Market efficiency is negatively associated with abnormal returns subsequent to earnings announcements.*

In the capital market research framework that links accounting earnings to stock returns, market efficiency is only one of several factors that helps us understand how earnings news is reflected in share prices. As noted by Nichols and Wahlen (2004: 269), market efficiency "is a matter of degree, which describes how much information prices reflect and how quickly prices react and reach new equilibrium levels. A highly efficient market with respect to accounting earnings numbers would react quickly and completely when new earnings-related information becomes available." The PEAD, as evidence of market efficiency violation, assumes further that earnings numbers reflect reliable and relevant information, that market correctly forms expectations about new information in earnings (proxied by analysts' forecast consensus), and that asset pricing models correctly incorporate sufficient rate of return necessary to compensate consumption and bearing risk of holding a security.[7] We therefore evaluate and confirm whether, and to what extent, market efficiency plays a role in explaining the PEAD magnitude and persistence, holding the other assumptions (value relevance, earnings expectations, and asset pricing methodology) constant.

3. Research design and data

Order imbalances and liquidity: Estimation of market efficiency

Previous research on the PEAD typically considers all traded firms on various exchanges and selects the final samples based on data availability of the PEAD and its determinants. Consistent with the literature, we collect intraday trade and quote data from the Trade and Quote (TAQ) database for all NYSE, American Stock Exchange (AMEX) and NASDAQ firms over the period January 1, 1993 to June 30, 2004.[8] Following CRS, we compute stock returns over five-minute intervals using the midpoints of bid and ask prices quoted at the end of the intervals. For order imbalance, we compute two measures for each five-minute interval t: the number of trades $OIB\#_t$ and the dollar trades $OIB\$_t$, defined as:

$$OIB\#_t = \{[(Number\ of\ buyer\ initiated\ trades_t) - (Number\ of\ seller\ initiated\ trades_t)]/ (Total\ number\ of\ trades_t)\} \quad (1),$$

7. We acknowledge that, given the dynamic nature of these assumptions, it is difficult to control for them individually. As a consequence, the investors' underreaction (and the PEAD) is often problematic to interpret from the market efficiency point of view.
8. All three exchanges experienced the same exogenous shocks to their minimum trading tick sizes during similar time periods. Before mid-1997, firms on all three exchanges (AMEX, NASDAQ, and NYSE) traded in increments of eighths of a dollar. On May 7, 1997, the AMEX became the first of the three U.S. exchanges to adopt the minimum tick of sixteenths. The NASDAQ followed next, and began its new quotation system on June 2, 1997. Lastly, the NYSE officially changed to same lower ticks on June 24, 1997. With regard to the change to a decimal regime, the NYSE and the AMEX adopted the minimum decimal tick size on January 29, 2001; the NASDAQ immediately followed with a pilot project of changing the minimum tick size for some companies with a full adoption for remaining constituents on April 9, 2001.

$$OIB\$_t = \{[(Dollar\ traded\ from\ buyer\ initiated\ trades_t) - (Dollar\ traded\ from\ seller\ initiated\ trades_t)]/(Total\ dollar\ traded_t)\} \quad (2)$$

Each trade is classified as either a buyer-initiated or seller-initiated trade using the well-established Lee and Ready 1991 algorithm with the same modification as implemented by CRS; each transaction is matched to a bid-ask quote, which is the first quote immediately prior to the trade for years after 1998 and at least five seconds prior to the trade for years before 1999. In order to analyze the informational efficiency in connection with the PEAD, we use the same approach as Chung and Hrazdil 2010a and estimate the market efficiency measure from the following time-series regression on a firm-level basis:[9]

$$Return_t = \alpha + \beta_1 OrderImbalance_{t-1} + \beta_2(OrderImbalance_{t-1} * Illiquidity_t) + \varepsilon_t \quad (3),$$

where $Return_t$ is the value-weighted return over a five-minute interval t (computed using the midpoints of the first and last quotes within each trading interval) for each firms listed on an exchange, $OrderImbalance_t$ is either $OIB\#_t$ or $OIB\$_t$, and $Illiquidity_t$ is a dummy variable that is coded one if the daily average effective spread for the firms is at least one standard deviation above the de-trended expected effective spread for the trading day, and zero otherwise. We include the interaction variable of $OrderImbalance_t$ and $Illiquidity_t$ to account for the effect of liquidity changes on market efficiency. The negative of the adjusted R^2 from (3) utilizing dollar trades order imbalances ($OIB\$_t$) represents our market efficiency measure (hereafter ME).[10] For these time-series regressions, we require firms to have at least 30 observations within a calendar month. The corresponding ME for firm i that we analyze in connection with the post-earnings announcement returns is estimated over the month prior to the month during which the earnings were announced. We verify that this measure of efficiency is comparable across several months surrounding the earnings announcement month, which suggests that variations in the speed of price adjustments are minimal from month to month. Defining the ME measure over the month prior to earnings announcements has further implications to practitioners and researchers who wish to estimate, ex ante, the degree of ME and utilize the information about the speed of adjustment in connection with various informational events.

Variable definition

Traditionally, the PEAD has been documented subsequent to unexpected earnings measured as seasonal changes in quarterly earnings. However, more recent studies argue and provide evidence that earnings expectations based on analysts' forecasts from the I/B/E/S provide a more precise measure of earnings surprise than previously employed time-series methodology based on the COMPUSTAT quarterly data. Doyle, Lundholm, and Soliman (2006) and Livnat and Mendenhall (2006) document economically larger abnormal returns when unexpected earnings are defined based on I/B/E/S analysts forecasts and I/B/E/S actual earnings, thus providing a greater hurdle for market efficiency proponents to

9. Similar to CRS, we also analyze the portfolio regressions for the 500 largest NYSE firms, from which 193 are continuously traded, and replicate their results. As our final tables are virtually identical to those reported by CRS in their Table 5, we only report the firm-level changes in market efficiency and transaction costs for our sample of firms over time. For detailed empirical evidence on the differences in market efficiency for portfolios of all publicly traded firms on NYSE and NASDAQ formed on the basis of trading frequency, market capitalization, and trading volume, and for validating the return predictability as measure for market efficiency on a firm-level basis, see Chung and Hrazdil 2010a, b.

10. In cases where the adjusted R^2 is negative, we assign it a value of zero. The results are almost identical when we use ordinary R^2 as a measure of market efficiency. When we use $OIB\#$ as an explanatory variable in regression (3), results are very similar to those reported in section 4.

explain this phenomenon. Ng et al. (2008) show that, unlike the PEAD strategy with earnings surprises measured as seasonal changes in quarterly earnings, economically significant profits remain for the PEAD strategy with earnings surprises measured using I/B/E/S analyst numbers. We thus follow prior literature and define unexpected earnings ($UE_{i,t}$) for firm i in fiscal quarter q as:

$$UE_{i,q} = (E_{i,q} - \bar{\hat{E}}_{i,q})/P_{i,q} \quad (4),$$

where $E_{i,q}$ is the most recent reported quarterly earnings per share (EPS) from the I/B/E/S Detail file, $\bar{\hat{E}}_{i,q}$ is the median of analysts' forecasts of EPS from I/B/E/S during the month prior to the earnings announcement, and $P_{i,q}$ is the price per share from COMPUSTAT for firm i at the end of quarter q.[11] Consistent with prior literature, we group firms within each fiscal quarter into ten deciles based on their unexpected earnings; lowest decile firms experience most negative earnings surprises whereas highest decile firms experience most positive unexpected earnings.

Following the tradition in the PEAD literature (e.g., Livnat and Mendenhall 2006), we define the size-adjusted and book-to-market (B/M)-adjusted abnormal return ($AR_{i,t}$) as the raw daily return ($R_{i,t}$) from the Center for Research in Security Pricing (CRSP) less the daily equal-weighted return on the portfolio p of firms with approximately the same size and book-to market ($R_{p,t}$). The daily returns for the six (two size and three B/M) portfolios along with the cutoff points can be obtained from Kenneth French's data library.[12] The corresponding cumulative abnormal returns ($CAR_{i,t}$) for firm i on day t during the 60-day interval (starting one day after earnings announcement) can be expressed as follows:

$$CAR_{i,t} = \sum_{t=1}^{60} AR_{i,t} = \sum_{t=1}^{60} (R_{i,t} - R_{p,t}) \quad (5).$$

For each firm-quarter, we also collect and estimate control variables such as: residual (idiosyncratic) volatility as a proxy for risk; institutional ownership and analysts following to proxy for the investor sophistication; and price, volume, and various proxies for transaction costs. These variables have been previously analyzed in connection with the drift as its main determinants.

One implication of the semi-strong form of the efficient market hypothesis is that prices should respond swiftly and in an unbiased manner to new information. To provide further insight into how new information affects the market efficiency, we follow prior literature (e.g., Visaltanachoti and Yang 2010; Chung and Hrazdil 2010a) and include historical return volatility and measures of adverse selection to control for the information flow and information asymmetry effects, respectively. First, we compute annualized historical volatility ($VOLAT_{i,t}$) as the standard deviation of daily returns over a period of 12 months prior to the earnings announcement date, multiplied by the square root of 252 (minimum number of valid daily returns required is 24). Second, we define $ADV\_LSB_{i,t}$ and $ADV\_HS_{i,t}$ that represent the average adverse selection component of the bid-ask spread for the quarter estimated on a firm-by-firm basis for each month using the decomposition models of Lin, Sanger, and Booth 1995 (hereafter LSB) and Huang and Stoll 1997 (hereafter HS), respectively (a further discussion of the estimation of the ADV_LSB and ADV_HS measures is provided in Appendix 1). Both models have been shown to capture different aspects of adverse selection (Van Ness, Van Ness, and Warr 2001) and adverse

11. We only analyze firms with the same earnings report date from both I/B/E/S and COMPUSTAT.
12. Data are available from: http://mba.tuck.dartmouth.edu/pages/faculty/ken.french/data_library.html.

selection has been shown to be negatively associated with market efficiency (Chung and Hrazdil 2010a). Lastly, $SIZE_{i,q}$, is proxied by the total assets (COMPUSTAT AT) in the quarter prior to the earnings announcement. Ross (1989) finds that volatility is directly related to the rate of the flow of information in the market and that larger companies are usually considered to have a better information environment and less information asymmetry. In a later study, Visaltanachoti and Yang (2010) further document that higher volatility significantly increases the speed of convergence to market efficiency. Therefore, we expect volatility and size to be positively related to market efficiency.

Hou and Moskowitz (2005) examine price delay in connection with cross-sectional returns and their results show that residual volatility, as opposed to covariance with the market, is a better measure of risk for firms with high market frictions. In light of Hou and Moskowitz's findings, we use residual volatility ($RVOLAT_{i,t}$) as another proxy for risk and we compute this measure as the standard deviation of residuals from the market model regression of daily returns on the Standard & Poor's (S&P) 500 index over the 12-month period ending in the announcement month. Using daily returns to derive this measure is consistent with Ng et al. 2008, who find that the ability of volatility to explain the magnitude of the PEAD is stronger when daily returns is used as opposed to monthly returns. Prior research has, however, provided mixed results on the pricing role of residual volatility.[13] Hou and Moskowitz (2005) argue that one possible reason for the disparity of results is that most studies examine the relation between idiosyncratic risk and average returns for average firms that may be widely held and recognized and that may not face significant frictions. Therefore, the average firm should not be expected to have priced idiosyncratic risk. Indeed, Hou and Moskowitz (2005) document that idiosyncratic risk is priced only among the most constrained and severely price delayed firms. Therefore, we do not form an expectation for idiosyncratic volatility in connection with post-earnings announcement returns and predict that idiosyncratic volatility is related to the PEAD only for the low efficient firms.[14]

To control for investor sophistication, we follow Bartov et al. 2000 who show that the percentage of ownership of institutional investors is the variable most significantly (negatively) related to the PEAD. The intuition behind this result is based on the model in Hand 1990, which shows that the likelihood that prices properly reflect a type of information depends on whether or not the marginal investor is sophisticated (proxied by institutional ownership). We use the CDA/Spectrum Institutional (13f) Holdings database and compute the institutional ownership ($INSOWN_{i,q}$) variable for firm i in quarter q as the fraction of shares held by institutions in the calendar quarter prior to the earnings announcement quarter.[15] In addition to the institutional ownership percentage of a firm, Walther (1997) and Bhushan (1994) also used the number of analysts and firm size as alternative proxies for the likelihood that the marginal investor is sophisticated. We define $NUMEST_{i,q}$, obtained from the I/B/E/S, as the number of analysts following firm i in quarter q prior to the earnings announcement month. To better isolate the effect of investor sophistication on market efficiency, we also capture the effect of those analysts who are actively following a firm and actually making changes to the forecasts that they provide. We include $ACTIVE_{i,q}$ (active analysts) as an additional variable to measure the proportion of analysts who have revised their one-year-ahead EPS forecasts for firm i,

13. Fama and MacBeth (1973) and Tinic and West (1986) find no association between idiosyncratic risk and average returns, whereas Malkiel and Xu (2003) find some cross-sectional predictability.

14. Given the findings of Hou and Moskowitz 2005, we refrain from using residual volatility as a proxy for arbitrage risk (unlike Mendenhall 2004 and Ng et al. 2008).

15. Data for this variable are available for institutions required by the Securities and Exchange Commission to file Form 13f.

either up or down, during the quarter q. Boehmer and Kelley (2009) provide evidence that stocks with greater institutional ownership are priced more efficiently and that variation in liquidity does not drive this result. Consistent with prior literature, we therefore expect the proxies for investor sophistication to be positively related to market efficiency and negatively associated with the PEAD.

Finally, to proxy for transactions costs, we control for recent stock price and recent dollar trading volume, which have been shown to be significantly associated with the cost of trading and the PEAD (e.g., Bhushan 1994; Stoll 2000). We measure $PRICE_{i,q}$ as a closing monthly price of firm i in quarter q during the month prior to the earnings announcement month. The dollar trading volume ($VOL_{i,q}$) is then obtained by multiplying the price by the number of common shares of firm i in quarter q traded during the pre-earnings announcement month. In terms of more direct measures of trading costs, we follow Korajczyk and Sadka 2004 and use proportional quoted bid-ask spread ($QSPR_{i,q}$) and proportional effective bid-ask spread ($ESPR_{i,q}$). Both computations for firm i are averaged first across all trades during a day and then across all trading days over each quarter q during our sample period.

$$QSPR_{i,q} = \frac{(Ask - Bid)}{\left[\frac{(Ask+Bid)}{2}\right]} \quad (6),$$

$$ESPR_{i,q} = \frac{\left\{\left(\left[TradePrice - \frac{(Ask+Bid)}{2}\right]\right) * 2\right\}}{\left[\frac{(Ask+Bid)}{2}\right]} \quad (7).$$

As an alternate proxy for transaction costs, we further estimate the limited dependent variable ($LDV_{i,q}$) measure, developed by Lesmond et al. 1999, for each firm i for each quarter q, which is based on the transaction costs implied by the trading behavior of investors. The measure has two main advantages. First, when the model's assumptions are satisfied, the measure incorporates all costs that are important to traders and that are reflected in their trading behavior. This is important because several aspects of transaction costs are hard to estimate directly. Second, Lesmond et al. (1999) find that the measure is highly correlated with directly observable measures of transaction costs, is relatively easy to compute, and is available for any period for which daily stock returns from CRSP are available. A further discussion of the estimation of the LDV measure is provided in Appendix 2. Market microstructure literature establishes a negative relation between price and trading costs and between volume and trading costs (e.g., Stoll 2003). Because higher trading costs adversely affect market efficiency (based on CRS), we expect the trading costs (except $PRICE$ and VOL) to be negatively associated with market efficiency and positively related to the PEAD.

Variable transformation

Most PEAD studies classify firms into ten groups based on their earnings surprises in order to control for outliers and nonlinearities in the earnings–return relation. We follow this traditional approach and present our univariate results of PEAD in connection with market efficiency for individual UE decile firms. For the regression analysis where cumulative abnormal returns are regressed on a set of variables, further transformation of UE and all other control variables is often performed in order to facilitate the interpretation of the coefficients. For instance, Bernard and Thomas (1990) further reassign the UE deciles into scores ranging from 0 to 1, which allows the slope coefficient to be interpreted as the difference in cumulative abnormal returns between the lowest and the highest UE

deciles. A common modification implemented by others further subtracts 0.5 from the coded *UE* scores in order to assign a score of zero to a mythical median observation (e.g., Affleck-Graves and Mendenhall 1992; Mendenhall 2004; Livnat and Mendenhall 2006). When the cumulative abnormal returns are regressed on the *UE*, the intercept can be interpreted as the abnormal return for a hypothetical median observation between the two middle *UE* deciles.[16] Similar to Mendenhall 2004, for every quarter we rank each variable into ten deciles from lowest to highest and transform these ranks into values ranging between −0.5 to +0.5. We interpret our multivariate results based on the transformed ranks toward the end of the next section.

Sample selection

We analyze 61,526 firm-quarter (4,649 firms) observations, for which we have our dependent and control variable data available from the COMPUSTAT, CRSP, I/B/E/S, TAQ, and CDA Spectrum databases. Our initial sample selection procedure covers the period between January 1993 and June 2004, during which we require the firms to: (a) have identical earnings report dates on the COMPUSTAT quarterly and the I/B/E/S; (b) have actual EPS, average and median of EPS forecasts data available from the I/B/E/S; (c) have price (unadjusted for stock splits) from the COMPUSTAT quarterly; (d) have daily returns data available from the CRSP daily; and (e) be actively traded companies that belong to the NYSE, NASDAQ, or AMEX exchanges.[17] This initial sample identification procedure yields 77,514 firm-quarter (5,458 firms) observations. We lose about 15 percent of the firms due to control variable data requirements. Specifically, we require our final sample firms to have market efficiency measures available based on more than 30 time-series observations within each calendar month, have institutional common stock ownership data from the CDA Spectrum database, and have average daily dollar trading volume from the CRSP.[18] All variables are winsorised at the 1 percent levels for the correlation and the analysis of market efficiency determinants. Table 1 summarizes the sample selection procedure.

We provide detailed descriptive statistics of the PEAD and various proxies for transaction costs in Table 2. Table 2, panel A summarizes an average PEAD for the period January 1, 1993 to June 30, 2004 across ten *UE* deciles. Confirming findings of previous studies, the top *UE* (good news, Decile 10) firms experience significant positive 60-day drift compared to the bottom *UE* (bad news, Decile 1) firms. The profit from a strategy that shorts decile 1 firms and buys decile 10 firms would yield an average profit of 5.48 percent (4.90 percent median) during a 60-day period subsequent to an earnings announcement date. Worth noticing is the reversed U-shaped pattern of the *ME* measures (defined as negative of adjusted R^2 from (3)). Our results in panel A thus suggest that firms in the extreme *UE* deciles are in fact least efficient in incorporating earnings information into prices. Table 2, panel B also documents that, while the average transaction costs of all firms are comparable with previous studies, the transaction costs of the shares of the firms in the extreme earnings surprises portfolios are the highest.

16. Mendenhall (2004) points out that the resulting coefficient estimates may be biased without this adjustment.
17. Some authors, such as Nichols and Wahlen 2004, examine firms with December 31 fiscal year-end, for which the fiscal quarter corresponds to a calendar quarter. Our results are robust to this additional data requirement.
18. The maximum likelihood estimation of *LDV* produces some invalid estimates due to convergence problems and cases involving boundary or corner solutions, which reduces the number of observations to 55,286 for the *LDV* variable. Further, after excluding invalid estimates generated by the LSB and HS decomposition models, the numbers of observations for *ADV_LSB* and *ADV_HS* are reduced to 57,839 and 57,834, respectively.

TABLE 1
Sample selection

	Number of firms (percentage)	Number of observations (percentage)
Firms/observations with necessary quarterly data on COMPUSTAT and I/B/E/S[a]	5,458 (100)	77,514 (100)
No market efficiency measures data[b]	430 (8)	9,719 (12)
No institutional ownership data[c]	48 (1)	1,217 (2)
No CRSP data[d]	331 (6)	5,052 (7)
Final sample[e]	4,649 (85)	61,526 (79)

Notes:

[a] During January 1993 and June 2004, sample firms are required to: (a) have identical earnings report dates on the COMPUSTAT quarterly and the I/B/E/S; (b) have actual EPS, average and median of EPS forecasts data available from the I/B/E/S; (c) have price (unadjusted for stock splits) from the COMPUSTAT quarterly; (d) have daily returns data available from the CRSP daily; (e) be actively traded companies that belong to the NYSE, NASDAQ, or AMEX exchanges.

[b] Sample firms with no market efficiency measures available (based on the TAQ database) or sample firms with less than 30 time-series observations within a calendar month are eliminated.

[c] Sample firms without institutional common stock ownership data from the CDA Spectrum database are eliminated.

[d] Firms without dollar trading volume, residual return volatility, and transaction costs (proportional quoted bid-ask spread and proportional effective bid-ask spread) data available from the CRSP are eliminated.

[e] All variables are winsorised at the 1 percent level for analyses in Tables 2–5 and 7.

CRS report increasing market efficiency (decreasing return predictability) over three trading regimes, over which the three major U.S. exchanges experienced the same exogenous shocks to their minimum trading tick sizes. Although we rely on CRS and Chung and Hrazdil 2010a, b, we provide graphical illustration of transaction costs and return predictability changes over our sample period in Figure 1.

Several studies argue (e.g., Ng et al. 2008; Chordia et al. 2009) that transaction costs provide the most significant explanation for the existence and persistence of the drift. In the multivariate regression setting, we reexamine whether the trading and transaction costs continue to be significantly associated with the long-window post-announcement abnormal returns once we consider the impact of the aggregate level of barriers to arbitrage on the drift.

Descriptive statistics

Table 3 provides descriptive statistics for the sample of 61,526 firm-quarters before the explanatory variables are transformed and coded. The *UE* seems to be distributed evenly around zero (with mean and median of −0.002 and 0.000, respectively) with an approximately similar number of unexpected earnings deflated by low or high prices. The market efficiency (*ME*) measure (negative adjusted R^2 from (3) based on individual firm time-series regressions) also follows a normal distribution, which is proportionate to

TABLE 2
Post-earnings announcement drift (PEAD): Descriptive statistics

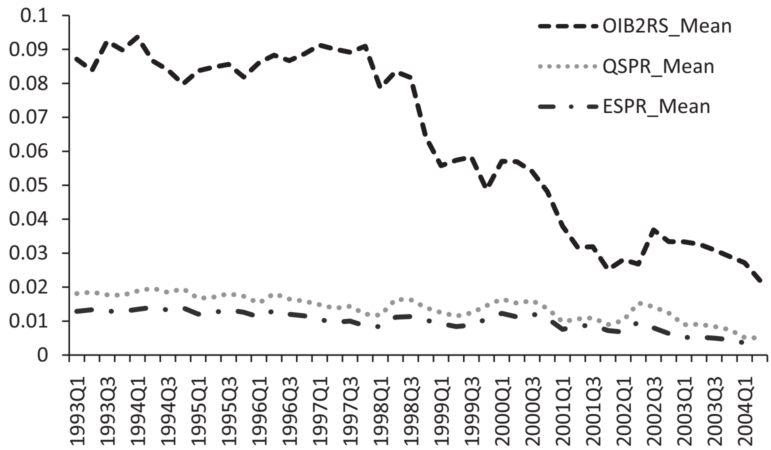
Notes:

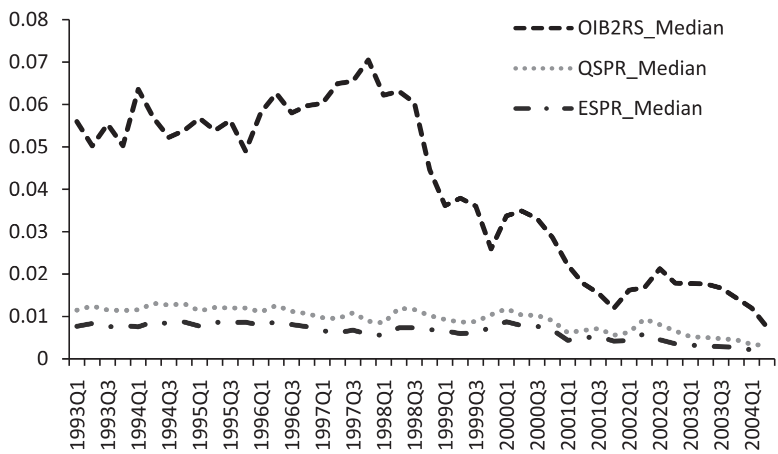
Each quarter, firms are sorted into deciles based on the magnitude of their unexpected earnings (*UE*) defined in (4) as a difference between the most recent reported quarterly earnings per share (EPS) (from the I/B/E/S Detail file) and the median of analysts' forecasts of EPS during the month prior to the earnings announcement, deflated by the price per share at the end of quarter. In panel A, firms in decile 1 (decile 10) experience most negative (positive) earnings surprises without considering transaction costs. The corresponding cumulative abnormal returns (*CAR*), defined in (5) and winsorised at 1 percent levels, are presented for a 60-trading-day interval starting one day following the quarterly earnings announcements. The last row presents the mean and median differences in *CAR* between the extreme deciles, which are all significant at 1 percent levels. Market efficiency (*ME*) is defined as a negative adjusted R^2 from (3). Panel B presents the proxies for transaction costs (*QSPR* and *ESPR*) defined in (6) and (7), respectively, for individual *UE* deciles. The last row presents combined transaction costs for the extreme *UE* deciles, which represents costs of hedge returns, which are all significant at 1 percent levels.

Figure 1 Graphical illustrations of transaction costs and return predictability over time.

A



B



Notes:

These figures depict the changes in transaction costs and short-horizon return predictability (an inverse indicator of market efficiency) over time. *OIB2RS* represents the adjusted R^2 from (3). *QSPR* and *ESPR* are used as proxies for transactions costs and are defined as (6) and (7), respectively. Mean and median values are presented in Figure 1A and Figure 1B, respectively. The sample period spans over January 1993 to June 2004 and consists of all stocks that we analyze in connection with the PEAD. The eighth regime ends on (a) June 23, 1997 for the NYSE firms; (b) June 2, 1997 for the NASDAQ firms; (c) May 7, 1997 for the AMEX firms. The sixteenth regime spans (a) June 24, 1997, to January 29, 2001 for the NYSE firms; (b) June 3, 1997, to January 29, 2001 for the NASDAQ firms; (c) May 8, 1997, to April 9, 2001 for the AMEX firms. The decimal regime begins on (a) January 30, 2001 for the NYSE firms; (b) June 3, 2001 for the NASDAQ firms; (c) April 10, 2001 for the AMEX firms.

Notes:

This table provides descriptive statistics for the sample of 61,526 firm-quarters during the period January 1993–June 2004, before the explanatory variables are transformed and coded. *UE* is the actual quarterly EPS less the median of analysts' forecasts of EPS during the month prior to the earnings announcement (from I/B/E/S), divided by the price per share at the end of quarter. *ME* represents the market efficiency, measured as the negative of adjusted R^2 from (3). Annualized historical volatility (*VOLAT*) is calculated as the standard deviation of daily returns over a period of 12 months prior to the earnings announcement date, multiplied by the square root of 252; minimum number of valid daily returns required is 24. Residual volatility (*RVOLAT*) is the standard deviation of residuals from the market model regression of daily returns on the S&P 500 index over the 12-month period ending in the announcement month. *ADV_LSB* and *ADV_HS* (based on approach described in Appendix 1) represent the quarterly average of the adverse selection component of the bid-ask spread estimated on a firm-by-firm basis for each month using the decomposition models of Lin, Sanger, and Booth 1995 and Huang and Stoll 1997, respectively. We exclude invalid estimates generated by the decomposition models reducing the numbers of observations for *ADV_LSB* and *ADV_HS* to 57,839 and 57,834, respectively.

Proxies for investor sophistication are: *INSOWN* (institutional ownership) is defined as the fraction of shares held (from the CDA Spectrum database) by institutions in the calendar quarter prior to the earnings announcement quarter; *NUMEST*, obtained from the I/B/E/S, is the number of analysts following a firm during the quarter prior to the earnings announcement month; *ACTIVE* (active analysts) represents the proportion of analysts who have revised their one-year-ahead EPS forecasts, either up or down, during the quarter. *PRICE* is a closing monthly price during the month prior to the earnings announcement. The dollar trading volume (*VOL*) is then obtained by multiplying the price by the number of common shares traded during the pre-earnings announcement month. *QSPR* and *ESPR* are based on (6) and (7), respectively. *LDV* is based on the approach described in Appendix 2. The maximum likelihood estimation of *LDV* produces some invalid estimates due to reasons such as convergence problems and cases involving boundary or corner solutions. We exclude these invalid estimates from further analysis and the number of observations for *LDV* goes down to 55,286. *SIZE* is defined as the total assets (COMPUSTAT AT) in quarter prior to the earnings announcement. For the correlation analysis, and the analysis of determinants of market efficiency, all variables are winsorised at 1 percent levels, and variables denoted by * are log transformed.

results presented in Table 2. For the correlation and the analysis of market efficiency determinants, *PRICE*, *VOL*, and *SIZE* are further log transformed.

Table 4 reports the Pearson and Spearman correlations among various dependent and explanatory variables. Consistent with prior literature, certain variables are significantly correlated as expected. For example, the Pearson and Spearman correlations between the proxies for investor sophistication (*NUMEST*, *INSOWN*, and *ACTIVE*) are positive and significant at the 1 percent level. Proxies for transaction costs (*VOL* and *PRICE*) and (*QSPR*, *ESPR*, and *LDV*) are also positively correlated, given the nature of their definitions. With the near-perfect correlation between return volatility (*VOLAT*) and residual volatility (*RVOLAT*) close to 99 percent, we present results for only the residual volatility in subsequent multivariate tests.[19] The important result from Table 4 is the significant correlation between the *ME* and all explanatory variables. These correlations are further consistent with previous studies that examine transaction costs, information asymmetry, and investor sophistication in connection with the PEAD, and also with other studies that find supporting evidence for the manifestation of inefficient processing of quarterly earnings news into prices (e.g., Bartov et al. 2000).[20]

4. Tests and main empirical results

Determinants of market efficiency

Before we analyze whether short-horizon return predictability is significantly associated with the PEAD and whether it dominates other control variables previously analyzed in the literature, we provide further insight into the significance of various market efficiency determinants. Chung and Hrazdil (2010a, b) elaborate on CRS by documenting decreasing return predictability over time for all firms traded on NASDAQ and NYSE and validating the short-horizon return predictability as a proxy for market efficiency across portfolios of different sizes, volumes, and trading frequencies. Extending their analysis, we examine additional determinants of market efficiency and demonstrate that trading costs represent only a portion of return predictability. In Table 5, models I–VIII present individually the effects of residual volatility and information asymmetry, investor sophistication, trading costs, and size on market efficiency. Models IX–XII then combine various control variables together. In order to control for residual autocorrelation within firms over time (the firm effect) and residual correlation across firms in each time period (the time effect), we implement the two-way clustering approach proposed by Petersen 2009 and Thompson 2010. Below each coefficient presented in the regression analysis (Tables 5 and 6), we show the *t*-statistic of the double-clustered standard error.

Consistent with Chung and Hrazdil 2010a, b, we find that volume is most strongly associated with the market efficiency measure (adjusted R^2 is about 18 percent). The proxies for transaction costs explain about 2 percent of the variation, whereas proxies for risk along with information asymmetry and investor sophistication explain over 16 percent and 8 percent of the variation, respectively. The adjusted R^2 increases to almost 40 percent when we consider the combined effect of all variables on market efficiency. Consistent with Visaltanachoti and Yang 2010 and Chung and Hrazdil 2010a, volatility improves

19. Using return volatility (*VOLAT*) in the regression tests yields almost identical results.
20. Consistent with theoretical predictions, the correlations between return volatility (residual volatility) and post-earnings announcement returns (*CAR*) are close to zero (albeit significant). In further nontabulated analysis, we obtain results similar to Hou and Moskowitz 2005, consistent with the interpretation that idiosyncratic risk is priced only among the least efficient stocks. Our results show correlations between *RVOLAT* and *CAR* that are much larger (positive and significant) for firms in the lowest market efficiency decile (least efficient firms) compared to firms in the highest efficiency decile (where correlations are all insignificant). The difference in the correlations between *RVOLAT* and *CAR* based on market efficiency deciles is even more pronounced for the extreme *UE* deciles.

Notes:

This table provides the Pearson (above the diagonal) and Spearman (below the diagonal) correlations. Bolded correlations are significantly different from zero at the 1 percent level (two-tailed test) or better. All variables are defined in the preceding tables. The number of observations for all variables is 61,526 with the exception of *ADV_LSB*, *ADV_HS*, and *LDV* (57,839, 57,834, and 55,286 observations, respectively).

market efficiency and proxies for information asymmetry (*ADV_LSB* and *ADV_HS*) have the expected significant signs across all models. The proxies for investor sophistication have the positive sign consistent with Bartov et al. 2000, who argue that sophisticated investors characterize correctly the process underlying earnings, and that the greater the

Notes:

This table is based on pooled panel data estimation. It summarizes the regression analysis of various determinants of market efficiency (the dependent variable). All variables are defined in Table 3. Brackets contain the t-statistic of standard errors derived using the two-way clustering approach proposed by Petersen 2009 and Thompson 2010 to correct for the effects of residual autocorrelation within firms over time and residual correlation across firms in each time period. ***, **, and * denote 1 percent, 5 percent, and 10 percent significance levels, respectively (one-tailed, when the coefficient sign is predicted). All variables are winsorised at the 1 percent levels.

Notes:

This table is based on pooled panel data estimation. It summarizes the regression analysis of market efficiency in relation to the post-earnings announcement drift (the dependent variable). Cumulative abnormal returns (defined in 5) over the post-earnings announcement [+1; +60] period are regressed on various control variables (all defined in Table 3). All explanatory variables are converted to coded scores ranging from −0.5 to +0.5 based on their standing within each earnings announcement calendar quarter. All coefficients are multiplied by 100. Brackets contain the *t*-statistic of standard errors derived using the two-way clustering approach proposed by Petersen 2009 and Thompson 2010. ***, **, and * denote 1 percent, 5 percent, and 10 percent significant levels, respectively (one-tailed when the coefficient sign is predicted).

involvement of sophisticated investors in a stock, the greater their influence on its price. The number of analysts following the firm (*NUMEST*) is significantly positively associated with market efficiency in models II and III, and the proportion of active analysts (*ACTIVE*) has significant incremental effect in contributing to market efficiency. Lastly, all proxies for transaction costs in models IV–VIII are significantly related to market efficiency as expected. Because trading volume itself incorporates the impact of variables such as *NUMEST*, transaction costs, and other indirect trading costs, it is difficult to isolate the individual effect from each of these variables. We attempt to sort out these effects in models IX–XII and results from these models show that even after controlling for the volume and size effects, the major variables for information (*RVOLAT*, *ADV_LSB*, *ADV_HS*) and investor sophistication (*INSOWN* and *ACTIVE*) consistently remain significant and have the hypothesized sign.[21]

The important result from Table 5 is that, in addition to volume, other variables also explain significant variations in the market efficiency measure. Because all of our control variables characterize the information environment, which reflects the extent to which information is efficiently impounded in prices, it would be sufficient to analyze return predictability alone in connection with the PEAD. However, we are interested in whether the market efficiency measure dominates the other variables from prior research claimed to be responsible for the presence and magnitude of the drift. We turn to how the market efficiency measure compares with these other variables in the next section.

Determinants of the PEAD

We examine the coefficients from regressions of 60-day cumulative abnormal returns (*CAR*) on unexpected earnings (*UE*), a set of control variables and a set of control variables interacted with the *UE*. Table 6 reports the parameter estimates (all coefficients are multiplied by 100) and their significance levels from the following regression:

$$\begin{aligned} CAR = \alpha_0 &+ \beta_1 UE + \beta_2 UE * ME + \beta_3 UE * RVOLAT + \beta_4 UE * INSOWN \\ &+ \beta_5 UE * NUMEST + \beta_6 UE * PRICE + \beta_7 UE * VOL + \beta_8 UE * TC \\ &+ \beta_9 UE * SIZE + \sum \beta_k Control\,Variable_k + \varepsilon \end{aligned} \tag{8}$$

where *TC* represents various proxies for transaction costs and where all explanatory variables are defined in section 3 and transformed according to the previous discussion.[22] Consistent with Ng et al. 2008, we include the main effect for these variables as $Control\ Variable_k$ and focus on interpreting the interaction coefficients. Coding variables from −0.5 to +0.5 allows the coefficients to be interpreted in a more meaningful way: α_0 represents a hypothetical median observation between the two middle *UE* deciles and should be close to zero; β_1 coefficient can be interpreted as a difference in cumulative abnormal returns between the lowest and the highest *UE* decile; interaction coefficient (for instance, β_2) represents additional spreads in *CAR* between the extreme *UE* deciles for observations in the highest versus the lowest *ME* decile; we predict and test whether the slope coefficients on *UE***ME* are negative and significant. Further, consistent with predictions developed in prior studies, we expect the estimated coefficient of β_8 to be positive, and the coefficients of β_4 to β_7 to be negative. Model I in Table 6 shows an aggregate proxy for

21. With *VOL* in the same regression, the sign of *NUMEST* becomes negative. This is likely due to the high correlation between these two variables. Our result also suggests that, after controlling for the effects of trading volume and firm size, it is the effect of active analysts (*ACTIVE*) and not the total number of analysts that enhances market efficiency.
22. We are interested in analyzing variables that have been previously documented as significant determinants of the PEAD.

market efficiency in connection with the PEAD. Models II–VI then analyze proxies for information asymmetry, investor sophistication, and trading costs in connection with the drift, whereas models VII–XI provide a comprehensive evaluation of the combined determinants of the PEAD.[23]

During the 60 days after earnings announcements, model I indicates that the difference in abnormal returns between the lowest *UE* decile and the highest *UE* decile is about 4.7 percent and that this spread is about 3.1 percent, significantly lower for the highest *ME* decile firms than for the lowest *ME* decile firms. Further, the interaction coefficients in models II–VI indicate that the drift is more pronounced for firms with high transaction costs (coefficients are insignificant, except for *UE***VOLUME*) and low investor sophistication (coefficients are significant for *UE***NUMEST*). When we include the market efficiency measure as additional regressor in models VII–XI, the results suggest that, after controlling for other variables, the drift remains significantly lower for more efficient firms compared to less efficient firms. Even after including the effects of residual volatility, volume, transaction costs, and investor sophistication (previously documented as primary determinants of the drift), the *UE* interacted with the market efficiency (*UE***ME*) remains to be most significantly associated with the PEAD. Also worth noticing is the magnitude of this coefficient, which indicates its economic significance in explaining the drift. One interpretation of this result is that the market efficiency measure is an important proxy for the extent of arbitrage activities that make price converge to fundamental value and that it is not subsumed by any proxy for barriers to arbitrage used in prior literature. Provided that the lack of short-horizon return predictability is a valid characterization of efficiency in the market, these findings suggest that the PEADs result from investors' underreaction to earnings news, where price convergence to fundamental value after earnings announcements is constrained by high barriers to arbitrage.[24] Because short-horizon return predictability captures other factors that affect arbitrage activities, such as residual return volatility, adverse selection, investor sophistication, volume, size, and trading costs, we evaluate whether transaction costs alone can provide an explanation not only for the persistence but also for the existence of PEAD. We extend our analysis to the PEAD trading strategy with the market efficiency focus.

Analysis of profits

In Table 7, we present the profitability analyses of equal-weighted abnormal returns for the PEAD strategy after considering the effects of market efficiency (i.e., estimate short-horizon return predictability from historical order flows prior to earnings announcements and identify portfolio of lowest deciles and highest deciles efficient firms; observe news in earnings; buy high *UE* decile and short-sell low *UE* decile firms for three months). We compute profits by deducting various proxies for transaction costs from the abnormal returns. In particular, for firms in the top *UE* decile, we subtract the transaction costs from the returns (*CAR*); for firms in the bottom decile of unexpected earnings, we add the transaction costs to negative abnormal returns. We report the corresponding profits for each extreme *UE* and *ME* decile (determined each quarter) and compute various hedge profits by subtracting *UE* decile 1 returns from *UE* decile 10 returns. *Profit* is the difference between *UE* decile 1 returns and *UE* decile 10 returns. *QProfit*, *EProfit*, and *LProfit* are the profits after adjusting for quoted spreads, effective spreads, and *LDV*, respectively.

23. As in Table 5, we apply the conservative approach (Petersen 2009 and Thompson 2010) to compute all *t*-statistics in Table 6 using the double-clustered standard errors.
24. We associate low market efficiency with an underreaction, as opposed to an overreaction, to earnings news because investors are less likely to enter the market when transaction costs and arbitrage risk are high.

Notes:

This table presents the profitability analysis using equal-weighted size and book-to-market abnormal returns adjusted for various proxies for transaction costs. The original sample size is 61,526 quarterly earnings announcements of NYSE, NASDAQ, and AMEX firms from January 1993 and June 2004 (55,286 for the *LDV* profit analysis). Each quarter, firms are sorted into deciles based on the magnitude of their unexpected earnings (*UE*). *UE* is defined in (4). For parsimony, only the analyses for the extreme deciles are reported. The corresponding cumulative abnormal returns (*CAR*), defined in (5) and winsorised at 1 percent levels, are presented for a 60-trading-day interval starting one day following the quarterly earnings announcements. The hedge numbers reflect the profitability of buying stocks in the top *UE* decile and shorting stocks in the bottom *UE* decile. *Profit* is the difference between *UE* decile 1 returns and *UE* decile 10 returns. *QProfit*, *EProfit*, and *LProfit* are the profits after adjusting for quoted spreads, effective spreads, and *LDV*, respectively. The *p*-value of the hedge profit is based on analysis of variance for means and Wilcoxon two-sided test for medians. Period 1 corresponds to the eighth regime (January 1, 1993 to June 23, 1997); Period 2 corresponds to the sixteenth regime (June 24, 1997 to January 29, 2001); Period 3 corresponds to the decimal regime (January 30, 2001 to June 30, 2004).

We provide the abnormal return comparison during January 1993 and June 2004 for three periods characterized by different minimum tick sizes.[25]

Results in Table 7 indicate that both extreme *ME* decile firms experience significant PEAD. Not surprisingly, the PEAD is lower in magnitude for more efficient firms (3.90 percent mean, 4.89 percent median) than for low efficient firms (7.53 percent mean, 7.03 percent median). More importantly, after taking transaction costs into consideration, no significant hedge profits can be generated for high *ME* firms; all transaction-cost-adjusted estimated profits are statistically insignificant and sometimes negative (results are robust across three periods based on the minimum tick size regimes). Therefore, consistent with prior literature, we find that taking into account these transaction costs significantly reduces the profitability of the trades and that transaction costs are responsible for the existence of the drift; however, this applies only to stocks for which information is efficiently impounded in prices and where arbitrage activities are effective in reducing the effect of underreaction to earnings news. In contrast, we document increasing drift for stocks with overall high barriers to arbitrage (*ME* decile 1 firms), even after incorporating the effect of transaction costs. These profits reach several percentage points (2.45–4.89 percent depending on the magnitude of transaction costs) and remain statistically significant.[26] Hence, it is not just transaction costs that are responsible for the magnitude and existence of the PEAD; rather, there are other factors (that *ME* captures more fully) preventing arbitrageurs from taking advantage of the drift.

Overall, consistent with our predictions, the patterns of price movements shown in Table 7 suggest that the information content of earnings news is impounded in stock prices more completely for the more efficient firms than for the low *ME* firms and, as a result, high *ME* firms experience less significant long-term PEAD.

Sensitivity and robustness tests

In this section, we provide an overview of some important robustness tests that mitigate the criticism from the literature on methodological pitfalls and the existence of PEAD.

In terms of variations in methodology, our results are robust to different approaches of estimating abnormal returns, as well as alternative definitions of unexpected earnings and market efficiency estimation. First, in computing the daily abnormal returns in (2), we adjust the raw returns (inclusive of dividends and other distributions) by the daily return on the S&P 500 index, and CRSP value-weighted index. Instead of cumulating the abnormal returns, we also examine the buy-and-hold returns that are more applicable to investors (e.g., Doyle et al. 2006). Second, we measure the five-minute order imbalances and their lagged values by the number of transactions (*OIB#*), as opposed to by dollars (*OIB$*), and use the resulting negative adjusted R^2 from (3) as an alternative measure of market efficiency. Third, we also follow other studies (e.g., Mendenhall 2004) and divide the unexpected earnings in (4) by the cross-sectional standard deviation of the forecasts $SD(\hat{E}_{i,q})$ instead of price.[27] All these modifications do not significantly alter the results presented in Tables 5–7.

25. Period 1 corresponds to the eighth regime (January 1, 1993 to June 23, 1997); Period 2 corresponds to the sixteenth regime (June 24, 1997 to January 29, 2001); Period 3 corresponds to the decimal regime (January 30, 2001 to June 30, 2004).
26. When we partition the profitability analysis into three periods based on the minimum tick size regimes, the hedge return on the portfolio buying good-news firms and selling bad-news firms for low efficient firms generates statistically and economically significant 60-day abnormal returns in period 1 and period 3. In period 2, transaction adjusted profits are not statistically significant.
27. Observations are required to have at least two forecasts. In case where the standard deviation is equal to zero, we remove this observation. This definition results in losing an additional 30 percent of observations due to data availability.

In terms of smaller sample sizes, we further partition the full sample into several groups and confirm the robustness of our results to additional data restrictions. First, we examine only firms with December 31 fiscal year end (as in Nichols and Wahlen 2004) and find that the coefficient on *UE**ME* in Table 6 is even larger and more significant. Second, to confirm that our results are not driven by the newly listed or delisted companies (as in Beaver, McNichols, and Price 2007), we analyze firms listed throughout January 1993 and June 2004, as well as for continuously traded firms, for which all monthly estimations of market efficiency are available. Results remain significant. Lastly, we run (8) separately for the three exchanges. While results in Table 6 are robust to firms traded on the NYSE and NASDAQ, we do not find significant coefficients of *UE**ME* for a sample of firms traded on the AMEX. This inconsistency is likely due to the small sample size of AMEX firms (1,279 firm-quarters, compared to 31,026 firm-quarters on NYSE and 29,221 firm-quarters on NASDAQ). Overall, results in Table 6 are robust to a battery of tests, which strengthens the validity of the market efficiency measures and their implication for the earnings announcement returns and the PEAD.

5. Conclusion

The key innovation of this paper is the use of short-horizon return predictability (a recently established market microstructure proxy for market efficiency based on Chordia et al. 2008) to examine whether the PEAD is directly associated with market efficiency. Compared to specific proxies used in previous literature, the short-horizon return predictability measure is more effective in capturing broadly the overall degree of frictions in the market and provides a more comprehensive approach for assessing the efficiency of market makers, traders, and arbitrageurs in their processing of current earnings information. Our study contributes to the literature by demonstrating that the existence of a 60-day PEAD results from inefficient incorporation of information into prices, largely attributable to an environment with high barriers to arbitrage.

We compare abnormal returns between firms in extreme low and high unexpected earnings and present evidence that more efficient firms experience significantly lower post-earnings announcement abnormal returns. In multiple cross-sectional regressions, we confirm the significance of the market efficiency variable and find that market efficiency dominates the other variables (residual volatility, volume, trading costs, and investor sophistication) documented in previous literature as main determinants of the drift. In further portfolio analyses, we estimate various proxies for transaction costs and analyze whether abnormal profits can be generated using the PEAD strategy after taking these costs into consideration. Although we find that transaction costs significantly reduce the profitability of the trades made in these portfolios, we demonstrate that transaction-cost-adjusted profits continue to remain statistically and economically significant for less efficient firms. Lastly, our detailed sensitivity analysis suggests that other explanations for the PEAD, such as methodological limitations or misestimating of abnormal returns, are not responsible for a significant component of the drift.

These findings strengthen the theory that the PEADs result from investors' underreaction to earnings news and question the degree to which earnings information is efficiently priced. Given that short-horizon return predictability is a valid proxy for capturing inefficient environment with high barriers to arbitrage, our findings show that the CRS measure of market efficiency better predicts and explains stock returns after earnings announcements. Whether this and similar market microstructure measures of market efficiency can also help explain other financial anomalies (accrual, cash flow, or momentum), or whether portfolio managers can utilize these measures further in designing profitable trading strategies remains a subject for future research.

Appendix 1

To measure the adverse selection effect, we use the decomposition models of Lin, Sanger, and Booth 1995 and Huang and Stoll 1997. We estimate these models on a firm-by-firm basis for each month and average the estimates across all months in the quarter ending in the announcement month.

First, we implement the Lin et al. 1995 model using bid-ask spreads and transaction data from the TAQ database compiled at 30-second intervals:

$$\Delta M_{t+1} = \lambda(z_t) + e_{t+1}$$

where $\Delta M_{t+1} = M_{t+1} - M_t$; M_t is the quoted bid-ask spread midpoint at time t; $z_t = P_t - M_t$; P_t is the transaction price at time t; λ is the adverse selection component of the bid-ask spread (*ADV_LSB*); and e is a normally distributed error term.

Second, we follow Huang and Stoll 1997 and estimate the decomposition model:

$$\Delta M_t = \alpha(\frac{S_{t-1}}{2}Q_{t-1}) + \nu_t$$

where $\Delta M_{t+1} = M_{t+1} - M_t$; M_t is the quoted bid-ask spread midpoint at time t; $(S_{t-1})/2$ is the half spread which is half the difference between the quoted ask and bid prices; Q_t is the trade type at time t and takes a value of $+1$ if the trade is an investor purchase and -1 if the trade is an investor sale; α is the combined adverse selection and inventory holding cost component of the bid-ask spread (*ADV_HS*).

Appendix 2

Following Lesmond, Ogden, and Trzcinka 1999 (1122), we estimate the limited dependent variable (*LDV*) and use it as an alternate proxy for transaction costs. Lesmond et al. (1999) specify the relation between the true return and the market return using the standard market model:

$$R^*_{jt} = \beta_j * R_{mt} + \varepsilon_{jt}.$$

The relation between the measured return,R_{jt}, and the true return, R_{jt}on the security with the following system can then be described as:

$$R_{jt} = R^*_{jt} - \alpha_{1j}, \ ... \ if \ R^*_{jt} < \alpha_{1j}$$

$$R_{jt} = 0, \ .... \ if \ \alpha_{1j} < R^*_{jt} < \alpha_{2j}$$

$$R_{jt} = R^*_{jt} - \alpha_{2j}, \ldots if \ R^*_{jt} > \alpha_{2j}.$$

For firm j, the transaction cost threshold is α_{1j} for trades on negative information and α_{2j} for trades on positive information. The difference between the two thresholds, $\alpha_{2j} - \alpha_{1j}$, provides an estimate of the roundtrip transaction costs. Following standard finance literature, the model assumes daily returns are distributed normally. The limited dependent variable (*LDV*) is then estimated using the following log likelihood function:

$$\ln L = \sum_1 \ln \frac{1}{(2\pi\sigma_j^2)^{\frac{1}{2}}} - \sum_1 \ln \frac{1}{2\sigma_j^2}(R_{jt} + \alpha_{1j} - \beta * R_{mt})^2 + \sum_2 \ln \frac{1}{(2\pi\sigma_j^2)^{\frac{1}{2}}} - \sum_2 \ln \frac{1}{2\sigma_j^2}(R_{jt} + \alpha_{2j} - \beta * R_{mt})^2 + \sum_2 \ln \left[\phi_2\left(\frac{\alpha_{2j} - \beta_j * R_{mt}}{\sigma_j}\right) - \phi_1\left(\frac{\alpha_{1j} - \beta_j * R_{mt}}{\sigma_j}\right) \right]$$

Ownership Concentration, Managerial Ownership and Firm Performance: Evidence from Turkey

Pınar Evrim Mandacı, Guluzar Kurt Gumus*

Abstract:

This study examines the effects of ownership concentration and managerial ownership on the profitability and the value of non-financial firms listed on the Istanbul Stock Exchange (ISE) in the context of an emerging market. We measure the firm's performance by Return on Assets (ROA) and Tobin's Q ratios, where the former measures profitability and the latter the value of the firm. In addition, we give detailed information on the main characteristics of the ownership structures of the firms in our sample and find that ownership of Turkish firms is highly concentrated. In addition, the unlisted holding companies have the highest average percentage of shares, which supports the belief that individuals or families establish the holding companies in order to control their listed firms. After controlling for investment intensity, leverage, growth and size, we find that ownership concentration has a significantly positive effect on both firm value and profitability, while managerial ownership has a significantly negative effect on firm value.

Keywords: Corporate governance, ownership concentration, managerial ownership, firm performance, Turkey

1. Introduction

Good corporate governance depends on the combination of the protection of the rights of investors and proper ownership concentration. It has been observed that ownership concentration is high in less developed countries, where the rights of investors are not protected due to the outright lack of or insufficient regulation provided by the relevant laws (see Shleifer and Vishny, 1997 and La Porta et al., 1999). The relationship between ownership structure and firm performance provides an idea about the effectiveness of alternative corporate governance mechanisms.

Grossman and Hart (1986) argued that when the ownership structure of a firm is overly diffused, shareholders are not motivated to monitor management decisions closely, because the benefits that they can attain are mostly lower than the cost they would have to afford to control the managers. Yet, this setting may influence performance negatively. On the other side, Shleifer and Vishny (1986) argued that when the ownership structure is concentrated, shareholders will control the activities of the managers easily, thereby avoiding inefficiency in management, and improving firm performance. However, according to the agency theory, Jenson and Meckling (1976) argued that high concentration may simultaneously lead major shareholders to give priority to their own interests, and

subsequently agency problems[1] may occur between the shareholders and managers. In order to minimize agency problems, shareholders have to endure agency costs[2]. In addition, according to them, managerial ownership prevents conflicts of interest between the managers and owners and increases the value of the firm. Significant managerial ownership can align managers' interests with those of the outside shareholders so that managers can have strong incentive to pursue value-maximizing behavior (alignment effects). In contrast, Demsetz (1983) argued that too large an ownership stake by managers could potentially lead them to worry more about their own interests, not those of outside shareholders, hence decreasing the firm's value (entrenchment effects).

In this paper we aim to measure the effects of managerial ownership and ownership concentration on the profitability and value of Turkish non-financial firms listed on the Istanbul Stock Exchange (ISE). In Turkey, the listed corporations are mostly owned by families. Standards of corporate governance and investor protection are lower in Turkey than in the U.S. and other major countries. Hence, we hope that this study will add an interesting dimension to the relation between these variables and performance in a developing country under a poor governance system.

Our paper is organized as follows. The second part consists of a literature review. In the third part, data and summary statistics are presented. Methodology and empirical results are presented in the fourth part, and the final part offers concluding comments.

2. Literature Review

Although initially Berle and Means (1932) suggested a positive correlation between ownership concentration and performance, some of the following studies did not observe a relation between these two variables (see Demsetz, 1983; Demsetz and Lehn, 1985 and etc). The study by Demsetz and Lehn (1985) that examined the relationship between accounting profit rate and percentage of shares owned by the five and ten largest shareholders where ownership structure is treated as an endogenous variable found no evidence of a relation between these variables for U.S. companies. They argued that although greater ownership concentration results in stronger incentives to monitor, the expected gain from active monitoring and the cost of alternative ownership structures vary across firms. Morck et al. (1988) ignored the endogenous issue and similar to Demsetz and Lehn (1985) found no significant relation in the linear regressions they calculated by using accounting profits and Tobin's Q as an alternative measure of performance. Shleifer and Vishny (1997) argued that making the ownership structure relatively centralized could promote the shareholder's controlling ability and therefore the existence of the big shareholder was favorable to the growth of a company's value. Himmelberg et al. (1999) argued that the empirical findings might be the result of unobservable firm heterogeneity, which might affect both ownership concentration and performance. These unobserved exogenous firm characteristics might induce a spurious relationship between Tobin's Q and ownership concentration. They found no relation between these two variables after estimating firm fixed effects. Loderer and Martin (1997) and Demsetz and Villalonga (2001) found no influence of ownership concentration on performance for U.S. firms. Their finding is consistent with the view that while exacerbating some agency problems, diffuse ownership also yields compensating advantages that generally offset such problems. On the other hand, Morck et al. (1988) and Hiraki et al. (2003) for Japanese firms, and Gorton and Schmid (2000) for German companies, found a positive relation between ownership concentration and firm value.

In addition to studies on developed countries, most of the studies for developing countries found a positive relation between ownership concentration and performance. Claesses and Djankov (1999) examined Czech companies and argued that the more concentrated the ownership, the higher the firm's profitability; this finding signified the same positive relation as indicated in studies on Czech firms by Claessens (1997) and Weiss and Nikitin (1998). However, their findings were ambiguous when the type of ownership was taken as the control variable. Similar to their previous study in 1997, Xu and Wang (1999) examined Chinese listed firms and found a positive correlation between the shareholding ratio of the first five and ten big shareholders and performance. Sun et al. (2002) proved that relatively bigger holding companies and other big shareholders which had a certain concentration degree could help improve the performance of Chinese firms. Barberis et al. (1996) also found a positive relation for Russian firms. Joh (2003), who examined Korean firms, found that after controlling

[1] It is likely that managers may place personal goals ahead of corporate goals (Gitman, 2006: 20).

[2] The costs borne by stockholders to maintain a governance structure that minimizes agency problems and contributes to the maximization of owner wealth (Gitman, 2006: 20).

firm and industry characteristics, firms with low ownership concentration recorded low profitability. Yammeesri et al. (2006) examined Tai non-financial firms, and as the literature proved previously, found a positive association between concentrated ownership and performance. Similarly, Omran et al. (2008), in their studies on a group of Arab countries (Egypt, Jordan, Oman, Tunisia), found that ownership concentration was positively correlated with various performance measures, and that large-size firms were more likely to achieve better performance. However, parallel to the findings of Demsetz and Lehn (1985), and Himmelberg et al. (1999), Chen et al. (2005) found for Hong Kong firms that concentrated ownership was not associated with better operating performance or higher firm valuation. Comparably, Gunasekarage et al. (2007) proved that ownership concentration is negatively related to firm performance in China when market-to-book ratio is used as a performance indicator. Gursoy and Aydogan (2002) examined the impact of ownership concentration and ownership mix on firm performance of Turkish non-financial firms between 1992 and 1998 and found that higher concentration led to better market performance but lower accounting performance. They used price-to-earnings ratio and stock returns to measure market performance.

There are many studies with contending results on the relationship between managerial ownership and performance. Among them, Jensen and Meckling (1976) stated that when managerial ownership increased, conflict would decrease and performance would increase. In contrast, Fama and Jensen (1983) and Stulz (1988) argued that greater stock ownership by managers increased the power of the internal owners and decreased the power of the external owners in terms of influencing performance. Morck et al. (1988) found a significant non-monotonic relationship between Tobin's Q and board member ownership. Accordingly, the relation increases between 0% and 5%, decreases between 5% and 25%, and increases beyond 25%. Their outcomes were also significant when some control variables such as R&D and advertising ratios, leverage, size, growth and industry dummies were included in models. However, they were not significant when accounting profit rates were used as an alternative performance measure. Similar to the study of Morck et al. (1988), McConnel and Servaes (1990), Hermalin and Weisbach (1991), Cho (1998) and most recently Florackis et al. (2009) found a positive relation for low levels of ownership and a negative relation for high levels of ownership. Yet, unlike Morck et al. (1988), McConnel and Servaes (1990) found that this relationship was also significant when they used accounting profits instead of Tobin's Q. In contrast to other studies, Florackis et al. (2009) found a negative relationship by using a semi-parametric estimation approach. As in Morck et al. (1988), Holderness et al. (1999) found a significant positive relation between firm performance and managerial ownership within the 0% to 5% range of managerial shareholdings; but in contrast to Morck et al. (1988), they did not find a statistically significant relation beyond 5%. Demsetz and Lehn (1985), Loderer and Martin (1997), and Himmelberg et al. (1999) as well as Demsetz and Villalonga (2001) did not find a significant relation between managerial ownership and performance. Most of those studies examined the association between insider ownership and performance account for the endogeneity of ownership structure except Morck et al. (1988) and McConnell and Servaes (1990). Demsetz and Villalonga (2001) examined US firms and their evidence supported the belief that ownership structure was endogenous but belied the belief that ownership structure affected firm performance. They argued that if there were compensating advantages in a firm, there would be no systematic relation between managerial shareholdings and firm performance. In addition, they argued that it might indicate that this relationship depends on location, special local laws and governance practices. There is no study which examines the relationship between managerial ownership and the performance of Turkish firms.

As can be seen from the above, the empirical results on the effects of managerial ownership and ownership concentration on firm performance are conflicting. In addition, the previous studies focused mostly on large industrialized countries, which completed their institutionalization process; therefore, their outcomes might not be relevant for developing countries. In this study, we try to fill this gap by examining this issue for a developing country, namely Turkey.

3. Data and Summary Statistics

Our sample includes all non-financial firms listed on the ISE in the year 2005. The number of firms in our sample is 203. We excluded banks and leasing, investment, insurance and holding companies since their financial tables are different from non-financial firms. We collected data on market values of the sample firms from the Monthly (December) Bulletins of the ISE. We used annual company reports issued by the ISE to obtain data on ownership structure (ownership concentration, managerial ownership, etc.). We obtained the remaining data by using the balance sheets and income statements from the ISE's website.

In line with previous studies (such as Morck et al.,1988; McConnel and Servaes, 1990 and etc.), we also focused on one year of data by taking into consideration the fact that the ownership structure of the firm does not vary frequently. In addition, the International Financial Reporting Standards have been applied in Turkey since the beginning of 2005. The firms are required to incorporate the new standards and to prepare more detailed annual reports which provide more data to finance researchers and consequently facilitate the analysis of firms' ownership structures. Hence, this study takes 2005 to be the starting line.

Table 1 depicts the number of the different types of shareholders of the present study's sample firms operating in different industries. According to this table, individuals and families, unlisted holding companies and unlisted non-financial firms pre-dominate the ownership positions in the sample firms. Furthermore, this predominance is mostly seen in the textile industry. Additionally, most of the shareholders are foreign companies in the food industry, listed holding companies in the metal products industry and listed non-financial firms in the stone and soil industry. The ownership positions of the state, foundations and labor unions are very low compared to other parties.

Table 2 denotes the average percentage of shares held by the owners of the sample firms in different industries. The highest average percentage of shares is held by unlisted holding companies, which supports the belief that individuals or families establish the holding companies in order to control their listed firms. It is followed by the unlisted non-financial firms and individuals and families respectively.

Table 3 depicts the proportion of shares held by the Board members and managers as well as their relatives. In Turkey it is often observed that the family members are the CEOs, Boards of Directors or top managers of the firms. As a result, management control is in the hands of these family members (see Yurtoğlu, 1998 and Demirağ and Serter, 2003). Table 3 denotes that CEOs, Boards of directors and top managers have almost 8.38% of shares outstanding. And their relatives have almost 3% of the outstanding shares. Board members and general

Table 2: Ownership Structure of Non- financial Firms in Different Industries (in %, Year 2005)

managers have a considerable share in the technology industry (24.05 percent). The average of openness-to-public is 33 percent within sample firms.

Table 4 gives the percentage of shares owned by the largest three, five and ten shareholders for the sample firms in different industries. It shows that the largest shareholder has around 48 percent of shares, which indicates that one person or an institution has almost half of a listed company. The averages for the largest three, five and ten are 61.27; 64.20 and 65.93 respectively. Moreover, the highest ownership concentration is in *education, sport and health* industry for the largest shareholder and in the telecommunication industry for the largest three, five and ten shareholders.

Industry	Share of Board Members and General Manager	Share of Family Members	Open-to-Public (%)

Table 4: The Ownership Concentration Rates for Non-financial Firms (in %, Year 2005)

We used two measures of performance as dependent variables, Return on Assets (ROA) and Tobin's Q ratios, where the former measures profitability and the latter the value of the firm. We used two independent variables, the percentage of shares held by the largest three shareholders and the percentage of shares held by the managers. We observed that the studies on Turkish firms (such as Gursoy and Aydogan, 2002 and Demirağ and Serter, 2003) prefer using the share of the largest three shareholders to measure ownership concentration. Depending on these previous studies as well as our outcomes about the concentration rates presented in Table 4, we used the percentage of shares held by the largest three shareholders to measure ownership concentration. Our control variables are the investment intensity, leverage, growth and size which are assumed to have an effect on firm performance. In addition to these we employ industry dummy variables in order to point out whether the performance measures differ across industries. The study's variables and their definitions are presented in Table 5.

Dependent Variables	Definition
TOBIN'S Q	Market value of assets (total debt plus market value of equity)/ total assets
ROA	Net Income/Total Assets
Independent Variables	
CON3	Total share of the largest three shareholders in the firm
OWNER	Managerial Ownership: Percentage of Shares Owned by the managers
Control Variables	
CAPEXP	Capital Expenditures/Sales (investment intensity)
DEBTTA	Total Debt/Total Equity (Leverage)
GROWTH	Average growth in net sales over three-year period (2003-2005)
SIZE	Logarithm of total assets
INDUSTRY DUMMIES	Education-health; electricity; food-beverage; chemical-petroleum-plastic; metal products-machinery; wood-paper-printing; non-metal mineral products; technology; textile-leather; wholesale and retail trade; transportation.

Table 5: Variables and Definitions

Table 7B. Correlation Matrix (between Tobins Q and independent variables)

The descriptive statistics for variables are presented in Table 6. For the year 2005, the average ROA was 0.05 while the highest ROA was 0.59. Mean of Debt-to-Total Assets indicates that Turkish companies prefer financing their companies with capital instead of debt. The highest standard deviation belongs to capital expenditures and Tobin's Q, showing the highest variance among companies.

Tables 7 A and B show the correlation matrix for each dependent variable. The correlation coefficients among independent variables are low. Additionally, correlation coefficients between independent and dependent variables are consistent with the direction of the relation and coefficients found in the regressions analysis.

4. Methodology and Empirical Results

We applied multiple regression analysis to measure the effects of ownership concentration and managerial ownership on firm performance. We developed two different groups of hypotheses on the relationship of ownership concentration and managerial ownership with firm performance. In parallel to most of the previous studies on developing countries, we expected a positive relationship between ownership concentration and firm performance. Since the ownership concentration is high in Turkey, the shareholder can easily control the managers and force them to focus on the maximization of the shareholders' wealth. Agency theory suggests that when the managerial ownership increases, the conflict of interest between the managers and owners will decrease and firm performance will increase. Although most of the previous studies did not observe a relation between managerial ownership and firm performance, in line with the theory, we expected a positive relationship between them. The hypotheses of the study are stated below;

$H1_0$. The ownership concentration is not significantly related to firm performance.

$H1_1$. The ownership concentration is positively correlated to firm performance.

$H2_0$. The level of managerial ownership is not significantly related to firm performance.
$H2_1$. The level of managerial ownership is positively correlated to firm performance.

Different models were constructed to explore the effects of the independent variables. In models where the ROA and TOBINSQ are the dependent variables, first all variables other than industry dummies were included in the analysis, and then the industry dummies were included to investigate the industry effects on firm value and profitability. The four models of the study are presented below.

Model 1:

$$ROA_i = \beta_0 + \beta_1 CON3_i + \beta_2 OWNER_i + \beta_4 CAPEXP_i + \beta_5 DEBTTA_i + \beta_6 GROWTH_i + \beta_7 SIZE_i + \varepsilon_i$$

Model 2:

$$ROA_i = \beta_0 + \beta_1 CON3_i + \beta_2 OWNER_i + \beta_4 CAPEXP_i + \beta_5 DEBTTA_i + \beta_6 GROWTH_i + \beta_7 SIZE_i + D_i + \varepsilon_i$$

Model 3:

$$TOBINSQ_i = \beta_0 + \beta_1 CON3_i + \beta_2 OWNER_i + \beta_4 CAPEXP_i + \beta_5 DEBTTA_i + \beta_6 GROWTH_i + \beta_7 SIZE_i + \varepsilon_i$$

Model 4:

$$TOBINSQ_I = \beta_0 + \beta_1 CON3_i + \beta_2 OWNER_i + \beta_4 CAPEXP_i + \beta_5 DEBTTA_i + \beta_6 GROWTH_i + \beta_7 SIZE_i + D_i + \varepsilon_i$$

Table 7 presents the regression results for ROA and Tobin's Q. In Models 1 and 2, we used ROA as a measure of profitability and found a significant positive effect among the largest three shareholders on firm profitability in the models in which the dummies were excluded. Debt-to-total assets and growth variables also had significant effects in all models. Additionally, the dummy for the education industry has a significant effect, but managerial ownership and capital expenditures did not have an effect on profitability. When we added the dummy variables in the model, the adjusted R^2 increased to 0.276 from 0.182.

In Models 3 and 4, we used Tobin's Q as an indicator of firm value and found that the largest three shareholders had a significant positive effect, and that managerial ownership had a significant negative effect on firm value. When we included the dummy variables, we did not find a significant relationship between managerial ownership and firm value. In addition, Debt-to-total assets and size variables were the other factors that affected firm value negatively. Capital expenditure and growth did not have a significant effect on firm value. The model with dummy variables of industries pointed out the significant effects of education, food and beverage and wholesale industries on firm performance. After we included the industry dummies, the adjusted R^2 increased to 0.34 from 0.18.

The positive relationship between ownership concentration and performance supports the study of Shleifer and Vishny (1997) who state that since investor protection is low in developing countries, ownership concentration is accepted as an alternative corporate governance tool in these countries. Our findings are also parallel to previous studies on developing countries such as Barberis et al. (1996), Claesses and Djankov (1999), Joh (2002), Yammeesri et al. (2006). However, our result on the relationship between the ownership concentration and profitability is the opposite of that of Gursoy and Aydogan (2002) which found a negative relationship between ownership concentration and profitability. The findings on the effects of managerial ownership are much more conflicted in the literature. Our finding does not support the agency theory. The negative relation between managerial ownership and firm value might be explained by Demsetz (1983), who argued that too much managerial ownership could potentially lead managers to worry more about their own interests, and not those of outside shareholders, hence decreasing firm value.

5. Concluding Comments

The empirical results on the effects of managerial ownership and ownership concentration on firm performance are conflicting. Previous studies focused mostly on large industrialized countries, which completed their institutionalization process and therefore, their outcomes might not be relevant for developing countries. In this study, we try to fill this gap by examining the effects of ownership concentration and managerial

Table 7: Regression Results

ownership on the performance of Turkish firms listed on the ISE in the context of a developing country. We measured firm performance by ROA (Return on Assets) and Tobin's Q, where the former measures profitability and the latter firm value. We tried to test the relationships between these performance measures and the percentage of shares owned by the largest three shareholders, and the percentage of shares held by board members and general managers. In addition to these independent variables, we used control variables including investment intensity, leverage, growth and size and industry dummies, which are assumed to have an effect on firm performance.

In addition, we analyzed the ownership structure of the sample firms and found that the highest average percentage of shares was held by the unlisted holding companies, unlisted non-financial firms and individuals and families, respectively, which confirms the widespread belief that in Turkey individuals or families set up their unlisted firms in order to control their listed companies. Supporting the studies of Gursoy and Aydogan (2002) and Gönenç (2004), we found that the ownership of Turkish firms is highly concentrated. Our regression results show that ownership concentration has a significant positive effect on both firm value and profitability. This result may support the idea of Schleifer and Vishny (1997) who state that since investor protection is low in developing countries, ownership concentration is accepted as an alternative corporate governance mechanism in these countries. On the other hand, in contrast to the agency theory, we found a negative relation between managerial ownership and firm value, which might support the argument of Demsetz, who states that too much managerial ownership could potentially lead managers to worry more about their own interests and decrease firm value. The finding does not support the idea of Jensen and Meckling (1976), who argue that as managerial ownership increases, the conflict between the managers and owners will decrease and performance will increase. The results of the study suggest that Turkish firms can increase their performance by increasing their ownership concentration and by decreasing managerial ownership.

We believe, despite the uniqueness of the results, that this study proves that the subject deserves greater attention and more detailed analysis. We did not add other agency variables such as the number of independent directors, board composition, etc., since the full data is not available in annual reports. Future studies might collect this data by directly contacting the firms. In addition, future studies might include financial firms and holding companies.

Abstract

This paper analyzes the phenomenon known as accrual anomaly in Brazil. In particular, we examine two hypotheses: (a) that the earnings expectation included in the stock price fails to reflect the difference in persistence of the earnings components (accruals and cash flows); and (b) that the construction of a hedge portfolio by taking a long (short) position in assets with low (high) accruals generates consistently abnormal returns. The data set includes nonfinancial firms listed on the BM&FBOVESPA between 1990 and 2008. The empirical tests required conducting panel data regressions to identify the persistence of earnings and their components; the Mishkin test to identify whether the market rationally prices earnings; and the composition of a zero-investment (hedge) portfolio to analyze whether a trading strategy based on accruals consistently provides abnormal positive returns. The results indicate that the accrual component is not mispriced by the Brazilian market, and that a trading strategy based on accruals does not provide consistently positive returns. Although this evidence does not encourage arbitrage, the results are relevant from various perspectives. The methodology applied permitted identifying the quality of earnings and of their components, as well as association between the components of earnings and returns.

Key words: accrual anomaly; earnings quality; persistence of accruals.

Introduction

This article investigates the relationship between accruals and stock returns in the Brazilian capital market. This topic is relevant for various users of financial statements. Investment analysts follow the reported results to support their estimates or revise their forecasts. Executives often have bonuses tied to earnings, being rewarded when performance expectations are attained (executive equity compensation). Creditors use earnings as a parameter in contractual debt covenants and to monitor the borrower's capacity to honor obligations (Smith & Warner, 1979). The focus on earnings is so intense that some authors believe the market neglects other performance measures (Chan, Chan, Jegadeesh, & Lakonishok, 2006). The **fixation on earnings** can carry some hidden pitfalls, mainly because of the often non-convergent interests concerning reported earnings (Jensen & Meckling, 1976).

The present article provides an expanded panorama of the relationship between accruals and stock returns in the Brazilian market. The analyses take into account specific firm characteristics (such as operational performance, risk factors and economic segment), the rationality of agents in pricing earnings and their components, and the implementation of investment strategies that seek to obtain abnormal gains from the level of accruals. The empirical tests applied to the sample permitted analyzing the phenomenon known as accrual anomaly, besides identifying the most important components of the formation, variability and persistence of the accruals of firms listed on the BMF&BOVESPA.

Our aim was to identify whether the market rationally prices earnings in the formation of expectations of future returns. The information available on the market price of assets was incorporated by applying the Mishkin test. This procedure is usually included in the studies of accrual anomaly and permits identifying possible bias between the intrinsic value of an asset and its market value. If there is asymmetry between rational valuation and market valuation, there will be an opportunity for abnormal gains by exploiting the persistence of earnings and their components.

For final verification of the occurrence of accrual anomaly in the Brazilian capital market, we constructed a zero-investment portfolio based on the magnitude of accruals. The occurrence of an anomaly is only confirmed if the zero-investment portfolio provides positive and consistent returns (Bernard, Thomas, & Wahlen, 1997). Sloan (1996) showed that a hedge strategy with a long position in assets of low accruals and a short position in assets of high accruals generates significant abnormal returns. The accrual anomaly has been intensely debated in recent international academic literature in finance (Desai, Rajgopal, & Venkatachalam, 2004; Dopuch, Seethamraju, & Xu, 2010).

However, more than a decade after publication of the seminal article by Sloan (1996), there has been no discussion of this anomaly in the Brazilian market, at least according to our search of the CAPES thesis database and Google Academic. This observation is strange since Brazil has some peculiar characteristics in relation to other countries, especially the USA. For example, Lopes and Galdi (2006, p. 28) points to the strong influence of tax rules in accounting statements in Brazil. Another aspect is international investors' strong interest in the Brazilian market.

This study is also relevant for identifying whether agents (such as portfolio managers) correctly price the components of earnings included in the market price of stocks to form their expectations of future dividends. Lack of knowledge of the components of earnings can increase information asymmetry and contribute to mispricing of assets, enabling wealth to be unduly transferred to companies with low earnings quality.

Literature Review

Accrual anomaly

Sloan (1996) empirically identified that investors tend to overvalue accruals in forming expectations about the future earnings of U.S. firms and are surprised when the persistence of this earnings component is shorter than predicted. In the view of Defond and Park (2001), the market exaggerates in measuring accruals because investors' expectations are biased in anticipating future reversal of this earnings component. As a consequence, companies with high (low) levels of accruals obtain negative (positive) abnormal returns, a phenomenon known as accrual anomaly. Since then, various works have examined this anomaly. Indeed, it is one of the most studied topics in recent studies of capital markets (Green, Hand, & Soliman, 2011).

This research basically has three categories of focus. One group of studies relates accrual anomaly with other anomalies, such as the works of Collins and Hribar (2000), Desai, Rajgopal and Venkatachalam (2004), and Fama and French (2008). The first work identified that accrual anomaly is different than post-earnings announcement drift (the tendency for the cumulative abnormal returns of an asset to accompany an earnings surprise for various days after its announcement, due to an overreaction of the market to the result disclosed). The second work examined accrual anomaly in the context of value glamour (the empirical regularity of firms [value companies] with low sales growth or high book-to-market, earnings-market price or cash flow-market price ratios to perform worse than firms [glamour companies] with contrary indicators). The third work found that, together with momentum (short-term returns tend to follow those observed in the recent past), accrual anomaly has the most evidence in the U.S. market.

A second group includes studies that relate abnormal returns to trading strategies based on accruals. Ali, Hwang and Trombley (2000) identified evidence contrary to the naive investor hypothesis in relation to large firms that are accompanied by analysts or held by institutional investors (the hypothesis postulates that the predictive capacity of accruals in relation to future earnings is small in these cases), and that asset price, trading volume and transaction costs do not condition the predictive capacity of accruals for future returns. Khan (2008), in turn, found that the difference in average returns of companies with very high or very low levels of accruals is explained by the difference in risk of the two types of assets.

The last category relates investors, analysts and other sophisticated users of financial statements with the properties of accruals. In this line, Bradshaw, Richardson and Sloan (2001) concluded that analysts overestimate the persistence of accruals, while Collins, Gong and Hribar (2003) found that the mispricing of accruals is reduced when there is strong institutional control. According to Lev and Nissim (2006), accrual anomaly is not eliminated in the function of systematic structural factors that prevent investors from consistently forming profitable strategies to exploit accrual anomaly, thus restricting the opportunity for arbitrage. Mashruwala, Rajgopal and Shevlin (2006) corroborated the work of Lev and Nissim (2006).

The findings of Sloan (1996) have been confirmed by other researchers, using different time periods and definitions of accruals. Among the relevant findings, there is evidence that the components of accruals, such as inventories and accounts receivable, are associated with the returns of hedge portfolios (Chan *et al.,* 2006; Hribar, 2000; Thomas & Zhang, 2002).

Accrual anomaly is an important discovery in the academic literature. Despite the evidence showing its presence in different markets and periods, the reasons for its occurrence are still an open question. Pincus, Rajgopal and Venkatachalam studied the phenomenon in various markets and identified mispricing of accruals and the existence of anomaly in countries like Australia, Canada, United Kingdom and United States. They indicate as a possible cause the divergence of institutional characteristics of the countries, such as the legal regime and protection of shareholders' rights. With respect to the legal regime, the authors argue that common law systems are more permissive (allow more flexibility) regarding accounting of accruals than are code law systems. Regarding shareholders' rights, in countries where legal protection is weak, there is more room for managerial discretion in detriment to the interests of the shareholders (mainly the minority ones).

Ball, Kothari and Robin (2000) support the idea that the legal regime, particularly regarding the type of governance implemented, impacts accrual anomaly. In common law countries, the corporate governance system tends to be aimed at all shareholders, by intense use of financial statements and other public disclosures to mitigate problems of asymmetric information, whereas in code law countries, the governance system is oriented to the interests of the main shareholders, in a relationship of private communication (insider information). The differences of the governance system can affect the relevance of accounting information, according to the intensity with which the opportunity and conservatism resulting from the adoption of a determined legal regime reduces/increases information asymmetry, encouraging or discouraging a setting propitious for the occurrence of accrual anomaly. But there is also evidence of the presence of mispricing of accruals in countries with different legal regimes, leading to the perception that the anomaly is more reasonably explained by some systematic risk or a behavioral bias of investors in the use of accruals (LaFond, 2005, p. 11).

Accruals in Brazil

Despite the growing number of empirical works on accruals in general, research on accrual anomaly is still incipient in Brazil. Of the clusters identified in the bibliometric analysis, the most common current of investigation in the Brazilian academic literature on accruals is "earnings management", in line with the international trend. Of the works researched on accruals, we gave greater emphasis to those listing the seminal article of Sloan in the references. When applying this criterion, it revealed another research line that relates accruals with their effect on the financial statements, particularly on distortions in the disclosed results (Colauto & Beuren, 2006, 2007).

There are also studies that examine the association of accruals and stock returns (Dantas, Medeiros, & Lustosa, 2006; Galdi & Lopes, 2009; Lopes & Galdi, 2006) and others covering the relationship between cash flows, accruals and earnings (Lustosa & Santos, 2007). In this work, the authors analyzed a sample of 92 Brazilian nonfinancial firms through time series data from 1996 to 2004 and concluded that cash flow alone is a better predictor of future flows than cash flow and accruals taken together. They also found that earnings have little informational value, a fact that urges the search for a new accounting model. Of the Brazilian works citing Sloan (1996), there are also works addressing the quality of earnings and accrual anomaly itself (Almeida, Lima, & Lima, 2009).

Methodology

Definition of variables

In this work, we used operating earnings as our earnings measure, defined as earnings before interest and taxes (EBIT). Accruals were calculated by balance sheet approach, according to Equation (1), and operating cash flows by the difference between earnings and accruals. Since accruals are calculated by the change observed between consecutive periods of the items making up working capital, there were no data available for 1990, the first year of the sample. The same situation applies to returns.

$$\mathrm{Acc} = (\Delta \mathrm{CA} - \Delta \mathrm{Cash}) - (\Delta \mathrm{CL} - \Delta \mathrm{Deb} - \Delta \mathrm{Tax}) - \mathrm{Dep} \quad (1)$$

where Δ represents the change in the observed variable, CA is Current Assets; Cash is cash and cash equivalents, CL is Current Liabilities; Deb is short-term debt; Tax is income taxes payable, and Dep is the depreciation and amortization expense.

The calculation of returns required some adjustments. The time window for its measurement is one year, starting four months after the end of the previous fiscal end. This procedure is employed in other works in the Brazilian literature, such as Lopes and Galdi (2006), and in most foreign studies (Francis, Lafond, Olsson, & Schipper, 2005; Sloan, 1996; Richardson, Sloan, Soliman, & Tuna, 2005, among others). This procedure is based on the fact there is a delay between the end of the year and the date when the financial statements are published. Obtaining stock prices only at the end of the fourth month of the next year aims to assure that all the necessary information is available to construct portfolios (Fama & French, 1995) and that investors make their trading decisions under an accruals strategy at the end of April of each year of the sample. The returns (Ret) are thus calculated by:

$$\mathrm{Ret}_t = \frac{(P_t - P_{t-1})}{P_{t-1}} \tag{2a}$$

where P is the closing price of the stock four months after the end of the fiscal year, based on the assumption that investors follow a buy-and-hold strategy until the next period.

Our definition of abnormal returns follows Sloan (1996, p. 294) and requires adjustment by the "size" variable to calculate the returns of the control portfolio. The explanatory power of the size variable for returns has been stressed in the literature (Bernard & Thomas, 1990). The returns scaled by size were calculated as the average of the excess return of individual assets over the return of a control portfolio, formed by assets of equivalent sizes, with the return given by applying a buy-and-hold strategy during the period. Specifically, the method consists of several steps. The first involves calculating the gross return of the individual assets. The next step is to identify to what control portfolio the individual asset belongs. For this, the distribution of the series is divided into quantiles by size, whose proxy is the natural logarithm of the company's market value. Next, the return of the control portfolio is identified by the average of the gross returns of the individual assets with equivalent sizes. Formally,

$$\mathrm{Ab\_Ret}_{i,t} = \mathrm{Ret}_{i,t} - \frac{1}{n}\sum_{i=1}^{n} \mathrm{Ret}_{i,t} \tag{2b}$$

where $\mathrm{Ab\_Ret}_{i,t}$ is the abnormal return of asset i in period t and $\frac{1}{n}\sum_{i=1}^{n} \mathrm{Ret}_{i,t}$ is the average of the returns of the assets that compose the control portfolio. The other definitions (time window and buy-and-hold returns) are identical to those used to calculate the gross returns.

This is the method of calculating abnormal returns not only in studies of accrual anomaly (Penman & Zhang, 2002; Sloan, 1996; Xie, 2001) but also in examinations of other anomalies in the financial literature (Bernard *et al.*, 1997).

Data and sample selection

The sample consists of all the firms listed for trading on the São Paulo Stock Exchange (BM&FBOVESPA) that are followed by Economatica. We excluded financial companies, as is common for studies in this area (Chan *et al.*, 2006; Sloan, 1996, among others). The main reason for excluding financial firms is that they are subject to specific regulation by the Brazilian Central Bank and have specific accounting rules (Richardson, Teoh, & Wysocki, 1999), notably on the treatment of accruals (LaFond, 2005).

The empirical tests relied on past accounting figures and share prices (on an annual basis) for the period between 1990 and 2008, besides time series and cross-sections of the earnings variable and its components (accruals and cash flow). All observations were adjusted for inflation. Since the magnitude of the balance sheet items varies by cross-section unit, all the variables were standardized to permit comparisons between firms, following practice widely employed in similar studies (Sloan, 1996). The standardization measure used was average total assets.

To avoid the influence of a small number of extreme observations (outliers), we excluded data above and below two standard deviations from the mean of the series. We also eliminated data without economic significance, probably generated by problems of the data gathered from the provider of financial information (*e.g.*, market value or total assets less than zero). Taken together, the adjustments reduced the sample by approximately 1.8%.

Hypothesis tests

Pricing of earnings and its components (first hypothesis)

In pricing by rational expectations, investors base their decisions on the information available about all the relevant variables that affect stock returns. Using the Mishkin test enabled verification of whether stock prices reflect the difference in the persistence of the components of earnings. Mishkin (1983) established a test of market rationality and efficiency that consists of a nonlinear estimation procedure by maximum likelihood. The test was initially conceived to test the rational expectations hypothesis in macroeconomics, to supply a statistical comparison between a measure of pricing by the market (valuation coefficient) and another of rational expectations (forecasting coefficient) given by a relevant variable.

In the Mishkin test as applied by Sloan (1996), the hypothesis to be tested is that the market's subjective expectation about stock returns is identical to the objective expectation, conditional on past information. Assuming that the model for expected return is adequately specified (*i.e.*, the equilibrium pricing equation is correct), the parameter estimated by the model is compared with the coefficient given by an earnings regression (dependent variable) and by lagged variables (explanatory variables). If the estimate of the parameters of the two equations is different, the conclusion is that the market is not rationally using past information (*i.e.*, the market is inefficient). For example, if the valuation coefficient is significantly higher than the forecasting coefficient, the Mishkin test indicates that the market overestimates the relevant variable (earnings and its components). The interpretation is the same (but with opposite effect) when the valuation coefficient is significantly lower than the forecasting coefficient. In this case, the market underestimates the respective variable.

The hypothesis inherent to rational expectation of future earnings states that the market's subjective estimation is equal to the objective estimation based on the available information:

$$E_{m_t}(\text{Earnings}_{t+1}|\emptyset_t) = E_t(\text{Earnings}_{t+1}|\emptyset_t) \tag{3}$$

where

. $\emptyset_t$ = set of information available in period *t*

. $E_{m_t}(\text{Earnings}_{t+1}|\emptyset_t)$ = subjective expectation of the market conditional on $\emptyset_t$

. $E_t(\text{Earnings}_{t+1}|\emptyset_t)$ = objective expectation conditional on $\emptyset_t$

The specification given in (3) implies that the market's expectation of earnings is equal to the true expectation conditional on all past information. Assuming the market is efficient,

$$E_t(Y_{t+1}) = \text{Ret}_{t+1} - E_{m_t}(\text{Ret}_{t+1}|\emptyset_t) \tag{4}$$

where

. Y_{t+1} = the abnormal return in period *t* + 1

. Ret_{t+1} = the return in period *t* + 1

. $E_{m_t}(\text{Ret}_{t+1}|\emptyset_t)$ = subjective expectation of the market of Ret_{t+1}, conditional on $\emptyset_t$

Equation (4) establishes that Y_{t+1} must not be correlated with past information. The empirical content of Equation (4) depends on a market equilibrium model, which will determine $\mathrm{E}_{\mathrm{m}_t}(\mathrm{Ret}_{t+1}|\emptyset_t)$. Abel and Mishkin (1983) provided a broad discussion of various equilibrium models for this purpose. The market efficiency condition is:

$$Y_{t+1} = \beta\big(Earnings_{t+1} - E_t(Earnings_{t+1}|\emptyset_t)\big) + \varepsilon_{t+1} \tag{5}$$

where ε_{t+1} is the error term, β is the coefficient of response of earnings and $E_t(\varepsilon_{t+1}|\emptyset_t) = 0$.

Based on the earnings forecast used in Sloan (1996), the test of market rationality is based on the pricing and forecasting equations of the following system:

$$\mathrm{Earnings}_{t+1} = \alpha_0 + \alpha_1 \mathrm{Earnings}_t + \upsilon_{t+1} \tag{6a}$$

$$\mathrm{Y}_{t+1} = \beta(\mathrm{Earnings}_{t+1} - \alpha_0 - \alpha_1^* \mathrm{Earnings}_t) + \varepsilon_{t+1} \tag{6b}$$

The forecasting Equation (6a) uses past information to predict future earnings. The weight given to past information, α_1, is an objective measure of how $\mathrm{Earnings}_t$ are related to future earnings. By nonlinear estimation of the system of equations (6a) and (6b), the information on returns can be used to infer how the market uses information on $\mathrm{Earnings}_t$ to predict $\mathrm{Earnings}_{t+1}$. Equation (3) implies that the market's subjective expectation, conditional on past information (which can be inferred from Equation (6a)) should be equal to the objective earnings expectation, which can be estimated by Equation (6b). Therefore, the test for rationality is $\alpha_1 = \alpha_1^*$.

To conduct the test of equality of the coefficients, the system is estimated jointly using the nonlinear least-squares procedure. To obtain estimates of both β and α_1, it is necessary to assume that α_0 in the prediction Equation (6a) is equal to α_0 in the returns Equation (6b). In turn, if $\alpha_1 = \alpha_1^*$, then the sum of the squares of the residuals of the constrained estimation ($\mathrm{SSR^c}$), in which $\alpha_1 = \alpha_1^*$, should be equal to the sum of the squares of the residuals of the unconstrained estimation ($\mathrm{SSR^u}$), with $\alpha_1 = \alpha_1^*$. Mishkin (1983) showed that this restriction can be tested using the likelihood ratio test (asymptotically distributed as χ^2 (*q*) under the null hypothesis):

$$2n * \ln\left(\frac{\mathrm{SSR^c}}{\mathrm{SSR^u}}\right) \tag{7}$$

where *q* is the number of constraints imposed when pricing is rational, *n* is the number of observations in each equation (2*n* is the number of observations in the stacked regression), $\mathrm{SSR^c}$ is the sum of the squares of the residuals of constrained system and $\mathrm{SSR^u}$ is the sum of the squares of the residuals of the unconstrained system.

When earnings are decomposed into operating cash flows (OCF) and accruals (Acc), the prediction and pricing equations become:

$$\mathrm{Earnings}_{t+1} = \gamma_0 + \gamma_1 \mathrm{OCF}_t + \gamma_2 \mathrm{Acc}_t + \upsilon_{t+1} \tag{8a}$$

$$Y_{t+1} = \beta(\mathrm{Earnings}_{t+1} - \gamma_0 - \gamma_1^* \mathrm{OCF}_t - \gamma_2^* \mathrm{Acc}_t) + \varepsilon_{t+1} \tag{8b}$$

Here the assumption of market efficiency imposes the restrictions $\gamma_1 = \gamma_1^*$ and $\gamma_2 = \gamma_2^*$, implying that the weights assigned to cash flow and accruals in the prediction equation are the same as assigned by the market to the components in the equilibrium pricing equation.

Trading strategy (second hypothesis)

The second hypothesis establishes that a trading strategy based on the magnitude of accruals provides consistent returns in the Brazilian capital market. The procedure generally used to test this property consists of analyzing a zero-investment portfolio.

Bernard, Thomas and Wahlen (1997) pointed out that an anomaly based on accounting numbers will indicate mispricing by the market only if the returns provided by a zero-investment portfolio are consistently positive. A zero-investment portfolio that produces a positive return resulting from cross-sectional differences in risk will demonstrate the variability of annual returns (Cheng & Thomas, 2006).

To verify whether a zero-investment portfolio based on accruals produces consistently positive returns in the Brazilian market, we distributed the assets by quintiles formed by the magnitude of the accruals component of earnings, resulting in the composition of five portfolios, one for each quintile (1 to 5). We repeated this procedure for each year of the sample.

In studies of accrual anomaly, this strategy is known as forming a hedge portfolio, so named because of the assumption of reduction of risk between assets with different magnitudes of the accruals component. Sloan (1996) demonstrated that such a hedge portfolio provides higher returns than maintaining a single position (long or short) based on the level of accruals.

Analysis of the Results

Descriptive statistics

Table 1 contains the descriptive statistics of the accounting variables used in the tests, divided into two panels. Panel A contains the components of working capital, and panel B contains earnings, cash flow and the components of accruals. For all the items, the annual observations were divided by the average of the total assets for the year of occurrence.

The accruals are formed by the variation of the working capital items – see Equation (1). The analysis of the working capital items provides preliminary information on the accruals, as demonstrated in panel A. Current assets are the dominant item of working capital (34% of the total assets). In turn, the accounts receivable and inventory components are the most relevant items (9.4% and 6.9% of total assets, respectively) of current assets, a similar situation to that found in international studies (Wu, Zhang, & Zhang, 2010). The current liabilities account represents 28.4% of total assets, with accounts payable (generally composed of short-term obligations to suppliers and similar creditors) being the most important item (4.6% of total assets).

Panel B contains statistics related to the variables depreciation, accruals, cash flow and variation of working capital items (third section shows details about procedures for variables' selection). The most representative item in the formation of accruals is depreciation. However, it has small variability in relation to other items, such as Δ Accounts Receivable. According to Chan, Chan, Jegadeesh, and Lakonishok (2006), the identification of variables with greatest dispersion helps map the components that effectively permit distinguishing the accruals in the sample.

In relation to total accruals, more than half the observations are negative (median of –3.8% of total assets), indicating that the companies in general have income-decreasing accruals. The value found is very near that identified by Sloan (1996) for the U.S. market (median of 3%), and similar to the one documented by Lopes and Galdi (2006) for the Brazilian market from 1994 to 2004 (mean of –0.0319).

Δ Other Current Liabilities	0.0084	0.0482	-0.0105	0.0038	0.0246
Accruals	-0.0397	0.0899	-0.0860	-0.0384	0.0060
Earnings	0.0414	0.0903	-0.0061	0.0443	0.0993
Cash Flow	0.0847	0.1185	0.0165	0.0866	0.1580

Note. The sample is formed of all Brazilian nonfinancial firms listed on the BM&FBOVESPA with data in the Economatica database for the period from 1990 to 2008. Panel A presents a statistical summary of the components of working capital, while panel B offers statistics of the variation (Δ) of the nonfinancial items of current assets (Δ Current Assets – Δ Cash and Cash Equivalents), current liabilities (Δ Current Liabilities – Δ Short-term Debts – Δ Taxes Payable), accounts receivable, other current assets, accounts payable and other current liabilities. Panel B also contains the statistics depreciation, accruals (Δ Current Assets – Δ Current Liabilities – Depreciation), earnings (operating income) and cash flow (Earnings – Accruals). The values of the variables are divided by average total assets.

Results of the hypotheses

Pricing of earnings and their components (first hypothesis)

The Mishkin test consists of two steps. Initially the forecasting and valuation equations are estimated without imposing any restriction on the coefficients. In the second step, the same procedure is carried out with the rational pricing constraint, implying that the coefficients of earnings and the respective components are equal both in the forecasting and the valuation equation. The statistics utilized to test the null hypothesis that the market rationally prices earnings and their components is given by the likelihood ratio (Equation (7)), which is distributed asymptotically as $\chi^2(q)$, where q is the number of restrictions. Rational pricing is rejected if the likelihood ratio is sufficiently high.

To estimate the pricing of earnings and the respective components, we analyzed the average persistence of the following variables in future earnings: (a) current earnings, (b) cash flow and accruals. Categories (a) and (b), in turn, constitute distinct specifications under which the indicated sets of variables were tested. The results are presented in the following sub-sections. The estimates given by resolving the system composed of Equations (7a) and (7b) are shown in Table 2. The coefficient of earnings γ_1 is significant both in the forecasting and the valuation equation. The estimate of the valuation equation (0.7562) is higher than that of the forecasting equation (0.6371), suggesting that the market **exaggerates** the effect of current earnings when estimating earnings in the following period. To find out if this effect is statistically significant, we again estimated the coefficients of Equations (6a) and (6b) imposing the constraint that $\gamma_1 = \gamma_1^*$. The likelihood ratio demonstrates that the null hypothesis of rational pricing cannot be rejected, indicating that the difference between the coefficients γ_1 and γ_1^* is not significant. In panel B of Table 2, the real values of the observations were replaced by the corresponding quintiles of the distribution of the variables used in the Mishkin test. Specifically, the procedure consisted of first performing the classification by quintile for each period of the sample and then applying the Mishkin test employing this classification.

Table 2

Estimate of Pricing by the Market (Mishkin test) of Current Earnings in relation to the Implications on Earnings in the Next Period

Panel A – Regressions using real values of the variables

$$\text{Earnings}_{t+1} = \gamma_0 + \gamma_1 \text{Earnings}_t + \upsilon_{t+1} \quad (6a)$$

$$\text{Ab\_Ret}_{t+1} = \alpha + \beta(\text{Earnings}_{t+1} - \gamma_0 - \gamma_1^* \text{Earnings}_t) + \varepsilon_{t+1} \quad (6b)^{a.b}$$

Forecasting coefficient			Valuation coefficient		
Parameter	Estimate	T-statistic	Parameter	Estimate	T-statistic
γ_1	0.6371	56.0530	γ_1^*	0.7562	2.5696

Rational Pricing Test of Earnings

Null Hypothesis	Likelihood Ratio	Marginal Significance
Earnings: $\gamma_1^* = \gamma_1$	0.8289[c]	0.2895

Panel B – Regressions using classification of the variables by quantiles

Forecasting coefficient			Valuation coefficient		
Parameter	Estimate	T-statistic	Parameter	Estimate	T-statistic
γ_1	0.6363	55.41540	γ_1^*	1.0042	2.7994

Rational Pricing Test of Earnings

Null hypothesis	Likelihood ratio	Marginal significance
Earnings: $\gamma_1^* = \gamma_1$	4.9059	0.0155

Note. [a] Equations (6a) and (6b) were estimated jointly using the iterative nonlinear least-squares method, as proposed by Mishkin (1983 as cited in Sloan, R. G. (1996). Do stock prices fully reflect information in accruals and cash flows about future earnings? *Accounting Review, 71*(3), 289-315). We utilized all the observations available for the period from 1990 to 2008 for nonfinancial companies with information in the Economatica database. [b] The earnings variable refers to earnings before interest and taxes (EBIT) divided by the average total assets. [c] $2N \, \text{Ln}(SSR^c/SSR^u) = 2 \times 7.742 \times \text{Ln}(18{,}443.85/18{,}442.86) = 0.8289$, where N is the number of observations, Ln is the natural logarithm, $SSR^c(SSR^u)$ is the sum of the squares of the constrained (unconstrained) residuals of the regression.

In panel B, the constraint imposed of equality of the rational expectations (past data) and subjective expectations (market perception) is not rejected only at a more rigorous significance of 1%. This indicates that variations within the quintile have a relevant impact on the coefficients obtained. While in panel A the hypothesis cannot be rejected that the market correctly prices earnings, in panel B the evidence is different: the market is unable to identify the impact of current earnings on future earnings. It should also be stressed that the persistence found for the effect of current earnings on earnings for the subsequent period for the Brazilian market is lower than that found for the U.S. market. For example, Sloan (1996) found a coefficient of 0.841 for the period from 1962 to 1991, and Dechow and Ge (2006) identified an estimate of 0.696 for the period from 1988 to 2002. To summarize, the Mishkin test demonstrated that the hypothesis cannot be rejected that the market rationally prices this persistence in its estimate of the implications on future earnings.

Table 3

Estimate of Pricing by the Market (Mishkin test) of the Components or Earnings in Relation to their Implications on Future Earnings

Panel A – Regressions using real values of the variables

$$\text{Earnings}_{t+1} = \gamma_0 + \gamma_1 \text{OCF}_t + \gamma_2 \text{Acc}_t + \upsilon_{t+1} \quad (8a)$$

$$\text{Ab\_Ret}_{t+1} = \alpha + \beta(\text{Earnings}_{t+1} - \gamma_0 - \gamma_1^* \text{OCF}_t - \gamma_2^* \text{Acc}_t) + \varepsilon_{t+1} \quad (8b)^{a,b}$$

Forecasting coefficient			Valuation coefficient		
Parameter	Estimate	T-statistic	Parameter	Estimate	T-statistic
γ_1	0.6262	52.8613	γ_1^*	0.8333	3.3072
γ_2	0.5763	38.3354	γ_2^*	0.6523	2.0905

Rational Pricing Test of Earnings

Null hypothesis	Likelihood Ratio	Marginal Significance
OCF: $\gamma_1^* = \gamma_1$	3.5325	0.0363
Acc: $\gamma_2^* = \gamma_2$	0.2907	0.6399
OCF, Acc: $\gamma_1^* = \gamma_1$ and $\gamma_2^* = \gamma_2$	4.1177	0.0638

Panel B – Regressions using classification of the variables by quintiles

Forecasting coefficient			Valuation coefficient		
Parameter	Estimate	T-statistic	Parameter	Estimate	T-statistic
γ_1	0.6723	42.8437	γ_1^*	1.0968	1.7907
γ_2	0.4114	26.3778	γ_2^*	0.2864	0.5056

Rational Pricing Test of Earnings

Null hypothesis	Likelihood ratio	Marginal significance
OCF: $\gamma_1^* = \gamma_1$	0.8517	0.0974
Acc: $\gamma_2^* = \gamma_2$	0.0741	0.8552
OCF, Acc: $\gamma_1^* = \gamma_1$ and $\gamma_2^* = \gamma_2$	1.7787	0.0567

Note. [a] Equations (9a) and (9b) were estimated jointly utilizing the iterative nonlinear least-squares procedure, as proposed by Mishkin (1983 as cited in Sloan, R. G. (1996). Do stock prices fully reflect information in accruals and cash flows about future earnings? *Accounting Review, 71*(3), 289-315). We utilized all the observations available for the period from 1990 to 2008 for nonfinancial companies with information in the Economatica database. [b] The accruals (Acc) variable was obtained by focus on the balance sheet, according to Equation (1). Operating cash flow (OCF) corresponds to the difference between earnings and accruals. All the values except for abnormal returns were scaled by average total assets.

Table 3 presents the estimates of the system given by Equations (8a) and (8b), related respectively to the rational pricing by past data of the components of earnings (cash flow and accruals) and the valuation by the market of the implications of the earnings components on the result of the subsequent period. Evidence indicates that the market attributes a greater weight to the persistence of cash flow (0.8333) and accruals (0.6523) than to the estimates based on past data (0.6262 for cash flow and 0.5763 for accruals). The coefficients identified were submitted to some constraints to permit additional inferences.

The data presented in panel B basically paint the same picture. The small differences are related to the valuation coefficients. The level of significance of cash flow (t = 1.7907) is smaller than that found for the regression with real data (t = 3.3072). The valuation coefficient of accruals also attracts attention, both for its magnitude (0.2864) and its statistical significance (t = 0.5056). The differences between the results presented in panels A and B corroborate the evidence discussed previously: there are fluctuations in the real values that are not captured by the standardization by quintiles. These oscillations largely result from the operational activity of the company, and in principle should not be disregarded.

Trading strategy (second hypothesis)

According to Sloan (1996), one of the ways to verify the economic significance of the results obtained by a trading strategy based on accrual anomaly is to identify the deviations of the expected returns under the hypothesis of market efficiency. Specifically, the procedure consists of forming zero-investment portfolios from assets that compose the sample, based on the magnitude of the accruals, and identifying the returns obtained by taking a long (short) position in assets with low (high) accruals and by hedging the returns of assets with extreme accruals. For our purposes here, we separated the earnings components in various ways to identify the predictive power they have for future returns. The results are presented below.

The first analysis focuses on the accruals component of earnings. The gross and abnormal returns are separated into zero-investment portfolios, with the firms grouped according to the magnitude of their accruals. If accrual anomaly occurs in the Brazilian market, the application of this strategy will enable obtaining positive abnormal returns. To corroborate the predictive power of the accruals for returns, we also present panel regressions for the firms contained in the sample.

The predictive power of earnings surprises for future returns has been evidenced in various academic works, such as Bernard and Thomas (1990) and Chan, Jegadeesh and Lakonishok (1996). A broader analysis is to include accruals in the association of earnings with returns. This focus permits verifying whether the market assigns different weights to companies that report earnings with low or high levels of accruals. This analysis is reported in Table 4.

Table 4

Returns of the Portfolios Classified by Accruals and Variation of Earnings

Note. The sample is formed of all Brazilian nonfinancial firms listed on the BM&FBOVESPA with data in the Economatica database for the period from 1990 to 2008. The companies were classified in each year by accruals (in relation to average total assets) and independently by the variation of operating income (also in relation to average total assets). The variation of earnings is given by the difference between earnings in the reference year and those in the preceding year. The intersection of the two classifications (accruals and variation of earnings) resulted in 25 portfolios. Panel A presents the average returns (calculated by $\frac{(P_t - P_{t-1})}{P_{t-1}}$, where P is the closing price of each stock four months after the end of the fiscal year) of the portfolios equally weighted by quintiles of the classification variables (accruals and variation of earnings). Panel B provides the abnormal returns, calculated as the excess return over the control portfolio formed by companies of equivalent size. The classification variable for formation of the control portfolio was the natural logarithm of market value.

Panel A shows the returns, calculated by the percentage difference observed in the price of each asset between two consecutive periods. The accumulation period of the returns starts four months after the end of the year and ends four months after the end of the next year. The firms that ceased being listed during the study period because of going private or liquidation were excluded from the sample.

The returns are presented in relation to average total assets and associated with the intersection of the classifications by quintiles for accruals and variation of earnings. Therefore, the return in the first line of panel A (0.1454) represents 14.54% of the average total assets and refers to companies that had lower variation in earnings and lower level of accruals. The marginal effect of the earnings surprise (accruals) for each category of accruals (earnings surprise) is given by the spreads. The spreads were calculated by the difference between the returns of the first (last) and the last (first) quintile of the accruals (variation of earnings) and are shown in the last column (line) of panel A. The spread of the accruals for the first class of variation in earnings is positive and represents 13.77% of the total average total assets. If this behavior continued, it could be inferred that the market does a better job of pricing firms that have a lower level of accruals. However, the spread for the last class of variation in earnings (–4.74%) shows that this deduction is hasty for the data in the sample.

Panel B demonstrates the results of the same procedures detailed for panel A, but in relation to abnormal returns. The adjustments in the expected return to calculate the abnormal return followed the line indicated by Sloan (1996), in which abnormal returns are identified as the buy-and-hold return of a determined asset in excess of the average buy-and-hold return of a portfolio formed of assets of equivalent size. For this purpose, the size of the firms was given by the log of equity of each firm and grouped in quintiles to calculate the average return.

The conclusion of the analysis for abnormal returns is similar to that for panel A, where the spread of the variation of earnings (last line in the table) is positive for all the accrual quintiles. The marginal effect of the accruals on the analysis of the variation of earnings, once again, is not clear. The spread is positive for three earnings variation quintiles and negative for the other two (last column of the table). The finding that stands out is that the market is fairly efficient in pricing the variation of earnings and pays less attention to the level of accruals. In general, these results do not correspond to those obtained in other countries, where the usual finding is that returns (including abnormal ones) are higher for firms with lower accruals (Chan *et al.*, 2006; Sloan, 1996).

Table 5 presents the relationship between current earnings and risk proxies for future returns. The signs of the coefficients are as expected, as demonstrated in the matrix of correlations, in line with similar works (Sloan, 1996). Except for the coefficient of the book-to-market variable in the specification by fixed effects, the others are statistically significant. The regression mainly confirms that current earnings are positively related to future returns and that this relationship is significant.

Table 5

Regression of the Future Returns by Current Values of Earnings and Risk Proxies

$$\text{Ret}_{t+1} = \beta_0+\beta_1\text{Earnings}_t+\beta_2\text{Size}_t+\beta_3\text{BM}_t + \upsilon_{t+1} \quad (9)$$

Note. The sample is formed of all Brazilian nonfinancial firms listed on the BM&FBOVESPA with data in the Economatica database for the period from 1990 to 2008. The returns for the next period (Ret_{t+1}) were regressed by the current values of earnings (Earnings_t), size ($Size_t$) and book-to-market ratio (BM_t) in panel data for the entire time series. The t-statistic (*p* value) of the coefficients (Hausman test) is presented between parentheses. The returns are calculated by $\frac{(P_t-P_{t-1})}{P_{t-1}}$ (where *P* is the closing price of each stock four months after the end of the fiscal year) in a buy-and-hold strategy. Size is the control variable for firm size, identified by the logarithm of the equity, and BM is the control variable given by the book-to-market ratio.

Table 6 shows the results obtained when the future returns are regressed by the components of earnings (accruals and cash flow). The coefficients obtained for the earnings components are positive and significant, indicating that for the sample chosen accruals have positive explanatory power for future returns. This finding differs from that of Sloan (1996). The institutional environment (defined as the legal regime and corporate governance practices) and some characteristics of the Brazilian capital market (such as the small number of listed companies) are some possible explanations for this divergence in the results. The Wald test does not reject the constraint imposed of equality of the coefficients of the components of earnings ($\beta_1 = \beta_2$), indicating that the coefficients of the effect of accruals and cash flow on future returns can be considered equivalent.

Table 6

Regression of Future Returns by Current Values of Cash Flow, Accruals and Risk Proxies

$$\text{Ret}_{t+1} = \beta_0+\beta_1\text{OCF}_t+\beta_2\text{Acc}_t+\beta_3\text{Size}_t+\beta_4\text{BM}_t + \upsilon_{t+1} \quad (10)$$

	(–0.0895)	(2,6883)	
Probability of $\beta_1 = \beta_2$: 0.1414			

Note. The returns in the following period (Ret_{t+1}) were regressed by operating cash flow (OCF_t), accruals (Acc_t) and the control variables size and BM ratio, in panel data for the entire time series. Acc refers to accruals, obtained by focus on the balance sheet of Equation (1). The OCF represents the difference between earnings and accruals. The other variables and sample selection procedures are as described in the note to Table 5.

When gross returns are substituted by abnormal returns in the variable to be explained, the components of earnings (accruals and cash flow) do not present statistically significant coefficients, suggesting a weak relationship between accruals and cash flow with abnormal future gains.

Note. The abnormal returns in the following period (Ab_Ret_{t+1}) were regressed on the current period by the variables operating cash flow (OCF) and accruals (Acc) in panel data for the entire time series. Accruals were obtained by focus on the balance sheet of Equation (1), and OCF represents the difference between earnings and accruals. The probability of equality of the coefficients was given by the *F*-statistic and the Wald test. The other variables and sample selection procedures are as described in the note to Table 5.

Although not documented, studies have been conducted at the aggregate level by industry, but the results were unsatisfactory, probably because few companies integrate the division into sectors suggested by Economatica. In this regard it is noteworthy that more than half of the sectors analyzed have less than 30 companies in each segment and some, like **software**, had only three companies listed for the test period. The reduced number of companies imposes a restriction on the scope of the results that did not show statistical significance for the analysis of abnormal returns by business segment.

Conclusions and Recommendations

The first hypothesis investigated establishes that the persistence of earnings and their components is mispriced by the market. To test this assumption, we applied an adaptation of Sloan (1996) to the Mishkin test. The results suggest that the market **exaggerates** in pricing cash flow but rationally prices the accruals component of earnings. This conclusion was submitted to some constraints to identify its robustness. Among the restrictions, the most rigorous one requires that the valuation coefficients (by the market) and forecasting coefficients (by rational expectations) be equal. In this case, we found that the hypothesis that accruals and cash flow are on average correctly priced by the market cannot be rejected.

The second hypothesis states that a hedge portfolio, based on the characteristics of accruals in the Brazilian market, consistently generates abnormal returns. We tested this hypothesis in various arrangements. In the first of these, we found that accruals do not have a marginal effect on earnings surprises. While the results of the hedge portfolio for the variation of earnings were positive and consistent, the returns related to the magnitude of accruals were unstable, fluctuating between positive and negative values. Overall, the evidence indicates that the market is somewhat efficient in pricing the variation of earnings but pays less attention to firms' levels of accruals. These results do not correspond to those found for other countries, in that returns (including abnormal ones) are greater for firms with smaller accruals.

As an alternative procedure to the analyses based on trading strategy, the predictive power of the components of earnings for returns was identified by panel data regressions. The first of these confirmed that current earnings are positively and significantly related to future returns. When current returns were replaced by their components (accruals and cash flow), the coefficients obtained were positive and significant, indicating that for the sample chosen the accruals have positive explanatory power for future returns. This finding differs from that for the U.S. market, where this relationship has been found to be negative.

It should be pointed out that the evidence of the occurrence of accrual anomaly is modest. Besides the United States, there are only a few other countries where this anomaly has been detected, including Canada, Australia and the United Kingdom (Chan *et al.*, 2006; Clinch, Fuller, Govendir, & Wells, 2012; LaFond, 2005; Pincus, Rajgopal, & Venkatachalam, 2007). In the Brazilian market, the evidence of accrual anomaly is not favorable to the existence of arbitrage opportunities. The empirical tests did not identify consistent and statistically significant abnormal returns, a necessary condition for such a trading strategy (based on a zero-investment portfolio) to be efficient.

In the Brazilian case, besides the findings pointed out above, this study revealed that accruals are negatively related to cash flow; that earnings management is common with the intent of decreasing the reported earnings; and that variations in the magnitude of abnormal accruals between two consecutive periods are high. The peculiarities of the Brazilian market are thus not few.

Some specific circumstances in the Brazilian capital markets and corporate reporting system, such as poor corporate governance, concentrated ownership, lack of transparency in the disclosure of accounting numbers and strong tax influence (Lopes & Galdi, 2006), may provide explanation for these results.

The field of research into themes related to accruals is fertile. Some researchers argue that accruals should be considered a negative measure (Trammell, 2010). In reality, accruals can be used, together with other variables, to identify problems related to the operational aspects of firms. In this spirit, institutional differences, the legal regime followed (code law versus common law tradition), corporate governance, the role of auditing, the influence of sophisticated investors and the relevance of accounting information are some of the many variables that can be employed to study the effect of accruals in the Brazilian capital market.

Earnings transparency

ABSTRACT

We provide evidence that firms with more transparent earnings enjoy a lower cost of capital. We base our earnings transparency measure on the extent to which earnings and change in earnings covary contemporaneously with returns. We find a significant negative relation between our transparency measure and subsequent excess and portfolio mean returns, and expected cost of capital, even after controlling for previously documented determinants of cost of capital.

1. Introduction

This study provides evidence that firms with more transparent earnings enjoy a lower cost of capital. Firms with more transparent earnings are those whose earnings better reflect changes in the economic value of the firm. We operationalize transparency by developing a measure based on the explanatory power of the returns-earnings relation, i.e., the extent to which earnings and change in earnings covary contemporaneously with stock returns. We find that firms with more transparent earnings have a lower cost of capital as reflected in subsequent excess returns and portfolio mean subsequent returns. We also find that firms with more transparent earnings have a lower expected cost of capital. Our findings are based on tests that include controls for growth and other firm fundamentals that are known to be associated with cost of capital.

The Financial Accounting Standards Board (FASB) and the International Accounting Standards Board (IASB) state that a key purpose of financial statements is to improve decision-making by investors, lenders, and other providers of capital. To the extent that a firm's financial statements, including its earnings, are more transparent, uncertainty regarding the value of its equity may be lower, and therefore it will enjoy a lower cost of capital. Arthur Levitt, former chairman of the Securities and Exchange Commission (SEC), embraces this notion by suggesting that "high quality accounting standards … improve liquidity [and] reduce capital costs."[1]

We predict that earnings transparency is negatively associated with cost of capital. The basis for our prediction is the well-established positive relation between information asymmetry and cost of capital and our expectation that earnings transparency is negatively associated with information asymmetry. We expect a negative relation between earnings transparency and information asymmetry because when earnings transparency is low, some investors will engage in private information acquisition. Acquiring information about a firm's economic value beyond that reflected in earnings—which is low cost information about firm value—is costly. When this cost varies across investors, investors will differ in the extent to which they acquire information, which contributes to information asymmetry. Also, information asymmetry among investors can vary across firms such that it is negatively associated with transparency if investors' marginal acquisition costs are higher when there is less information about firm value beyond that reflected in earnings. However, ultimately it is an empirical question whether transparency is cross-sectionally negatively associated with information asymmetry. To the extent that earnings transparency is not negatively associated with information asymmetry, we will be unlikely to find a significant negative relation between earnings transparency and cost of capital.[2]

We base our measure of earnings transparency on the explanatory power of the returns-earnings relation because the relation measures the extent to which earnings captures changes in firm value. The intuition is that the higher is the explanatory power, the more earnings captures changes in firm value. Although investors can obtain information about changes in firm value from earnings or from other sources, our measure reflects only the extent to which earnings and change in earnings, and information correlated with earnings and change in earnings, explain returns.

Because both earnings transparency and cost of capital can differ across firms and vary over time, we base our earnings transparency measure on only current information and design the measure to permit cross-sectional and intertemporal variation. We permit intertemporal variation in our measure by estimating annual returns-earnings relations because there are several sources of intertemporal variation in earnings transparency that we expect to lead to economically meaningful variation in the cost of capital. One source is changes in accounting standards. We permit cross-sectional variation by exploiting industry and industry-neutral commonalities among firms in the returns-earnings relation, where industry-neutral commonalities are commonalities unrelated to the firm's primary industry. To exploit industry commonalities, we estimate annual returns-earnings relations by industry. To exploit industry-neutral commonalities, we estimate annual returns-earnings relations by quartile portfolios based on the residuals from the industry estimations. These portfolio estimations capture cross-sectional differences in the returns-earnings relation that are not captured fully by industry estimation. The portfolios are industry-neutral because each portfolio has the same industry composition. Our earnings transparency measure for each firm-year is the sum of the explanatory powers from that firm-year's returns-earnings industry and industry-neutral relations.

Application of accounting standards can result in variation in the explanatory power of the returns-earnings relation reflecting variation in earnings transparency as well as variation in firm fundamentals known to be related to cost of capital. For example, earnings captures poorly changes in firm value for growth firms because changes in internally generated intangible assets and growth options are not recognized in earnings. As a result, earnings of high growth firms are not transparent and high growth firms will have low explanatory power in the returns-earnings relation. However, growth is known to be associated with cost of capital regardless of whether earnings of high growth firms lack transparency. As a result, variation in our earnings transparency measure is likely correlated with intertemporal changes and cross-sectional differences in firm fundamentals such as growth. Therefore, detecting a relation between our earnings transparency measure and cost of capital could be attributable to earnings transparency or such firm fundamentals. To address this possibility, our tests include controls for growth and other firm fundamentals that are known to be associated with cost of capital.

If greater earnings transparency is associated with lower cost of capital, we should observe a negative relation between our earnings transparency measure and subsequent returns. We test whether this is the case using two approaches. The first tests for a relation between earnings transparency and subsequent excess returns, and the second tests for a relation between earnings transparency and portfolio mean subsequent returns. In our excess returns tests, we estimate cross-sectional relations between our earnings transparency measure and firms' subsequent returns in excess of returns predicted based on the Fama-French and momentum factors, which reflect known determinants of cost of capital. In our portfolio mean returns tests, we sort firms into portfolios based on our earnings transparency measure and test whether, after controlling for the Fama-French and momentum factors, mean returns are lower for higher transparency portfolios. If greater earnings transparency is associated with lower cost of capital, we also should observe a negative relation between our earnings transparency measure and a proxy for expected cost of capital. To test this, we estimate cross-sectional relations between our measure of earnings transparency and a proxy for expected cost of capital based on the Fama-French and momentum factors. We conduct our tests using a large sample of US firms over a 27-year period.

We find that our earnings transparency measure is significantly negatively related to subsequent excess and portfolio mean returns, which indicates that earnings transparency explains subsequent returns incremental to the Fama-French and momentum factors. We also find that our earnings transparency measure is significantly negatively related to our proxy for expected cost of capital, which indicates that earnings transparency and the combination of the Fama-French and

[2] Section 5 provides evidence that our earnings transparency measure is negatively associated with measures of information asymmetry used in prior research, which is consistent with the transparency measure reflecting intertemporal and cross-sectional variation in information asymmetry.

momentum factors reflect common information. However, the expected cost of capital finding obtains regardless of whether the fundamental risk characteristics underlying the factors are included in the estimating equation. This finding indicates that earnings transparency reflects information associated with expected cost of capital incremental to that reflected in these characteristics. Findings from all tests are robust to inclusion of explicit controls for leverage, growth, and the magnitude of the earnings response coefficient in the returns-earnings relation. In addition, findings relating to subsequent excess and portfolio mean returns are robust to inclusion of controls for changes in cash flow and cash flow risk, and findings relating to expected cost of capital are robust to using a measure of expected cost of capital implied by analysts' earnings forecasts. Collectively, these findings are consistent with greater earnings transparency being associated with lower cost of capital.

Using a relevance measure bearing some resemblance to our earnings transparency measure, Francis et al. (2004) reports evidence of negative relations between its measure and subsequent returns and a proxy for expected cost of capital. Although Francis et al. (2004) and we have similar predictions regarding the negative association between relevance/earnings transparency and cost of capital, the tests in Francis et al. (2004) do not support that study's inferences. The reported *t*-statistics in Francis et al. (2004) are biased upwards because the statistics do not take into account correlation of regression residuals. We show that after taking into account such correlation, there is no significant relation between the Francis et al. (2004) measure and cost of capital. A key distinction between our study and Francis et al. (2004) is that we develop an earnings transparency measure that is based only on current information, which likely accounts for our ability to find a significant relation between earnings transparency and cost of capital.

The remainder of this paper is organized as follows. Section 2 discusses the basis of our prediction and related research. Section 3 explains why earnings transparency varies across firms and over time. Section 4 develops the research design, Section 5 describes the sample, and Section 6 presents our results. Section 7 concludes the study.

2. Basis for prediction and related research

We predict that earnings transparency is negatively associated with cost of capital. There is an extensive literature showing that information asymmetry is positively associated with cost of capital (e.g., Diamond and Verrecchia, 1991). Therefore, earnings transparency will be negatively associated with cost of capital if transparency is negatively associated with information asymmetry. We expect that earnings transparency is negatively associated with information asymmetry based on the following reasoning.

When earnings transparency is low, earnings—which is informative and available at little or no cost—does not capture to a large extent changes in a firm's economic value. This will lead some investors to engage in private information acquisition. Acquiring information about a firm's economic value beyond that reflected in earnings is costly. It is likely that investors will differ in the extent to which they acquire information when there are differences in their marginal acquisition costs, which contributes to information asymmetry.[3] In addition, information asymmetry among investors can vary across firms such that it is negatively associated with transparency if investors' marginal acquisition costs are higher when there is less information about firm value beyond that reflected in earnings. To the extent that information asymmetry is not negatively associated with earnings transparency, we will be unlikely to find a significant negative relation between earnings transparency and cost of capital. Section 5 reports empirical evidence that our transparency measure is negatively associated with measures of information asymmetry used in prior research, which is consistent with earnings transparency and information asymmetry being negatively related.

Although there is an extensive empirical literature linking various characteristics of accounting information to proxies for equity cost of capital, with one exception, no study tests directly for a link between earnings transparency and cost of capital. Accounting characteristics these studies examine include proxies for voluntary disclosure levels (Welker, 1995; Botosan, 1997; Healy et al., 1999; Lang and Lundholm, 2000; Botosan and Plumlee, 2002), accruals quality (Francis et al., 2005; Ecker et al., 2006), and various accounting-based and/or market-based measures of accounting quality (Bhattacharya et al., 2003; Francis et al., 2004). Other studies provide empirical support for a link between quality of accounting information and proxies for cost of debt capital (Sengupta, 1998; Beatty et al., 2002; Francis et al., 2005).[4]

Only Francis et al. (2004) examines the relation between cost of capital and a measure that bears some resemblance to our earnings transparency measure. The measure is the adjusted R^2 from a regression of returns on earnings and change in earnings, which that study notes is adapted from the measure in an earlier version of our study.[5] Francis et al. (2004) refers to this measure as relevance, estimates it based on firm-by-firm time-series regressions using ten-year rolling windows of

[3] If information about firm value other than that reflected in earnings is available at little or no cost, it is possible that information asymmetry is low regardless of the level of earnings transparency. If this is the case, there will be no relation between earnings transparency and cost of capital.

[4] Although earnings quality and earnings transparency are likely related, firms with identical earnings quality can have different earnings transparency. For example, consider two hypothetical software firms, MegaSoft and TinySoft, each of which has proportionately similar revenues, expenses, and research and development costs, and each accounts for these items using US GAAP. Thus, the mapping from earnings to cash flows is the same for both firms and therefore the firms have the same earnings quality. Suppose information about MegaSoft's earnings is adequate for investors to have a clear understanding of valuation implications of earnings, but information about TinySoft's earnings is not. That is, even though the mapping from earnings to cash flows is the same for both firms, the explanatory power between earnings and return is likely to be higher for MegaSoft.

[5] Francis et al. (2004) defines transparency/relevance as the negative of adjusted R^2. This sign convention is opposite to ours. We apply our sign convention when discussing that study's findings.

fifteen-month returns, and uses it and a factor return constructed from it to test for an association between relevance and cost of capital using subsequent excess returns and a proxy for expected cost of capital. The study reports that the relevance factor is significantly negatively associated with subsequent returns and expected cost of capital. However, Francis et al. (2004) bases its inferences on test statistics that do not take account of correlation of regression residuals.[6]

3. Variation in earnings transparency

Cost of capital can vary cross-sectionally and intertemporally (e.g., Fama and French, 1992, 1993; Campbell et al., 2001; Xu and Malkiel, 2003). Variation in cost of capital can reflect differences in risk, including the risk arising from information asymmetry associated with earnings transparency, which also can vary cross-sectionally and intertemporally. Only if variation in earnings transparency reflects variation in information asymmetry will variation in earnings transparency explain variation in cost of capital incremental to other known determinants of cost of capital.

There are several sources of cross-sectional variation in earnings transparency. First, earnings is not designed to reflect all changes in economic value. For example, the accounting system is not designed to capture economic benefits associated with expected future contracts from current customer relationships. Second, the accounting system does not uniformly measure earnings in a manner that reflects changes in economic value.[7] Third, the way in which earnings maps into firm value can differ across firms for a variety of reasons that are not necessarily directly related to accounting.[8] Fourth, because of differences in incentives managers face, firms differ in the amount of discretion their managers apply opportunistically.

Similarly, there are several sources of intertemporal variation in earnings transparency, which we expect to lead to economically meaningful variation in the cost of capital. One source is changes in accounting standards. For example, Statement of Financial Accounting Standards No. 133 (SFAS 133, Financial Accounting Standards Board (FASB), 1998) requires recognition of derivative financial instruments that affects earnings, but recognition of these instruments was not required prior to SFAS 133. A second source is changes in the mix of a firm's assets. For example, until recently many insurance companies' assets and liabilities related only to insurance policies, but recently these companies have also invested in credit default swaps. As a result, insurance companies' asset mix changed and so likely did their earnings transparency. A third source is that, because of these changes or other reasons, e.g., changes in the clarity of firms' disclosures, the mapping of earnings into firm value can differ over time. Because there is cross-sectional variation in transparency, the effects of these intertemporal changes are likely to affect different firms differently.[9]

Because our sample comprises US firms, cross-sectional and intertemporal variations in transparency reflect effects of exposure to the US financial reporting system, which includes US GAAP, SEC regulation, and the US legal system. When a firm commits to the US financial reporting system, it commits to US reporting practices and changing practices when that system changes or when the way in which the system applies to the firm changes, e.g., when its asset mix changes. All aspects of the financial reporting system evolve and affect firms differently, thereby contributing to intertemporal and cross-sectional variation in earnings transparency.[10]

4. Research design

4.1. Earnings transparency measure

We operationalize earnings transparency by developing a measure based on the explanatory power of the returns-earnings relation, i.e., the extent to which earnings and change in earnings covary contemporaneously with stock returns. Regardless of the source of variation in earnings transparency, higher (lower) transparency will result in higher (lower) explanatory power in the returns-earnings relation. Although investors can obtain information about changes in firm value from earnings or from other sources, our measure reflects only the extent to which earnings and change in earnings, and information correlated with earnings and change in earnings, explain returns.

[6] Section 6.3 discusses tests using the Francis et al. (2004) relevance measure that take into account residual correlation. Findings reveal the Francis et al. (2004) relevance measure is not significantly related to cost of capital.

[7] Consider examples relating to fair value, pension, and oil and gas accounting. Firms with more assets measured at fair value could have higher explanatory power in their contemporaneous returns-earnings relations than those with more assets measured at modified historical cost. The effects of pension plan disclosures on transparency are likely to vary depending on whether a firm has defined benefit pension plans. Similarly, the effects of oil and gas disclosures on transparency are relevant only to firms with oil and gas activities.

[8] For example, firms may differ in the extent to which they convey information using conference calls or are covered by analysts.

[9] Consider the example of SFAS 133, which requires derivatives to be recognized at fair value, with changes in fair value recognized in income or other comprehensive income, and enhances derivatives disclosures. Application of SFAS 133 likely clarifies the valuation implications of bank earnings, but not necessarily those of retail firms that have few derivatives. Thus, it is possible a retail firm and a bank can have different earnings transparency in one year, e.g., before application of SFAS 133, but similar transparency in the next year, e.g., after application of SFAS 133.

[10] Based on Kyle (1985) and Diamond and Verrecchia (1991), Leuz and Verrecchia (2000) predicts that the relation between liquidity—a cost of capital proxy—and disclosure should be stronger when a firm credibly commits to higher financial reporting quality. Empirical studies testing this prediction typically focus on a firm's commitment to apply a set of accounting standards or a firm's decision to cross-list its shares on a foreign stock exchange (Leuz and Verrecchia, 2000; Leuz, 2003; Daske et al., 2008). We do not focus on cost of capital effects associated with a commitment to reporting quality because all sample firms are committed to the US financial reporting system, including application of US GAAP.

To construct our earnings transparency measure, *TRANS*, we use adjusted R^2s from annual cross-sectional regressions based on the relation between earnings and change in earnings deflated by price, E/P and $\Delta E/P$, and contemporaneous annual stock returns (Easton and Harris, 1991; Bushman et al., 2004). Appendix A, Section A.1, provides the details. We interpret higher explanatory power in these returns-earnings regressions as indicating greater earnings transparency. Valuation research establishes a link between equity book value and earnings and stock prices (Ohlson, 1995); earnings and change in earnings are the amounts corresponding to equity book value and earnings when explaining stock returns rather than stock prices.

We construct *TRANS* using a two-step estimation procedure designed to permit intertemporal and cross-sectional variation in our earnings transparency measure. Our measure for each firm-year is the sum of the explanatory powers from that firm-year's returns-earnings relations estimated in the two steps.[11] The first R^2 we use to construct *TRANS* is that from annual returns-earnings relations estimated by industry. By construction, this component of *TRANS* is the same for all firms for a given industry-year. There is a strong industry component to the returns-earnings relation as a result of accounting practices likely being similar within industries (Barth et al., 1999, 2005). However, estimating the returns-earnings relation by industry is not likely to capture fully differences across firms in the returns-earnings relation (Barth et al., 2005). First, some accounting practices that affect the returns-earnings relation apply to firms in all industries. Second, earnings can differ in the extent to which it reflects management's information and thus changes in the economic value of the firm. Third, identifying a firm's industry is difficult. Not only is the concept of industry not precisely defined, but also many firms operate in multiple industries.

The second R^2 we use to construct *TRANS* is that from the annual returns-earnings relation estimated by portfolio, where portfolio membership is based on the residuals from the industry regressions. As explained in Appendix A, there are four portfolios for each year, where, for example, the first portfolio is comprised of the quartile of observations from each annual industry regression with the most negative residuals. Thus, the portfolio regressions capture cross-sectional differences in the returns-earnings relation that are not captured fully by industry estimation. Also, the portfolios are industry-neutral because each portfolio has the same industry composition. Thus, differences in the R^2s from the portfolio regressions cannot be attributed to differences in industry membership. This approach is analogous to that used in Rouwenhorst (1998) in developing size- and country-neutral relative return portfolios.

If our grouping of firms into portfolios fails to reflect commonality in the returns-earnings relation among the firms within each portfolio, then the R^2s will be small. However, evidence in Table 2, Panel B, reveals substantial commonality among firms in each portfolio. In particular, the mean R^2s range from 17% to 42%, with a mean of 32%. All are substantially larger than untabulated mean R^2s from year-by-year regressions, 10%, and industry-by-industry regressions, 13%. The R^2s from our portfolio regressions are substantially higher than those reported in prior research (e.g., Lev, 1989).[12]

Our earnings transparency measure for firm *i* in year *t*, $TRANS_{i,t}$, is the sum of the R^2s pertaining to firm *i*'s industry and industry-neutral returns-earnings regressions in year *t*, which we label *TRANSI* and *TRANSIN*. Thus,

$$TRANS_{i,t} \equiv TRANSI_{j,t} + TRANSIN_{p,t}, \tag{1}$$

where *j* and *p* denote industry and portfolio.

If cross-sectional and intertemporal variation in *TRANS* is not reflective of variation in earnings transparency, e.g., if *TRANS* exhibits greater variation than earnings transparency, then basing our tests on *TRANS* will bias against detecting a relation between earnings transparency and cost of capital. Basing our tests on *TRANS* will bias in favor of detecting a relation between earnings transparency and cost of capital—even if none exists—if *TRANS* is correlated with other firm fundamentals that determine cost of capital, such as growth. For example, earnings captures poorly changes in firm value for growth firms because changes in internally generated intangible assets and growth options are not recognized in earnings. As a result, earnings of high growth firms are not transparent and high growth firms will have low *TRANS*. However, growth is known to be associated with cost of capital regardless of whether earnings of high growth firms lack transparency. As a result, detecting a relation between *TRANS* and cost of capital could be attributable to earnings transparency or growth because variation in *TRANS* is likely correlated with intertemporal changes and cross-sectional differences in growth. Thus, as explained in Section 4.2, our tests relating *TRANS* to cost of capital include controls for known risk factors, i.e., the Fama-French and momentum factors, that likely are associated with these firm fundamentals. In addition, Section 6.4 reports that our inferences are unaffected by inclusion of an explicit control for growth.

[11] Ideally, we would like to construct a firm- and year-specific measure of earnings transparency. To construct a firm-specific measure, one could estimate a time-series regression for each firm. However, such an approach does not permit intertemporal variation in earnings transparency. To construct a year-specific measure, one could estimate a separate cross-sectional regression for each year. However, such an approach does not permit cross-sectional variation in earnings transparency. To obtain an estimate of a firm's earnings transparency, it is necessary to group firm-year observations in some way. We use annual cross-sectional estimation and our grouping procedures to permit cross-sectional and intertemporal variation in earnings transparency within the constraints imposed by empirical estimation.

[12] Forming portfolios based on residuals from the industry regressions does not effectively group firms *ex ante* according to the magnitude of their returns. First, although for our sample the untabulated cross-industry mean correlation between returns and residuals from the annual industry returns-earnings regressions is 92%, the untabulated mean cross-portfolio correlation from the annual portfolio regressions is only 54%. Second, untabulated findings from regressions based on portfolios explicitly ranked on returns reveal little explanatory power; the mean (across 27 years) adjusted R^2 is only 4%. However, consistent with our predictions, grouping firms based on industry residuals groups firms with common risk characteristics as indicated by untabulated mean *ex post* annual raw returns that increase monotonically across portfolios.

4.2. Earnings transparency, subsequent excess returns, and portfolio mean returns

We test for a relation between *TRANS* and cost of capital using excess and portfolio mean subsequent returns. Such tests are commonly employed in the finance literature to determine whether posited risk factors are associated with cost of capital by determining whether such factors explain subsequent returns incremental to the Fama-French and momentum factors (e.g., Fama and French, 1993; Mohanram and Rajgopal, 2009; Konchitchki, 2011). The motivation for these tests is that firm risk is more complex than is captured by the projection of returns on the Fama-French and momentum factor returns. Evidence that a posited risk factor incrementally explains subsequent returns is viewed as evidence consistent with the risk factor reflecting dimensions of cost of capital not captured by the Fama-French and momentum factors.

To test for a relation between earnings transparency and subsequent excess returns, we regress on *TRANS* the firm's subsequent return in excess of the firm's predicted return based on the Fama-French and momentum factors. In particular, we estimate the following equation:

$$FFRET_{i,t+1} = \gamma_0 + \gamma_1 TRANS_{i,t} + \gamma_2 DBTA_{i,t+1} + \eta_{i,t+1}, \quad (2)$$

where the subscripts i and t denote firm and year.

The dependent variable, *FFRET*, is an annualized excess return computed using compounded monthly returns. In particular, *FFRET* for month m is the firm's realized month m return in excess of the risk-free rate minus the firm's predicted return based on the Fama-French and momentum factor betas estimated using Eq. (A5) in Appendix A, each multiplied by the month m realized factor returns. Thus, *FFRET* is the firm's realized return minus its expected return, conditional on the realized factor returns, assuming the firm's factor betas do not change during year $t+1$. To mitigate the effects of error in estimating the betas, we treat as missing observations for which *FFRET* or the monthly compounded risk-free rate adjusted annual return minus the predicted monthly compounded annual return from Eq. (A5) is less than -1.[13] If greater earnings transparency is associated with lower cost of capital, we should observe a negative relation between *TRANS* and subsequent excess returns. Thus, we predict γ_1 is negative.[14]

We include *DBTA*, the ratio of long-term debt to total assets, in Eq. (2) to avoid bias in the coefficient on *TRANS* resulting from omission of *DBTA* if leverage is related to cost of capital. However, we make no prediction for the sign of its coefficient, γ_2.[15] We estimate Eq. (2) pooling observations cross-sectionally and over time, and by year. For the pooled regression, we base tests statistics on residuals clustered by firm and including year fixed effects (Petersen, 2009). For the by-year regressions, following Fama and MacBeth (1973), we base test statistics on the mean and standard deviation of the coefficients.[16]

To test for a relation between earnings transparency and portfolio mean returns, we first sort firms into one of ten portfolios based on *TRANS* in month $m-1$. Firms with the highest (lowest) *TRANS* are placed into portfolio ten (one). Then, we estimate a regression, by portfolio, i.e., $p = 1,\ldots,10$, of the value-weighted month m portfolio return, $R_{p,m}$, on the month m Fama-French and momentum factors:[17]

$$R_{p,m} - R_{f,m} = \alpha_p + \beta_{RMRF,p}(R_{M,m} - R_{f,m}) + \beta_{SMB,p} SMB_m + \beta_{HML,p} HML_m + \beta_{MOM,p} MOM_m + \varepsilon_{p,m}. \quad (3)$$

α_p is portfolio p's mean realized return in excess of the risk-free rate conditional on the realized factor returns, permitting portfolio p's factor betas to be estimated contemporaneously with α_p. If greater earnings transparency is associated with lower cost of capital incremental to the Fama-French and momentum factors, we should observe a negative relation between *TRANS* and the portfolio alphas (Fama and French, 1993). Thus, we predict α_{10} is less than α_1. Because the residuals likely are correlated across the ten portfolio regressions, we estimate the portfolio regressions using seemingly unrelated regression (Zellner, 1962).[18] An advantage of conducting portfolio mean returns tests is that the estimation procedure permits factor betas, i.e., risk, to be estimated contemporaneously with returns.

By design, the factor betas in the portfolio mean returns tests reflect average risk over the estimation period. That is, the sensitivity of portfolio mean returns for each of the ten *TRANS*-based portfolios is assumed to be the same over the estimation period. This assumption differs from that associated with the excess returns tests, in which factor betas for each firm are estimated over a shorter period—60 months—but are predetermined when estimating excess returns. Because the tests rest on different assumptions regarding factor betas, finding consistent results for both tests

[13] These restrictions eliminate from the sample 323 firm-year observations.

[14] Although use of subsequent excess returns to test for associations with cost of capital is common in empirical finance (e.g., Fama and French, 1997), doing so requires several assumptions, including rational expectations and stationarity of factor betas. If betas are not stationary, subsequent excess returns can differ from zero because of changes in factor betas. As in prior research, we assume that any such changes only add noise to our tests. Subsequent excess returns also can differ from zero because of new information and, thus, such tests can lack power and be biased if the new information is correlated with *TRANS*. In Section 6.4, we report results from specifications of Eq. (2) that include controls for new information.

[15] We also estimated Eq. (2) omitting *DBTA*. Inferences relating to *TRANS* are unaffected.

[16] The Fama-MacBeth procedure is unaffected by cross-sectional correlation of residuals. Following Fama and French (1998), we do not attempt to adjust the by-year estimations for correlation of residuals across years because it is unlikely that excess returns, and thus residuals, are serially correlated.

[17] Untabulated findings relating to equal-weighted portfolio returns result in similar inferences.

[18] Although any remaining correlation between residuals for portfolios 1 and 10 could affect inferences from the test of whether α_{10} is less than α_1, untabulated Pearson and Spearman correlations are insignificant.

makes it less likely that our inferences are affected by changes in risk associated with the Fama-French and momentum factors.

To provide additional insights into the relation between earnings transparency and cost of capital, we also test whether the betas estimated using Eq. (3) vary systematically across the *TRANS* portfolios. Determining whether and which betas vary systematically reveals the factors with which *TRANS* is correlated. However, regardless of the pattern of the betas, finding that the portfolio alphas vary across *TRANS* portfolios indicates that earnings transparency reflects dimensions of cost of capital that the Fama-French and momentum factors do not.

4.3. Earnings transparency and expected cost of capital

We next test whether *TRANS* is negatively related to an estimate of expected cost of capital based on the Fama-French and momentum four-factor model. Finding such a relation indicates that earnings transparency and a combination of the factors reflect common information. The Fama-French model is an empirical factor-generating model and does not identify explicitly which economic risks underlie the factors. Several studies attempt to identify these risks (e.g., Lettau and Ludvigson, 2001; Petkova, 2006). Although these studies show that the factor returns appear to reflect empirically dimensions of risk identified by asset pricing models, it remains an open question what dimensions of risk the factors represent. Thus, it is possible that the factor returns reflect risk arising from information asymmetry (Hughes et al., 2007; Lambert et al., 2007).

We test whether greater earnings transparency is associated with lower expected cost of capital by estimating the following equation:

$$ECC_{i,t} = \gamma_0 + \gamma_1 TRANS_{i,t} + \gamma_2 DBTA_{i,t} + \gamma_3 MVE_{i,t} + \gamma_4 BM_{i,t} + \gamma_5 Beta_{i,t} + \gamma_6 FFMom_{i,t} + \eta_{i,t}, \tag{4}$$

where $ECC_{i,t}$ is firm *i*'s expected cost of capital for year $t+1$, based on information available as of the end of year *t*.[19] If greater earnings transparency is associated with lower expected cost of capital as measured by the four-factor model, we should observe a negative relation between *TRANS* and *ECC*. Thus, we predict γ_1 is negative.

As Section A.2 of Appendix A explains, to obtain an estimate of expected cost of capital, we use the four-factor model, with time-varying factor loadings, risk-free rates, and risk premia (Ang and Liu, 2004; Ibbotson Associates, 2005; Massa et al., 2005). As with Eq. (2), we include *DBTA* in Eq. (4) to avoid bias in the coefficient on *TRANS* that could result from omission of *DBTA*.[20]

To provide evidence on the extent to which any correlation between *TRANS* and *ECC* is attributable to fundamental risk characteristics identified in prior research, we estimate two versions of Eq. (4), one that excludes these characteristics, and one that includes them. The fundamental characteristics are *MVE*, the natural logarithm of market value of equity; *BM*, the equity book-to-market ratio; *Beta*, the CAPM beta; and *FFMom*, return momentum as implemented on the Fama and French website, i.e., return over the ten months that end two months prior to fiscal year-end. Based on prior research, we predict γ_3 and γ_4 are negative, and γ_5 and γ_6 are positive.

As with Eq. (2), we estimate Eq. (4) pooling observations cross-sectionally and over time, and by year. For the pooled regression, we base tests statistics on residuals clustered by firm and year (Gow et al., 2010). For the by-year regressions, we base test statistics on the mean and standard deviation of the coefficients obtained from estimation of a seemingly unrelated regression system of equations. We specify Eq. (4) with expected cost of capital as a function of earnings transparency, and not vice versa. This is because although expected cost of capital can affect a firm's future financial statement policy decisions and hence future earnings transparency, *TRANS* cannot be a function of expected cost of capital because a firm's current earnings transparency, *TRANS*, is known at the time investors assess the expected risk premium for its stock.

Finding a negative relation between *TRANS* and *ECC* is evidence that *TRANS* captures dimensions of risk reflected in the Fama-French and momentum factors. If so, γ_1 will be negative. If not, γ_1 will be insignificantly different from zero.

5. Sample and descriptive statistics

Our tests are based on a sample of US firms and 27 sample years, 1974–2000. Because construction of *TRANS* requires earnings lagged one year and *FFRET* and *ECC* require return data for 60 prior months, we use some data for years preceding 1974. To facilitate comparison of results, we restrict the sample period to be the same for all of our analyses. The final sample comprises 51,612 firm-year observations for 6,237 firms and reflects the data requirements described below.

To construct *TRANS* using Eqs. (A2) and (A3) in Appendix A, Section A.1, we obtain data from the CRSP Monthly Stock File and the Compustat Industrial Annual databases. To mitigate the effects of outliers, following Easton and Harris (1991) we treat as missing observations for which any of the earnings variables, E_t/P_{t-1}, E_{t-1}/P_{t-1}, or $\Delta E_t/P_{t-1}$, is not between $+1.5$ and -1.5. We also treat as missing observations for which annual return, *RET*, is in the extreme top and bottom one percentile (Kothari and Zimmerman, 1995; Collins et al., 1997; Fama and French, 1998; Barth et al., 1999), and observations with negative equity book value to avoid the ratio of long-term debt to total assets from exceeding 1. We also

[19] For expositional convenience, we use the same notation for coefficients and error terms in Eqs. (2) and (4). In all likelihood they differ.
[20] We also estimated Eq. (4) omitting *DBTA*. Inferences relating to *TRANS* are unaffected.

restrict the sample to observations with total assets and total revenue in excess of $10 million, and share price in excess of $1. We use the industry classifications in Barth et al. (1998). If the industry component of *TRANS*, *TRANSI*, is negative in year *t*, we set it to zero because negative explanatory power is not economically meaningful. To construct *FFRET* and *ECC*, we obtain monthly returns from CRSP and the factor returns from the Fama-French database. We winsorize *ECC* to be between 0.0 and 0.5 because it is unlikely that any firm has a negative expected cost of capital or one in excess of 50%.[21] *DBTA* is constructed using data from the Compustat Industrial Annual database.

Table 1 presents descriptive statistics for the variables used in our estimating equations. Panel A presents overall distributional statistics combining all industries and years, Panel B presents distributional statistics for each industry, and Panel C presents Pearson and Spearman correlations. Panel A reveals *TRANS* averages 42% and ranges from 3% to 143%. The industry statistics in Panel B indicate that this variation is attributable to both industry and industry-neutral differences. For example, mean *TRANSI* (excluding Other) ranges from 9% for computers, insurance and real estate, pharmaceuticals, services, and transportation to 17% for food. Panel A also indicates that expected cost of capital, *ECC*, also varies considerably, with a mean of 0.16 and a standard deviation of 0.12.

Panels A and B indicate that the industry component of *TRANS*, *TRANSI*, is, on average, substantially smaller than the industry-neutral component, *TRANSIN*. For the full sample, mean *TRANSI* is 11%, which is higher than the untabulated mean of 10% from annual regressions pooling observations without partitioning by industry. Strikingly, mean *TRANSIN* is 31%, which indicates that partitioning firm-year observations by the extent to which the industry specification fails to explain returns substantially improves the explanatory power of earnings and change in earnings. The means of both *TRANSI* and *TRANSIN* are representative for firms in all 15 industries.

Table 1, Panel C, indicates that *FFRET* is significantly negatively correlated with *TRANS* based on the Pearson but not the Spearman correlation.[22] Similarly, the components of *TRANS*, *TRANSI* and *TRANSIN*, are significantly negatively correlated with *FFRET* based on the Pearson but not the Spearman correlation. *ECC* is significantly negatively correlated with *TRANS* and with each of its components. However, we test our predictions using the multivariate regression Eqs. (2), (3), and (4). Table 1, Panel C, also indicates that *ECC* and *FFRET* are negatively correlated. *ECC* and *FFRET* need not be positively correlated because *ECC* reflects dimensions of cost of capital captured by the Fama-French and momentum factors, and *FFRET* reflects dimensions of cost of capital not captured by these factors.[23] Panel C also indicates that *DBTA* is positively correlated with *ECC* and negatively correlated with *FFRET*. These correlations are consistent with *ECC*, but not *FFRET*, reflecting financial risk as reflected in *DBTA*.

As an external validity check on *TRANS* as a proxy for earnings transparency, we calculate correlations between it and five disclosure/transparency measures used in prior research. These are AIMR disclosure indices (e.g., Botosan, 1997) and four S&P Ranking indices (Bailey et al., 2006).[24] Untabulated findings indicate that Pearson (Spearman) correlations range from 0.18 to 0.32 (0.16 to 0.33), all of which differ significantly from zero.[25] In addition, untabulated findings indicate that each of these proxies is significantly positively correlated with *TRANSI* and *TRANSIN*.

In addition, the economic intuition supporting a negative relation between *TRANS* and cost of capital depends on there being a negative association between *TRANS* and information asymmetry. Thus, we also calculate correlations between *TRANS* and five measures used in prior research reflecting information asymmetry: bid-ask spread (Brennan and Subrahmanyam, 1996), arbitrage risk (Mendenhall, 2004), and accrual quality and two measures related to accrual quality, the standard deviation of operating cash flows and the proportion of loss years in the prior ten years (Dechow and Dichev, 2002). We also use factor analysis to obtain a sixth information asymmetry measure based on the common variation in the individual information asymmetry measures. Untabulated findings support a negative association between *TRANS* and information asymmetry: Spearman (Pearson) correlations are significantly negative for all six measures, and range from -0.20 (-0.18) for the information asymmetry factor to -0.08 (-0.08) for the standard deviation of operating cash flows.[26]

Table 2, Panels A and B, presents summary statistics from estimating Eqs. (A2) and (A3) in Appendix A, which we use to calculate *TRANS*. All statistics are based on 27 annual regressions. Panel A presents results for the industry regressions used

[21] We set to zero fewer than 10% of the *TRANSI* observations. We set to zero fewer than 12%, and set to 0.5 fewer than 5%, of the *ECC* observations. Inferences from untabulated regressions in which we permit *TRANSI* to be negative and *ECC* to be negative or greater than 0.5 are identical to those from the tabulated findings.

[22] Throughout we use a five percent significance level under a one-sided alternative when we have a signed prediction and under a two-sided alternative otherwise.

[23] *FFRET* also reflects differences between realized and expected returns arising from new information. See Section 6.4.

[24] The four indices are: (1) the S&P Composite Ranking of ownership structure and investor rights, financial transparency and information disclosure, and board and management structure and processes; (2) the financial transparency and information disclosure sub-ranking; (3) the S&P Composite Ranking; and (4) the financial transparency and information disclosure sub-ranking. (1) and (2) are based on information in annual reports, 10-Ks, and proxy statements; (3) and (4) are based on information in annual reports.

[25] Sample sizes used to compute the correlations are limited because of the availability of these alternative proxies. For the AIMR correlations, there are 3,694 firm-year observations. We have 367 firms with S&P indices, which do not vary by year. Therefore, to correlate the S&P indices with *TRANS*, we compute the average *TRANS* for the 367 firms with S&P indices and correlate that average with the S&P index.

[26] Because *TRANS* and cost of capital reflect a common set of economic fundamentals, we also correlate the information asymmetry measures with residuals from a regression of *TRANS* on the fundamentals we control for in Eqs. (2), (3), and (4)—leverage, size, the equity book-to-market ratio, beta, and momentum—and residuals from a regression of *TRANS* on these fundamentals plus analysts' growth forecasts that we control for in Section 6.4.2. Untabulated findings reveal significant negative associations between these two residual *TRANS* measures and all the information asymmetry measures.

ECC	−0.121	−0.059	−0.121	−0.038	0.026	1.000

TRANS, earnings transparency, is the sum of the industry component, *TRANSI*, and the industry-neutral component, *TRANSIN*. *TRANSI* (*TRANSIN*) is the adjusted R^2 from annual regressions of returns, *RET*, for year *t* on earnings before discontinued operations and extraordinary items, deflated by lagged price, E_t/P_{t-1}, and change in earnings, deflated by lagged price, $\Delta E_t/P_{t-1}$, by industry as listed in Panel B (by portfolio based on the quartile of the residual from the industry regressions). *FFRET* is an annualized excess return computed using compounded monthly returns. Excess return is the firm's raw return in excess of the risk-free rate minus the firm's predicted return based on the Fama-French and momentum factor-mimicking portfolios, i.e., excess market return, size, book-to-market, and momentum. All returns begin three months subsequent to the firm's fiscal year end. *ECC* is expected cost of capital estimated based on the Fama-French and momentum factors. *DBTA* is the ratio of long-term debt to total assets. All correlations in Panel C are significantly different from zero, except for the Spearman correlation between *TRANS* and its components and *FFRET*. Sample of US firms, 1974−2000.

to calculate *TRANSI* and Panel B presents results for the portfolio regressions used to calculate *TRANSIN*. Table 2, Panel A, reveals that, on average, the R^2 from the industry regressions, which is *TRANSI*, is at least 9%, and is somewhat higher than that found in prior research (e.g., Easton and Harris, 1991).[27] There is considerable cross-industry variation and cross-year variation within each industry. The coefficients on earnings and change in earnings, E/P and $\Delta E/P$, also exhibit considerable cross-industry variation and cross-year variation within each industry. However, the E/P ($\Delta E/P$) coefficient mean *t*-statistics indicate that it is significantly positive for 6 (6) industries.

Table 2, Panel B, reveals that mean R^2 from the portfolio regressions, which is mean *TRANSIN*, is substantially higher than mean R^2 from the industry regressions and those in prior research. *TRANSIN* ranges from 17% to 42%. This range

[27] The sample size in Table 2, Panels A and B, exceeds that of Table 1, Panel A, because we estimate Eqs. (A2) and (A3) with all available firm-year observations. Construction of *FFRET* and missing data result in a smaller sample size for Eqs. (2) and (4).

Table 2
Summary statistics from regressions of annual returns on earnings and change in earnings. Means and standard deviations are across years.

Panel A: estimated by industry by year. $RET_{i,j,t} = \alpha_0^I + \alpha_1^I E_{i,j,t}/P_{i,j,t-1} + \alpha_2^I \Delta E_{i,j,t}/P_{i,j,t-1} + \varepsilon_{i,j,t}$

Dependent variable is *RET*, return for year t, E_t/P_{t-1} is earnings before discontinued operations and extraordinary items, deflated by lagged price, and Δ denotes annual change. i denotes firm, j denotes industry, and p denotes portfolio. Sample is described in Table 1.

reflects substantial cross-portfolio variation. This high variation in *TRANSIN* and hence *TRANS* is important because it helps to increase the power of our tests. The higher R^2s reflect the higher t-statistics for the E/P and $\Delta E/P$ coefficients relative to those obtained from the industry regressions. These findings indicate that grouping firms into portfolios based on the industry returns-earnings regression residuals successfully identifies firms with common returns-earnings relations.

Panels A and B also reveal how the industry and industry-neutral earnings and change in earnings coefficients differ. For example, for chemical firms, the mean coefficients on earnings and change in earnings, α_1^I and α_2^I, are 0.54 and 1.09. Regardless of industry, firms in portfolio 1 have mean earnings and change in earnings coefficients, α_1^{IN} and α_2^{IN}, of 0.48 and 0.30. The analogous coefficients for firms in portfolio 4 are 0.10 and 0.83. This illustrates that assuming all chemical firms have coefficients of 0.54 and 1.09 imposes a binding constraint, and therefore does not fully reflect the explanatory power of earnings and change in earnings for returns.

6. Results

6.1. Subsequent excess and portfolio mean returns

Table 3 presents summary statistics from estimating Eq. (2). The first column contains statistics based on pooling observations across industries and over time, and the next three columns contain statistics from by-year estimations. Table 3 reveals, as predicted, a significant negative relation between *TRANS* and subsequent excess returns. This finding indicates that earnings transparency is negatively associated with cost of capital.[28] The *TRANS* t-statistic from the pooled regression is -2.73, and the Fama-MacBeth t-statistic from the by-year estimations is -1.96. The *TRANS* coefficient is -0.04 for the pooled regression, and -0.05 on average across years. Evaluated at the mean of *TRANS*, 0.42, these findings are consistent with a cost of capital that is 1.7% and 2.1% lower than for a firm with *TRANS* equal to zero. The coefficient on leverage, *DBTA*, is significantly negative in both specifications.[29]

Table 4 presents findings from estimating Eq. (3) for each of the ten *TRANS* portfolios. Consistent with our predictions, the Fama-French alpha declines from 0.0065 in portfolio 1 to 0.0000 in portfolio 10. In addition, untabulated findings from a trend regression indicate that this decline is significant (t-statistic$=-1.95$). Consistent with this trend, as the final column indicates, the difference in alphas for portfolios 10 and 1, -0.0065, is significantly negative (χ^2-statistic$=9.96$). These findings indicate that firms with higher *TRANS* have lower Fama-French alphas and provide additional evidence that earnings transparency is negatively associated with cost of capital.

Table 4 also indicates that the *RMRF*, *SMB*, and *MOM* (*HML*) coefficients decrease (increase) from portfolio 1 to portfolio 10. For *RMRF*, the coefficient difference between portfolios 10 and 1, -0.0423, is insignificantly different from zero (χ^2-statistic$=0.77$). The corresponding difference for *MOM*, -0.2000, is significantly negative (χ^2-statistic$=17.57$). The decrease in the *RMRF* and *MOM* coefficients is consistent with predictions in Lambert et al. (2007). The related differences in *HML* and *SMB* coefficients between portfolios 10 and 1, 0.2574 and -0.1621, are significantly positive and negative (χ^2-statistics $=13.13$ and 6.92). These findings indicate that the Fama-French and momentum factors and earnings transparency reflect some common information about cost of capital. In particular, the Table 4 findings reveal that earnings transparency is negatively related to the *SMB* and *MOM* factors, and positively related to the *HML* factor. However, finding that the alphas vary across earnings transparency portfolios indicates that earnings transparency captures dimensions of cost of capital that the Fama-French and momentum factors do not.[30]

6.2. Expected cost of capital

Table 5 presents summary statistics analogous to those in Table 3, but relating to Eq. (4). The first (second) set of columns presents findings excluding (including) the fundamental risk characteristics. Regarding the specification that excludes the fundamental risk characteristics, Table 5 reveals, as predicted, a significant negative relation between earnings transparency, *TRANS*, and expected cost of capital, *ECC*. The *TRANS* t-statistic from the pooled regression is -2.18,

[28] Finding a negative relation between *TRANS* and *FFRET* could be attributable to periods of greater correspondence between prices and earnings being associated with lower cost of capital. That is, a negative relation could result from a temporal effect unrelated to earnings transparency. If this is the case, then one would observe a negative correlation between annual averages of *TRANS* and annual averages of *FFRET* as well as expected cost of capital, *ECC*. Untabulated findings based on annual means and medians reveal none of these correlations is significant.

[29] To assess whether the significance of *TRANS* is attributable to its industry component, industry-neutral component, or both, we also estimate Eq. (2) including *TRANSI* and *TRANSIN* in place of *TRANS*. Untabulated findings reveal that *TRANSIN* is negatively related to subsequent excess returns in both estimations, but not significantly so, and that *TRANSI* is significantly negatively related to subsequent excess returns in both the pooled and by-year estimations.

[30] Our findings indicate that earnings transparency is significantly negatively associated with subsequent returns, and therefore significantly negatively associated with cost of capital. These findings do not address whether earnings transparency is a priced risk factor. Untabulated findings from implementing a Fama and MacBeth (1973) approach fail to support an inference that earnings transparency is a priced risk factor. However, this finding is not surprising in light of prior research that implements similar tests and fails to support inferences that CAPM market beta, size, and momentum are priced risk factors (Jegadeesh and Titman, 1993; Jagannathan and Wang, 1996; Lettau and Ludvigson, 2001; Fama and French, 2002; Cochran, 2005; Petkova, 2006; Core et al., 2008).

FFRET is an annualized excess return computed using compounded monthly returns. Excess return is the firm's raw return in excess of the risk-free rate less the firm's predicted return based on the Fama-French and momentum factor-mimicking portfolios, i.e., excess market return, size, book-to-market, and momentum. All returns begin three months subsequent to the firm's fiscal year end. *TRANS*, earnings transparency, is the sum of the industry component, *TRANSI*, and the industry-neutral component, *TRANSIN*. *TRANSI* (*TRANSIN*) is the adjusted R^2 from annual regressions of returns for year t on earnings before discontinued operations and extraordinary items, deflated by lagged price, E_t/P_{t-1}, and change in earnings, deflated by lagged price, $\Delta E_t/P_{t-1}$, by industry as listed in Table 1, Panel B (by portfolio based on the quartile of the residual from the industry regressions). *DBTA* is the ratio of long-term debt to total assets. Statistics from the pooled estimation are based on pooling observations cross-sectionally and over time, and clustering residuals by firm and including year fixed effects. Statistics from the by-year estimations include mean coefficients and *t*-statistics, standard deviations of the coefficients and *t*-statistics, and Fama and MacBeth (1973) *t*-statistics. FM-*t* is the Fama-MacBeth (1973) *t*-statistic, i.e., the mean coefficient across years divided by the standard deviation of the mean. Sample is described in Table 1.

In each month, *m*, we form ten portfolios based on *TRANS*; firms with the highest (lowest) *TRANS* are in portfolio ten (one). For each portfolio, using seemingly unrelated regression (Zellner, 1962), we regress the value-weighted monthly portfolio excess returns, $R_{p,m} - R_{f,m}$, on the three Fama-French factors, $(R_{M,m} - R_{f,m})$, SMB_m, and HML_m, and the momentum factor, MOM_m. Portfolio value weights are based on equity market value at the beginning of month *m*. *TRANS*, earnings transparency, is the sum of the industry component, *TRANSI*, and the industry-neutral component, *TRANSIN*. *TRANSI* (*TRANSIN*) is the adjusted R^2 from annual regressions of returns for year t on earnings before discontinued operations and extraordinary items, deflated by lagged price, E_t/P_{t-1}, and change in earnings, deflated by lagged price, $\Delta E_t/P_{t-1}$, by industry as listed in Table 1, Panel B (by portfolio based on the quartile of the residual from the industry regressions). Sample is described in Table 1.

and its Fama-MacBeth *t*-statistic is −3.04 for the by-year estimations. The *TRANS* coefficient equals −0.08 in the pooled regression and −0.03 on average across years. Evaluated at the mean of *TRANS* in Table 1, Panel A, 0.42, and using the pooled (average across years) coefficient, these findings are consistent with an expected cost of capital that is 3.36%

ECC is expected equity cost of capital for year $t+1$ estimated using the Fama-French and momentum factors, based on information available at the end of year *t*. *TRANS*, earnings transparency, is the sum of the industry component, *TRANSI*, and the industry-neutral component, *TRANSIN*. *TRANSI* (*TRANSIN*) is the adjusted R^2 from annual regressions of returns for year *t* on earnings before discontinued operations and extraordinary items, deflated by lagged price, E_t/P_{t-1}, and change in earnings, deflated by lagged price, $\Delta E_t/P_{t-1}$, by industry as listed in Table 1, Panel B (by portfolio based on the quartile of the residual from the industry regressions). *DBTA* is the ratio of long-term debt to total assets. *MVE* is the natural logarithm of market value of equity, *BM* is the equity book-to-market ratio, *Beta* is the CAPM beta, and *FFMom* is return momentum, i.e., following Fama and French, return over the ten months that end two months prior to fiscal year-end. Statistics from the pooled estimation are based on pooling observations cross-sectionally and over time, and clustering residuals by firm and year. Statistics from the by-year estimations include mean coefficients and *t*-statistics, standard deviations of the coefficients and *t*-statistics, and Fama and MacBeth (1973) *t*-statistics. FM-*t* is the Fama-MacBeth (1973) *t*-statistic, i.e., the mean coefficient across years divided by the standard deviation of the mean. Sample is described in Table 1.

(1.26%) lower than for a firm with *TRANS* equal to zero. The findings also reveal that the coefficient on *DBTA* is significantly positive in the pooled and by-year estimations.[31,32]

Regarding the specification that includes the fundamental risk characteristics, findings from the pooled and by-year Fama-MacBeth estimations reveal that three of the four coefficients on the fundamental risk variables are significantly different from zero with predicted signs. More importantly, the findings reveal that the coefficient on *TRANS* is significantly negative (*t*-statistics = −2.06 and −1.68 in the pooled and Fama-MacBeth estimations). The lower significance level for the *TRANS* coefficient when fundamental risk characteristics are included in the estimating equation suggests that *TRANS* is correlated with them. Thus, consistent with the findings in Table 4 relating to the portfolio betas, these findings indicate that the fundamental risk characteristics and earnings transparency reflect some common information about cost of capital. However, finding that the *TRANS* coefficient is significantly negative when the risk characteristics are included in the estimating equation indicates that *TRANS* reflects information associated with *ECC* incremental to that reflected in these characteristics.

6.3. *Francis et al. (2004)*

Using a value relevance measure that bears some resemblance to our earnings transparency measure, Francis et al. (2004) reports evidence of a negative relation between that study's relevance measure and subsequent returns incremental to the three Fama-French factors, and a proxy for expected cost of capital.[33] However, as we establish below, had Francis et al. (2004) reported correctly calculated test statistics, those statistics would have revealed an insignificant relation between that study's relevance measure and cost of capital.

[31] The R^2s in the first specification in Table 5 appear low relative to those in prior research, e.g., Francis et al. (2004). However, the specification includes only *TRANS* and *DBTA*; *ECC* comprises the Fama-French and momentum factors, weighted by their betas. Thus, the R^2 only reflects the incremental effect associated with the two explanatory variables. Typically, prior research, e.g., Francis et al. (2004), includes the factors as additional explanatory variables, thereby increasing the R^2, as does the other specification in Table 5. This same observation applies to Tables 3 and 4.

[32] To assess whether the significance of *TRANS* is attributable to its industry component, industry-neutral component, or both, we estimate Eq. (4) including *TRANSI* and *TRANSIN* in place of *TRANS*. Untabulated findings reveal *TRANSIN* (*TRANSI*) is significantly negatively (insignificantly) related to *ECC* in both estimations.

[33] We apply our sign convention when discussing the Francis et al. (2004) findings (see footnote 5).

The Francis et al. (2004) relevance measure is the adjusted R^2 from firm-by-firm time-series returns-earnings regressions using ten-year rolling windows. Francis et al. (2004) uses its relevance measure and a factor return constructed from the measure to test for an association between relevance and cost of capital. Using subsequent returns as a measure of cost of capital, Francis et al. (2004) forms factor-mimicking portfolios based on its relevance measure to obtain factor returns for inclusion as an additional factor in firm-by-firm time-series regressions of returns on the three Fama-French factors, and estimates each firm's return sensitivity to the three Fama-French and the relevance factor returns. Using expected cost of capital implied by a model that incorporates analysts' earnings forecasts, Francis et al. (2004) estimates annual cross-sectional regressions of expected cost of capital on its relevance measure.

Francis et al. (2004) bases its inference from its subsequent returns tests on aggregated statistics from time-series regressions, and assesses significance of the relevance factor by implementing the Fama and MacBeth (1973) aggregation procedure to the time-series regression estimates. When aggregating estimates in the subsequent return tests, Francis et al. (2004) fails to adjust the resulting test statistics for cross-sectional correlation of residuals that results from the firm-specific coefficient estimates being based on observations from overlapping time periods (Schipper and Thompson, 1983). Francis et al. (2004) bases its inference from its expected cost of capital tests on aggregated statistics from year-by-year cross-sectional regressions, and assesses significance of the relevance measure by implementing the Fama and MacBeth (1973) aggregation procedure to the regression estimates. When aggregating estimates in the expected cost of capital tests, Francis et al. (2004) fails to adjust the resulting test statistics for intertemporal correlation of residuals.

We use two approaches to establish that the inference in Francis et al. (2004) that its relevance measure is negatively related to cost of capital is unfounded. First, we implement tests relating to returns analogous to those in Francis et al. (2004), taking into account cross-sectional correlation of residuals. We test whether returns on a factor-mimicking portfolio based on the Francis et al. (2004) relevance factor are significantly positively related to returns incremental to the Fama-French factors in portfolio- and firm-level tests. Untabulated findings from both tests reveal that the Francis et al. (2004) relevance factor return beta is insignificant. The adjusted Fama and MacBeth (1973) *t*-statistics corresponding to the portfolio- and firm-level tests are -0.75 and 0.50.[34] These findings indicate that after controlling for cross-sectional correlation of residuals, the Francis et al. (2004) relevance factor return is not significantly associated with returns incremental to the three Fama-French factors.[35] We also test whether the Francis et al. (2004) relevance measure is significantly negatively related to that study's expected cost of capital proxy. Untabulated findings reveal that it is not (*t*-statistic$=$0.77).

Second, we implement our tests to determine whether the Francis et al. (2004) relevance measure is significantly negatively related to subsequent excess and portfolio mean returns, and expected cost of capital. Untabulated findings relating to Eq. (2) indicate that the relevance measure is not significantly negatively related to subsequent excess returns. The pooled regression *t*-statistic is 0.68, and the Fama-MacBeth *t*-statistic from the year-by-year estimations is -0.13. Untabulated findings relating to Eq. (3) indicate that the alphas for portfolios 1 and 10 are insignificantly different (χ^2-statistic$=$0.89). Untabulated findings relating to Eq. (4) indicate that the Francis et al. (2004) relevance measure is not significantly negatively related to our measure of expected cost of capital (*t*-statistics$=$0.55 and 0.84 in the pooled and year-by-year estimations).

The apparent similarity between the Francis et al. (2004) relevance measure and our earnings transparency measure raises the question of why there is a significant negative relation between cost of capital and our earnings transparency measure but not the Francis et al. (2004) measure. To begin, the apparent similarity is false. Untabulated Pearson and Spearman correlations between the Francis et al. (2004) relevance measure and *TRANS* are both -0.02, and insignificantly different from zero. This lack of correlation is not surprising because the Francis et al. (2004) relevance measure is based on ten years of past data. As a result, the measure reflects dated information and exhibits essentially no intertemporal variation. In contrast, we construct *TRANS* using current data and permit it to vary intertemporally.

6.4. Alternative specifications

We consider alternative specifications of Eqs. (2) and (4) to assess the robustness of our inferences about the relation between earnings transparency and subsequent excess returns and expected cost of capital. Findings from these alternative specifications do not alter the inferences we draw from our primary findings.

6.4.1. New information in subsequent returns

Subsequent excess returns can differ from expected returns because of new information or if the four-factor model does not fully control for expected return. As a result, subsequent excess returns tests can lack power and can be biased if the

[34] Inferences from both the portfolio- and firm-level tests regarding significance of the Francis et al. (2004) relevance factor are unaffected by including a momentum factor return.

[35] Ecker et al. (2006) extends Francis et al. (2004) by showing that the loadings on a factor return based on a measure of accruals quality are correlated with proxies for earnings quality, including the Francis et al. (2004) relevance measure. This raises the possibility that accruals quality and transparency could be correlated and, therefore, reflect similar information insofar as explaining cross-sectional variation in returns. However, untabulated findings reveal that the Pearson (Spearman) correlation between *TRANS* and the Ecker et al. (2006) accruals quality measure is significant and negative, -0.15 (-0.16). In addition, untabulated findings from estimating the portfolio- and firm-level regressions of excess returns on the returns to the Fama-French factors and the Ecker et al. (2006) accruals quality factor, using the same estimation approach as described above relating to Francis et al. (2004), reveal that the accruals quality factor return is insignificantly associated with returns incremental to the Fama-French factor returns. The adjusted Fama and MacBeth (1973) *t*-statistics corresponding to the portfolio- and firm-level tests are 0.16 and -0.52.

new information or an omitted risk factor is correlated with *TRANS* (Elton, 1999; Vuolteenaho, 2002; Easton and Monahan, 2005). In particular, new information can alter investors' expectations of future cash flow. We include two measures of information about expected future cash flow as additional variables in our subsequent excess returns tests: change in operating cash flow (Minton and Schrand, 1999) and an indicator variable for whether earnings is negative. Change in operating cash flow, ΔCFO, is the difference between year $t+1$ and year t operating cash flow, *CFO*, deflated by total assets at the end of year t, where *CFO* is the annual equivalent to the quarterly *CFO*.[36] We set the negative earnings indicator variable, *NEG*, equal to one if earnings in year $t+1$, i.e., E_{t+1}, is negative and zero otherwise. Regarding a potential omitted risk factor, we include the coefficient of variation in cash flow as a control for cash flow risk (Minton and Schrand, 1999). The coefficient of variation in cash flow, *CVCF*, is the coefficient of variation in a firm's quarterly operating cash flow over the six-year period preceding each sample year minus the median coefficient of variation in cash flow for firms in the same two-digit SIC code.

Table 6 reports findings from specifications of Eq. (2) supplemented with combinations of each of the additional variables, *NEG*, ΔCFO, and *CVCF*. For the sake of parsimony, we tabulate only coefficients and test statistics corresponding to *TRANS*. Although untabulated findings indicate that the coefficients on *NEG*, ΔCFO, and *CVCF* are often significantly different from zero, the key result presented in Panel A is that in all specifications the coefficient on *TRANS* is significantly negative in both the pooled and by-year estimations. These findings indicate that our inferences relating to *TRANS* from the findings in Table 3 are unaffected by inclusion of controls for new information about expected future cash flow and cash flow risk.

6.4.2. *Correlation between TRANS and growth*

Because earnings of high growth firms are more likely to omit information about changes in future revenues and expenses, high growth firms have lower earnings transparency and lower R^2s in the returns-earnings relation, i.e., lower values of *TRANS*. However, this omission also results in *TRANS* being correlated with a firm's investment profile, which could confound our inferences that earnings transparency is related to cost of capital. To the extent that high growth firms are riskier, they will have higher costs of capital. As a result, *TRANS* could be negatively related to cost of capital solely because of the negative correlation between *TRANS* and growth.[37] To the extent that the Fama-French and momentum factors reflect dimensions of growth (Lettau and Ludvigson, 2001; Petkova, 2006), Eqs. (2), (3), and (4) implicitly control for the effect of growth on cost of capital. Thus, our finding a significant relation between *TRANS* and cost of capital in these equations cannot be attributed to growth as reflected in these factors. However, because the Fama-French and momentum factors may not reflect fully all dimensions of growth, we also estimate Eqs. (2), (3), and (4) including analysts' long-term earnings growth forecasts as an explicit proxy for growth. Untabulated findings reveal that although the growth proxy's coefficient is significantly different from zero in some specifications, the *TRANS* coefficient remains significantly negative. Thus, our inferences regarding the relation between earnings transparency and cost of capital are unchanged when we include an explicit proxy for growth.[38]

6.4.3. *Correlation between TRANS and earnings response coefficients*

Earnings response coefficients (ERCs) are positively correlated with model explanatory power (Johnston, 1984; Collins and Kothari, 1989; Kothari, 2001). Because *TRANS* is the sum of R^2s from two returns-earnings regressions, a positive correlation between ERCs and the R^2s from our regressions is a potential confounding factor or alternative explanation for our finding a negative relation between *TRANS* and cost of capital. A higher ERC is consistent with a lower cost of capital (Collins and Kothari, 1989). Therefore, finding that higher *TRANS* is associated with lower cost of capital could be a result of a positive correlation between *TRANS* and ERCs. For our sample, ERCs and R^2s are positively correlated. For example, focusing on the ERC for earnings, the correlation between ERC and R^2 from the first-stage (second-stage) regression is 0.40 (0.52). The analogous correlation between *TRANS* and the ERC is 0.34 (0.49). To mitigate the possibility that the correlation between *TRANS* and ERCs affects our inferences, we estimate Eqs. (2), (3), and (4) alternatively including the average of the ERCs from the two stages, and the ERC from each stage. Untabulated findings relating to all three specifications of each equation reveal our inferences regarding the relation between *TRANS* and cost of capital are unchanged.

6.4.4. *Implied expected cost of capital*

Our proxy for expected cost of capital used in estimation of Eq. (4) is based on the four-factor model. Use of the model assumes that the four factors reflect all dimensions of risk. Our findings in Table 3 indicate that this assumption may not

[36] Quarterly *CFO* is sales minus the sum of cost of goods sold, selling, general, and administrative expenses, and the change in working capital. Working capital is current assets other than cash and short-term investments minus current liabilities, and is calculated as the sum of accounts receivable, inventory, and other current assets minus the sum of accounts payable, income taxes payable, and other current liabilities. Quarterly selling, general, and administrative expenses exclude one-quarter of annual research and development costs and advertising expenses when those data items are available.

[37] Although some prior studies suggest that growth is positively related to cost of capital, others suggest it is negatively correlated (e.g., Fama and French, 1992). See Zhang (2005) for further discussion.

[38] It is possible that using alternative growth proxies or specifications could result in different inferences.

Table 6
Summary statistics from alternative specifications of the regression of subsequent excess returns on earnings transparency.

Model 1 : $FFRET_{i,t+1} = \gamma_0 + \gamma_1 TRANS_{i,t} + \gamma_2 DBTA_{i,t+1} + \gamma_3 NEG_{i,t+1} + \eta_{i,t+1}$

FFRET is an annualized excess return computed using compounded monthly returns. Excess return is the firm's raw return in excess of the risk-free rate less the firm's predicted return based on the Fama-French and momentum factor-mimicking portfolios, i.e., excess market return, size, book-to-market, and momentum. All returns begin three months subsequent to the firm's fiscal year end. *TRANS*, earnings transparency, is the sum of the industry component, *TRANSI*, and the industry-neutral component, *TRANSIN*. *TRANSI* (*TRANSIN*) is the adjusted R^2 from annual regressions of returns for year t on earnings before discontinued operations and extraordinary items, deflated by lagged price, E_t/P_{t-1}, and change in earnings, deflated by lagged price, $\Delta E_t/P_{t-1}$, by industry as listed in Table 1, Panel B (by portfolio based on the quartile of the residual from the industry regressions). *DBTA* is the ratio of long-term debt to total assets. *NEG* is an indicator variable that equals 1 if E_t is negative, and 0 otherwise. ΔOCF *is* annual change in realized operating cash flow, defined as the difference between one-year ahead and current year *OCF*, deflated by current year total assets. Current year *OCF* is the annual equivalent to the quarterly *OCF* defined in Minton and Schrand (1999). *CVCF* is the coefficient of variation in cash flow, defined following Minton and Schrand (1999) as the coefficient of variation in a firm's quarterly operating cash flow over the six-year period preceding each sample year. Statistics from the pooled estimation are based on pooling observations cross-sectionally and over time, and clustering residuals by firm and including year fixed effects. Statistics from the by-year estimations include mean coefficients and *t*-statistics, standard deviations of the coefficients and *t*-statistics, and Fama and MacBeth (1973) *t*-statistics. FM-*t* is the Fama-MacBeth (1973) *t*-statistic, i.e., the mean coefficient across years divided by the standard deviation of the mean. Sample is described in Table 1.

be warranted. An alternative approach is to use a measure of expected cost of capital implied by a model that incorporates analysts' earnings forecasts. Studies that adopt this approach, including Claus and Thomas (2001), Gebhardt et al. (2001), Gode and Mohanram (2003), and Easton (2004), develop somewhat different implied expected cost of capital measures. Therefore, to assess the robustness of our findings in Table 5, we estimate Eq. (4) using the mean of the several measures of implied expected cost of capital (Hail and Leuz, 2006; Dhaliwal et al., 2007; Barth et al., 2008). Also, because Gode and Mohanram (2008) and McInnis (2010) find that estimates of implied expected cost of capital reflect bias in analysts' forecasts, we use the procedure in Gode and Mohanram (2008) to correct the implied expected cost of capital measures for analysts' forecast bias. Untabulated findings reveal that *TRANS* is significantly negatively associated with the mean implied expected cost of capital measure, with a *t*-statistic of −2.33. Additional untabulated findings reveal that *TRANS* is significantly negatively associated with each of the four component measures.

7. Conclusion

This study examines whether firms with more transparent earnings enjoy a lower cost of capital. We base our measure of earnings transparency on the explanatory power of the returns-earnings relation, i.e., the extent to which earnings and change in earnings covary contemporaneously with returns.

We find that earnings transparency is significantly negatively associated with cost of capital by showing that our earnings transparency measure is negatively related to subsequent excess returns and differences in portfolio mean subsequent returns incremental to the three Fama-French and momentum factors. These findings indicate that earnings transparency captures dimensions of cost of capital that the factors do not. We also find a significant negative relation between our earnings transparency measure and an estimate of expected cost of capital based on the four-factor model.

This finding indicates that earnings transparency is systematically related to the Fama-French and momentum factors. However, we also find that earnings transparency reflects information associated with expected cost of capital incremental to that reflected in the fundamental risk characteristics underlying these factors. Inferences relating to the subsequent excess and portfolio mean returns and expected cost of capital tests are robust to inclusion of explicit controls for leverage, growth, and the magnitude of the earnings response coefficient in the returns-earnings relation. The subsequent excess and portfolio mean returns inferences are robust to including controls for changes in cash flow and cash flow risk. The expected cost of capital inferences are robust to using a measure of expected cost of capital implied by analysts' earnings forecasts. Taken together, our findings provide evidence that firms with more transparent earnings enjoy a lower cost of capital.

Appendix A

A.1. Calculation of earnings transparency proxy

Eq. (1), repeated here as Eq. (A1), expresses *TRANS* as the sum of two measures, *TRANSI* and *TRANSIN*:

$$TRANS_{i,t} \equiv TRANSI_{j,t} + TRANSIN_{p,t}. \tag{A1}$$

To calculate *TRANSI*, we estimate Eq. (A2):

$$RET_{i,j,t} = \alpha_0^I + \alpha_1^I E_{i,j,t}/P_{i,j,t-1} + \alpha_2^I \Delta E_{i,j,t}/P_{i,j,t-1} + \varepsilon_{i,j,t}. \tag{A2}$$

RET is annual return measured beginning three months after the firm's fiscal year end, E_t/P_{t-1} is earnings before extraordinary items and discontinued operations deflated by beginning of year price, and ΔE is change in earnings from year $t-1$ to year t.[39] We estimate this model for 27 years ($t=1974, \ldots, 2000$) and for 15 industries, provided there are at least 10 observations for that industry-year. This yields 396 separate industry components, $TRANSI_{j,t}$. This estimation procedure constrains the coefficients in Eq. (A2), α_0^I, α_1^I, and α_2^I, to be the same for firms within industry *j* in year *t*.

To calculate *TRANSIN*, we estimate Eq. (A3):

$$RET_{i,p,t} = \alpha_0^{IN} + \alpha_1^{IN} E_{i,p,t}/P_{i,p,t-1} + \alpha_2^{IN} \Delta E_{i,p,t}/P_{i,p,t-1} + \varepsilon_{i,p,t}. \tag{A3}$$

When estimating Eq. (A3), we place observations from each industry-year regression, i.e., Eq. (A2), into one of four portfolios based on the magnitude of their associated residuals from each annual regression for that industry.[40] We estimate Eq. (A3) by year, pooling observations in portfolio *p*, $p=1, \ldots, 4$. This permits the industry-neutral component of earnings transparency to vary over time. Because there are 27 years and 4 portfolios, we estimate 108 regressions, obtaining 108 industry-neutral components, $TRANSIN_{p,t}$. This estimation procedure does not constrain the coefficients in Eq. (A3), α_0^{IN}, α_1^{IN}, and α_2^{IN}, to be the same for firms within industry *j* in year *t*. Rather, it constrains firms within portfolio *p* to have the same coefficients in year *t*.

As an illustration, consider a hypothetical industry *j*, which has 100 observations per year. For each year, we rank the 100 residuals from 1 to 100 and place into portfolio 1 the 25 observations with the largest negative residuals, place into portfolio 2 the observations with the next largest 25 residuals, and so on, until each observation is assigned to a portfolio. We repeat this procedure for all 27 years and all 15 industries, so that portfolio 1 contains the quartile of observations with the largest negative residuals from each of the 15 industries in each year, portfolio 2 contains the quartile of observations with the next largest residuals from each of the 15 industries in each year, and so on. Thus, portfolios 1 and 4, which contain the observations with the largest negative and largest positive residuals from the annual industry regressions, comprise those firm-year observations for which the annual industry return regression model is least descriptive.

Selection of the optimal number of portfolios is an empirical matter reflecting a tradeoff between precision of estimation and forcing otherwise different groups of firms to have the same earnings transparency measure. For example, suppose instead of four portfolios we partitioned firms into eight portfolios, but firms in portfolios 1 and 2, 3 and 4, 5 and 6, and 7 and 8 have identical earnings transparency. This would result in a loss of estimation efficiency compared with partitioning firms into four portfolios, combining portfolios 1 and 2, 3 and 4, 5 and 6, and 7 and 8. In contrast, suppose instead eight portfolios capture differences in earnings transparency, then partitioning firms into four portfolios masks the cross-sectional earnings transparency differences.[41]

[39] Following Easton and Pae (2004), we also estimated versions of Eqs. (A2) and (A3) including year $t-1$ dividends and the effects of other comprehensive income. Untabulated findings indicate that none of our inferences is affected using this alternative specification.

[40] This procedure assumes that residuals of equal magnitude are equally informative about industry-neutral commonality regardless of the firm's industry regression standard error. To the extent that this procedure results in misclassifying firms across portfolios, our tests will be biased against finding an association between *TRANS* and cost of capital.

[41] Untabulated findings indicate that the significance of the *TRANS* coefficient in Eq. (2) is highest when we use four portfolios, although it is also significant for other numbers of portfolios.

A.2.Calculation of expected cost of capital proxy

We calculate our proxy for each firm's expected cost of capital for year $t+1$ as of year t, $ECC_{i,t}$, based on Eq. (A4):

$$ECC_{i,t}=\overline{R}_{f,t}+\hat{\beta}_{RMRF,i,t}\times\overline{(R_M-R_f)}_t+\hat{\beta}_{SMB,i,t}\times\overline{SMB}_t+\hat{\beta}_{HML,i,t}\times\overline{HML}_t+\hat{\beta}_{MOM,i,t}\times\overline{MOM}_t, \tag{A4}$$

where $\hat{\beta}_{RMRF,i,t}$,$\hat{\beta}_{SMB,i,t}$, $\hat{\beta}_{HML,i,t}$, and $\hat{\beta}_{MOM,i,t}$ are firm-specific coefficients estimated from Eq. (A5). $\overline{(R_M-R_f)}_t$, $\overline{SMB}_t$, $\overline{HML}_t$, and $\overline{MOM}_t$ are the expected annual Fama-French and momentum factor returns for year $t+1$. We estimate the expected annual factor returns by first calculating each factor's average monthly return over the 60 months prior to month m, and then compounding the resulting average monthly returns over the twelve months prior to the beginning of firm i's fiscal year.[42]

For each firm, we estimate the betas associated with the firm's return to each of the factors by estimating the following monthly time-series regression:

$$RET_{i,m}-R_{f,m}=\alpha_i+\beta_{RMRF,i}(R_{M,m}-R_{f,m})+\beta_{SMB,i}SMB_m+\beta_{HML,i}HML_m+\beta_{MOM,i}MOM_m+\varepsilon_{i,m}, \tag{A5}$$

where $RET_m-R_{f,m}$ is the firm's monthly return in excess of the risk-free rate, $R_{f,t}$. $R_{M,m}-R_{f,m}$ is the monthly return of the market portfolio in excess of the risk-free rate, HML_m and SMB_m are the monthly returns to the book-to-market and size factor mimicking portfolios as described in Fama and French (1993), and MOM_m is the monthly return to the momentum factor mimicking portfolio (Jegadeesh and Titman, 1993; Carhart, 1997). We estimate Eq. (A5) using the most recent 60 months returns prior to the beginning of firm i's fiscal year t. This results in estimated coefficients, $\hat{\beta}_{RMRF,i,t}$,$\hat{\beta}_{SMB,i,t}$, $\hat{\beta}_{HML,i,t}$, and $\hat{\beta}_{MOM,i,t}$ that are updated annually.

ABSTRACT

This paper formalizes a two-step representation of accounting measurement and uses it to formalize a general rationale for conservatism as a measurement principle. A transaction's economic substance manifests itself in characteristics of the transaction, and an accounting rule is a mapping from transaction characteristics to an accounting report. Managers who have stakes in the accounting report are able to influence transaction characteristics. Such earnings management is ex post rational for managers but ex ante inefficient. To safeguard against such ex post opportunism, the optimal ex ante accounting rule is conservative in the sense that it requires more verification of the transaction characteristics favorable to managers. Thus, this rationale for conservatism is as general as the managers' ability and incentive to inflate transaction characteristics. By opening the black box of accounting measurement, the two-step representation also formalizes some classic accounting concepts, such as relevance, reliability, verifiability, verification, and accounting-motivated transactions.

1. Introduction

When facing uncertainty, accounting measurement guided by conservatism requires more verification to recognize gains than to recognize losses. The long and pervasive influence of conservatism on accounting practice is evident by even a casual inspection of accounting practice and has been systematically documented in empirical studies (see Watts, 2003a, 2003b for a review).

Despite the persistent and pervasive influence of conservatism, the *general* value of conservatism as a measurement principle remains controversial in the theoretical literature and policy discourse. The core of the controversy might be understood as follows. In this literature, accounting measurement is treated as a black box that emanates an accounting report with certain statistical properties. With this reduced-form representation, conservatism is *defined* as trading an increase in the false negative (type II) error for an equal amount of decrease in the false positive (type I) error in the accounting report. The evaluation of conservatism is then conveniently transformed to an evaluation of the economic consequences of the report's measurement errors. As a result, the theories arrive at the conclusion that conservatism is

efficient if and only if the false negative error is less costly than the false positive error, a common thread underlying the results in many papers on conservatism (e.g, Gigler et al., 2009; Lu et al., 2011; Nan and Wen, 2011; Caskey and Hughes, 2012). In this framework, the generality of conservatism as a measurement principle is questionable to the extent that accounting reports are used in various settings in which the comparison of costs of measurement errors could go either direction. The controversy ensues.

Notwithstanding the empirical evidence, the lack of theoretical support for conservatism seems to be influencing standard setters both in the United States and around the world. Conservatism as a measurement principle was recently eliminated from the FASB and IASB's joint conceptual framework (FASB, 2010), which guides the making of future accounting standards. Given the enormous implications of the topic, Leuz (2001) has called for the reconciliation of this stark discrepancy between practice and theories, a theme echoed by Guay and Verrecchia (2006), Gigler et al. (2009), and Lambert (2010).

A careful examination of the discrepancy between theories and empirical works reveals the inadequacy of the reduced-form representation of accounting measurement. For example, one rationale for conservatism, discussed in most empirical works (e.g., Ball, 2001; Watts, 2003a; Kothari et al., 2010), views conservatism as a differential verification requirement and emphasizes managers' opportunistic influence on accounting measurement as the main justification, but neither feature shows up in the above framework that treats accounting measurement as a black box emanating an accounting report with certain statistical properties.

Opening the black box of accounting measurement invites a number of interesting questions. Conceptually, accounting measurement converts a firm's transactions and events into accounting reports by accounting rules, with the aim to capture the economic substance of the transactions. What is an accounting rule? How does an accounting rule relate the economic substance of a transaction to an accounting report? What are the major frictions in the process? What instruments does a rule designer control to influence the quality of an accounting report? What do we mean by a conservative accounting rule? As an institutional feature of accounting measurement, conservatism cannot be fully understood without answering these questions.

To answer these questions, I formalize a two-step representation of accounting measurement. This representation and its importance for understanding the design of accounting rules have long been noted in the classical accounting literatures (e.g., Ijiri, 1975; Watts and Zimmerman 1986; Ball, 1989; Leuz, 1998b). First, the state of nature, or the economic substance of a transaction, manifests itself in various characteristics of the transaction. Second, an accounting rule is defined as a mapping from transaction characteristics to an accounting report. While the goal of the rule is to measure the transaction's economic substance as accurately as possible, the design of the rule is subject to the restriction that it can only be written on transaction characteristics.

This restriction introduces a natural representation of two major frictions in accounting measurement. First, even in the absence of managers' influence, the correlation between a transaction's economic substance and its characteristics is likely to be imperfect. This correlation might be termed as a transaction characteristic's *relevance*. Second, firms could engage in activities to influence the characteristics of a transaction without improving its economic substance. These activities might be termed as *earnings management* and a transaction characteristic's vulnerability to earnings management could be interpreted as one measure of its *reliability*. Earnings management ranges from outright fabrication of evidence to the sophisticated accounting-motivated transactions such as off-balance-sheet financing activities. Such earnings management is ex post rational for managers but ex ante inefficient.

Facing these two frictions, the rule designer could use at least three instruments to influence the properties of the report. First, what transaction characteristics are admitted to the rule? Second, how much verification is required before the transaction characteristics are accepted? Finally, what is the evidence threshold above which an accounting treatment is accorded? While all the three instruments could be related to conservatism, I focus on the verification requirement. An accounting rule is conservative if it requires more verification of a positive transaction characteristic than of a negative one (e.g., Ball, 2001; Watts, 2003a; Kothari et al., 2010).[1]

By committing to more verification of transaction characteristics favorable to managers, the ex post benefit of earnings management diminishes and so does the incentive to engage in earnings management. This asymmetric verification requirement takes the form of conservatism when managers prefer better accounting reports. Thus, conservatism as a measurement principle is as *general* as managers' ability and incentive to *inflate* transaction characteristics.

This paper makes two contributions. First, it contributes to the literature on conservatism. By opening the black box of accounting measurement, the paper formalizes the notion that conservatism serves as ex ante safeguards against managers' ex post opportunistic influence on accounting measurement, which is widely cited in empirical works as the

[1] To make the representation more concrete, consider as an example a typical revenue recognition rule. The economic substance the rule aims to capture is the revenue earning process in a transaction. The characteristics of the transaction include cash receipt, product delivery, terms of warranty, customer credit worthiness, and so on. These characteristics are imperfectly correlated with the revenue earning process, and vulnerable to managers' influence. For example, even if the firm has not earned revenue from the transaction, the manager may be able to accelerate cash receipt or product delivery through "channel stuffing." A revenue recognition rule has at least three components. It identifies the subset of transaction characteristics to be used, imposes a verification requirement for each transaction characteristic, and prescribes a threshold of evidence above which revenue is recognized. It is conservative if it requires more verification of transaction characteristics that lead to revenue recognition (good news) than those that do not lead to revenue recognition (bad news).

contracting explanation of conservatism (e.g., Watts, 2003a).[2] It suggests that the reduced-form treatment of accounting measurement is responsible for the controversy about the general value of conservatism as a measurement principle discussed in the second paragraph of this Introduction. For most specifications of verification technologies discussed in the paper, the optimal accounting rule could be conservative even if the false negative error is more costly than the false positive error. Moreover, the optimal accounting rule is always conservative if the costs of measurement errors are equal. In other words, a conservative rule is the path to a "neutral" accounting report in presence of managers' opportunism.

The *simplicity* of this rationale for conservatism matches the persistent and pervasive influence conservatism has on accounting practice. Accounting rules are conservative as long as managers have incentive and ability to inflate transaction characteristics. Rewarding managers for good accounting performance is not only a general prescription from incentive theories but also a common feature of many real-world institutions. Empirically, most accounting frauds or irregularity involve inflated accounting reports.

The paper's second contribution is to clarify two related questions in the context of accounting standard setting. The first concerns the demand for accounting: given the properties of an accounting report, how is it optimally used and what are its economic consequences? The second concerns the supply of accounting: what are the optimal properties of an accounting rule that generates an accounting report with the targeted properties? While answers to both questions provide guidance for accounting standard setting, the first question has received most attention in the literature since Demski (1973). Various models have greatly advanced our understanding of the demand for accounting information by looking at how an accounting report with a given property affects market and non-market interactions, including valuation in capital markets, communication in product markets, and contracting within a firm. In this endeavor, accounting measurement is often treated as a black box that emanates a signal with certain statistical properties.

While this convenient representation could be justified on the ground of focusing on the first question, it could become misleading when the results from this framework are extrapolated as direct answers to the second question about the design of accounting rules. The two questions differ to the extent that the properties of an accounting report differs from those of an accounting rule that generates the report. This distinction is absent in the reduced-form representation, but it is for real for accounting standard setting. Suppose an accounting report with certain properties has been established as desirable (from answering the first question), we are still left with the second question of designing the measurement process that generates such a report. After all, it is this process that determines the *actual* properties of accounting reports and that is presumably the core of accounting as an independent discipline. To the extent that the properties of an accounting report are influenced only indirectly by the design of accounting rules, the answer to the first question cannot substitute for the answer to the second.

This paper illustrates the importance of differentiating these two questions. Even though conservatism is, at least implicitly, interpreted as a property of an accounting rule in the previous literature, it is nonetheless defined as a property of an accounting report, partially due to the reduced-form representation's inability to differentiate the two. With the two-step representation in this paper, conservatism is explicitly defined as a property of an accounting rule that generates the report. When we shift the focus from the first to the second question, a simple yet general rationale for conservatism as a measurement principle emerges. Thus, it is critical to look into the accounting measurement process in order to better guide accounting standard setting. The two-step representation of accounting measurement provides one useful framework to open the black box of accounting measurement.

Note that there is a large literature on biased performance measure and earnings management. However, most of that literature focuses on how *the use of an accounting report* (the demand side) is affected by earnings management (see Lambert, 2001 for a survey and see Glover et al., 2005; Arya and Glover, 2008 for recent examples). In contrast, this paper focuses on how the design of an accounting rule, or *the production of an accounting report* (the supply side), is constrained by earnings management. A review of literatures on conservatism and other efforts to open the black box of accounting measurement is deferred to Section 5.

The rest of the paper proceeds as follows. Section 2 describes the model. In Section 3, I show that the optimal accounting rule is conservative as long as the manager's one-sided earnings management is not contractible. Section 4 considers several extensions, including different verification technologies, renegotiation, and multi-period contracting. Section 5 provides a review of related literatures. Section 6 discusses the model's empirical and policy implications. Section 7 concludes.

2. A model of accounting measurement

To evaluate conservatism as a measurement principle, we require a setting in which the demand for accounting reports arises endogenously. I choose a corporate financing setting in which an accounting-based covenant is used. It will become clear that the rationale for conservatism goes beyond this specific setting. After describing the demand for an accounting-

[2] Watts and Zimmerman (1990) summarize it concisely: "Reacting to the incentive of managers to exercise accounting discretion opportunistically, the accepted set includes 'conservative' (e.g., lower of cost or market) and 'objective' (e.g., verifiable) accounting procedures."

Table 1
Expected payoffs at date 1.

State ω	Measure r	Probability	Action taken	Financier's payoff	Manager's payoff
G	g	$q_G(1-Q_G^b)$	a_M	pD	$p(Y-D)+X_G$
G	b	$q_G Q_G^b$	a_F	L	0
B	g	$q_B Q_B^g$	a_M	0	X_B
B	b	$q_B(1-Q_B^g)$	a_F	L	0

based debt covenant, I elaborate the structure of the accounting measurement process. Because the focus of the paper is on the latter, I keep the former part deliberately simple.

2.1. A setting with "the difficulty of selective intervention"

An owner–manager (henceforth the manager or the firm) with initial wealth of A has an indivisible project that requires an initial investment I at date 0. At date 1 after the firm is financed, the state of nature, ω, is realized. It is either *Good* or *Bad* with probability q_G and $q_B \equiv 1-q_G$, respectively, *i.e.*, $\omega \in \{G,B\}$. A firm in state ω is referred to as firm ω. After the realization of the state, one of the two actions has to be taken, *i.e.*, $a \in \{a_M,a_F\}$. The project's payoff depends on both state ω and action a. In state ω, action a_M yields the manager a private benefit $X_\omega > 0$ and a risky cash flow $\tilde{Y}_\omega$ at date 2.[3] $\tilde{Y}_G = Y$ with probability $p \in (0,1)$ and $\tilde{Y}_G = 0$ with probability $1-p$, and $\tilde{Y}_B = 0$ with probability 1. In contrast, action a_F yields no private benefit to the manager and a constant cash flow L, regardless of the state. For ease of reference, a_M is referred to as continuation and a_F as liquidation. I assume that $\Delta^{Under} \equiv pY+X_G-L > 0$ and $\Delta^{Over} \equiv L-X_B > 0$. That is, when the total payout of the firm is considered, continuation (a_M) of a good firm is a positive NPV decision whereas continuation of a bad firm is a negative NPV decision. Δ^{Under} is the efficiency loss of liquidating a good firm and Δ^{Over} of continuing a bad firm. Thus, if the manager could finance the firm with his own wealth, *i.e.*, $A \geq I$, he takes action a_M at date 1 if and only if the state is *Good*. The value of the project under this first best solution is $q_G(X_G+pY)+q_B L-I$.

I assume that the manager is wealth constrained ($A < I$) and has to finance the difference $I-A$ through a standard debt contract at date 0. The financier provides $I-A$ at date 0 and in return receives a prioritized payment up to the face value $D \leq Y$ at date 2. I call D face value or interest rate interchangeably. Both the manager and the financier are risk neutral and the risk free rate is 0. The lending market is assumed to be competitive at date 0. As a result, the financier's individual rationality (IR) condition binds in equilibrium and the surplus to the manager also measures the efficiency of the contract.

To simplify the notation, I assume that $L < D$ in equilibrium so that all the cash flow from action a_F goes to the financier. In addition, I assume that $pD < L$ in equilibrium.[4] Otherwise, if $pD \geq L$, the first best is achieved by giving the control right to the financier unconditionally (e.g., through a short-term debt contract or equity) and there is no need for a covenant. As a result of these two assumptions, the payoffs to the manager and the financier (M,F) under the combination of states and actions are simplified in Table 1 (the second and third columns are explained later).

This simple setting creates a classic problem of "the difficulty of selective intervention" as in Williamson (1985) and Aghion and Bolton (1992). While the socially optimal action is state-contingent, *i.e.*, $a^*(\omega = G) = a_M$ and $a^*(\omega = B) = a_F$, it is clear from Table 1 that the manager prefers a_M and the financier prefers a_F in both states, resulting in the demand for selective intervention. One way to implement the selective intervention is to use a state-contingent covenant that allocates the control right to the financier *in and only in* the *Bad* state. The implementation of such a covenant calls for the measurement of the state at date 1. That is, a state-contingent covenant is implemented as a measurement-contingent covenant in practice. Denote the measurement of the state as $r \in \{g,b\}$ with $r=g$ indicating a better state. Without loss of generality, if a covenant is ever used, it takes the following form: the firm retains the control right if and only if $r = g$.[5]

We now turn to the design of the accounting rule at date 0 that generates accounting report r at date 1 that settles the measurement-contingent covenant.

[3] As standard in the literature, the difference between cashflow and private benefit is that private benefit cannot be paid out to the financier. That is, X_ω is non-pledgable. Since the manager has spent time in initiating, developing, and implementing the project, he cares not only about the cashflow of the project but also about other non-monetary aspects such as social objectives, employee relationship, reputation, etc. Further, the manager may also accumulate skills and human capital from implementing the project in his own way that could improve his value in the labor market in the future. Most of these benefits are non-pledgable.

[4] The equilibrium value of D could be restricted by parameters, including p, Y, and A.

[5] Such accounting-based covenants are widely used in debt contracts, see, e.g., Watts and Zimmerman (1986), Christensen and Nikolaev (2012), and Tan (forthcoming).

2.2. A two-step representation of accounting measurement

To open the black box of accounting measurement, I use the following two-step representation. First, the state of nature ω, interpreted as a transaction's economic substance, manifests itself in the transaction's characteristics t. Second, an accounting rule is a mapping from transaction characteristics t to accounting report r.[6]

As discussed in the Introduction, the design of an accounting rule involves at least three instruments: the set of admissible transaction characteristics, the verification requirement, and the evidence threshold. This paper focuses on verification because the differential verification requirement is probably the most common interpretation of conservatism in the empirical literature (e.g., Watts and Zimmerman, 1983; Watts, 2003a; Kothari et al., 2010). Gao (2012) examines the third instrument and provides a rationale for the pervasive use of binary classifications and thresholds in accounting rules.

In particular, I assume that t is a scaler and binary. It is either positive P (good news) or negative N (bad news). To capture the idea that the mapping from ω to t could be noisy even in the absence of the manager's influence, I assume that $\Pr(t=P|\omega=G)=\phi_G$ and $\Pr(t=N|\omega=B)=\phi_B$. $\phi_G \in (\frac{1}{2},1]$ and $\phi_B \in (\frac{1}{2},1]$ are the relevance of the transaction characteristic. The verification requirement is operationalized as a vector $\{\gamma_t\}$, $t \in \{P,N\}$. If transaction characteristic t is presented, an accounting rule (verification requirement) γ_t requires that t be verified with probability γ_t. The technology of verification is specified later.

In this two-step representation, accounting report r relates to state ω through transaction characteristic t and the verification process γ_t. While the goal of accounting measurement is to capture ω as accurately as possible, the rule can only be written on t. This restriction introduces a natural representation of earnings management.

Earnings management is modeled as the manager's activities to inflate t. Between date 0 and date 1, that is, after signing the contract but before the realization of the state, the manager can increase by $\beta \in [0,\phi_B]$ the probability that the *Bad* state (transaction) exhibits the positive characteristic $t=P$.[7,8] Thus, with earnings management, the mapping from ω to t is altered to $\Pr(t=P|\omega=G,\beta)=\phi_G$ and $\Pr(t=P|\omega=B,\beta)=1-\phi_B+\beta$. The private cost of earnings management is $hK(\beta)$, $h>0$. A higher h means that it is more costly for the manager to manipulate transaction characteristics. Thus, h might be interpreted as the reliability (or "hardness" of Ijiri 1975) of a transaction characteristic. $K(\beta)$ has the standard properties of a cost function: it is increasing and convex with $K(0)=K'(0)=0$, and $K'(\phi_B)$ is sufficiently large. Further, $\frac{d}{d\beta}\left[\frac{K'}{K''}\right]=\frac{(K'')^2-K'K'''}{(K'')^2}>0$, which sets a bound on the speed at which K'' increases.[9] For example, the standard quadratic cost function $K(\beta)=\beta^2/2$ with h properly restricted satisfies these assumptions.

That transaction characteristics could be compromised by earnings management generates the demand for verification. There could be at least two views about the role verification plays in accounting measurement. The narrow view is that verification attests to the authenticity of transaction characteristics, such as whether an invoice is fabricated or not. To understand this view, we could interpret the above specification of earnings management in a different way. Let an indicator variable s denote the success of earnings management. $s=1$ indicates that the manager succeeds in generating the positive transaction characteristic in the *Bad* state and $s=0$ indicates otherwise. The probability that $s=1$ is β. The narrow view of verification amounts to a claim that verification reveals the realization of s in the model. In contrast, the broad view equates verification with information production in general. That is, verification reveals the realization of the state ω. I start with the narrow definition in the baseline model and examine the broad interpretation and various other specifications of verification technology in Section 4.

In the baseline model, if verification is conducted, s is revealed perfectly, earnings management is undone, and the authentic transaction characteristic is measured accordingly. If verification is not conducted, then the transaction characteristic is taken at its face value. Verification incurs a cost $\delta>0$ when it is conducted. Denote τ as the total probability that verification is conducted under accounting rule $\gamma_t: \tau \equiv \Pr(t=P)\gamma_P+\Pr(t=N)\gamma_N$. Thus, the total expected cost of verification is $\delta\tau$. Because $\delta\tau$ is known at date 0, I assume it is financed from the financier at date 0.

Finally, this two-step representation enables us to separate two critical concepts: the property of an accounting report versus the property of an accounting rule that generates the report. Define the (conditional) measurement errors of accounting report r as

$$Q_G^b \equiv \Pr(r=b|\omega=G)=1-\phi_G, \tag{1}$$

$$Q_B^g \equiv \Pr(r=g|\omega=B)=1-\phi_B+\beta(1-\gamma_P). \tag{2}$$

---

6 The idea of treating accounting rule as a mapping from transaction characteristics to accounting measures has a long history in accounting thoughts (see, e.g., Ijiri, 1975; Leuz, 1998a, 1998b).

7 The main results are qualitatively the same if it is assumed that the manager could alter the transaction characteristics *after* the state is observed by the manager. This different assumption only scales the cost function of earnings management by q_B, the probability that the *Bad* state occurs at date 1.

8 At one extreme, some firms simply fabricate evidence to recognize fictitious profit. For example, SEC (2011) claims that Satyam inflated its revenue by $1.1 billion by manufacturing false invoices for services never provided and, in some cases, for customers that did not exist.

At the other extreme, firms often structure their transactions to qualify for favorable accounting treatment at the expense of economic efficiency. Lys and Vincent (1995) report one striking example: "AT&T (in acquiring NCR) paid a documented $50 million and possibly as much as $500 million to satisfy pooling accounting, thus boosting EPS by roughly 17% but leaving cash flows unchanged." Systematic evidence on accounting-motivated transactions for accounting or regulation purpose has been documented by, among others, Imhoff and Thomas (1988) (through lease), Engel et al. (1999) (through hybrid securities), and Dechow et al. (2010) (through securitization).

9 This assumption on the cost function eliminates the "boil them in oil" results, in which earnings management is prevented entirely with sufficiently large punishment for even small amount of earnings management.

Definition 1. An accounting rule $\{\gamma_t\}$, $t \in \{P,N\}$, is conservative if it requires more verification of $t=P$ than of $t=N$, *i.e.*, $c \equiv \gamma_P - \gamma_N > 0$.

Definition 2. An accounting report r is neutral if the measurement errors are equal, *i.e.*, $Q_G^b = Q_B^g$.

Footnote 1 in page 2 provides a concrete example of this two-step representation of accounting measurement, which could also be depicted as follows:

$$\omega \underbrace{\text{-------------------}}_{\substack{\text{firm influence} \\ \text{(earnings management)}}} t \underbrace{\text{-------------------}}_{\substack{\text{rule design} \\ \text{(e.g., verification)}}} r$$

In sum, the timeline of the events is summarized as follows:

1. At date 0, the manager and the financier sign a debt contract with face value D, an accounting-based covenant in which the manager retains control right if and only if $r=g$, and the accounting rule (γ_P,γ_N) that generates r.
2. At date $\frac{1}{2}$ (between 0 and 1), the manager chooses the level of earnings management β.
3. At date 1, the state is realized, transaction characteristic t occurs, accounting report r is generated according to the accounting rule (γ_P,γ_N), the covenant is settled, and the action is taken.
4. At date 2, the project pays out and payment is made.

3. The main results

3.1. Preliminary analysis

The model is solved with backward induction. At date 1, the contracting parties' expected payoffs depend on both the state ω and its accounting measurement r. The probabilities of the combination of (ω,r) are summarized in Table 1 in page 4. Denote the financier's date-0 expectation of earnings management as $\hat{\beta}$ and the manager's actual choice of earnings management as β^*. The contracting problem at date 0 can be formulated as the following maximization problem, labeled as Problem 1

$$\max_{(D,\gamma_N,\gamma_P)} V(D,\gamma_N,\gamma_P) = q_G(1-Q_G^b)(p(Y-D)+X_G)+q_B Q_B^g(\beta^*)X_B - hK(\beta^*)$$

subject to

$$I-A+\delta\tau \le q_G(1-Q_G^b)pD + q_G Q_G^b L + q_B(1-Q_B^g(\hat{\beta}))L \tag{IR}$$

$$\beta^* = \arg\max_{\beta} q_G(1-Q_G^b)(p(Y-D)+X_G)+q_B Q_B^g(\beta)X_B - hK(\beta) \tag{IC}$$

$$\beta^* = \hat{\beta} \tag{rational expectations}$$

$$\gamma_t \in [0,1], \quad t \in \{P,N\}.$$

The manager chooses face value D and accounting rule γ_t at date 0 to maximize his expected payoff, subject to the financier' break-even condition, the anticipated ex post earnings management, the requirements of rational expectations and of γ_t being a probability. The objective function V is the manager's expected payoff at date 0, calculated as the inner product of the third and fifth columns of Table 1 with β being replaced by β^* net of the cost of earnings management $hK(\beta^*)$. The right-hand side of Constraint IR is the financier's expected payoff from the debt contract, calculated as the inner product of the third and fourth columns of Table 1 with β being replaced by $\hat{\beta}$. Constraint IC describes the manager's earnings management decision at date $\frac{1}{2}$, taking D and γ_t as given. Finally, the rational expectations require that the financier's conjecture about the manager's ex post earnings management be consistent with the manager's actual choice.

The assumption of a competitive market for financiers at date 0 assures that Constraint IR binds in equilibrium and we could solve for the expression of D as a function of $\hat{\beta}$ and γ_t. Substituting D into the objective function and imposing the requirement $\hat{\beta}=\beta^*$ in equilibrium, we rewrite Problem 1 as Problem 2

$$\max_{(\gamma_P,\gamma_N)} V(\gamma_P,\gamma_N) = V^{FB} - q_B Q_B^g(\beta^*)\Delta^{Over} - q_G Q_G^b \Delta^{Under} - hK(\beta^*) - \delta\tau(\beta^*) \tag{3}$$

subject to

$$\beta^* = \arg\max_{\beta} q_G(1-Q_G^b)(p(Y-D)+X_G)+q_B Q_B^g(\beta)X_B - hK(\beta) \tag{IC}$$

$$\gamma_t \in [0,1], \quad t \in \{P,N\}.$$

$V^{FB} \equiv q_G(X_G+pY)+q_BL-I+A$ is the manager's initial wealth plus the first-best firm value when the socially optimal actions are implemented in both states. Expression (3) states that, compared with V^{FB}, the actual firm value V is reduced by four terms. $q_BQ_B^g(\beta^*)\Delta^{Over}$ and $q_GQ_G^b\Delta^{Under}$ are the costs resulting from the suboptimal actions that are induced by the measurement errors $Q_B^g(\beta^*)$ and Q_G^b. $hK(\beta^*)$ and $\delta\tau(\beta^*)$ are the resources consumed by earnings management and verification.

3.2. Benchmark: contractible earnings management

To highlight the role of non-contractible earnings management, we first look at the benchmark in which ex post earnings management could be contracted upon ex ante. Ex ante and ex post refer to the timing of signing the contract. Thus, the IC constraint is dropped and β becomes a choice variable in Problem 2. Then the firm value could be rewritten as

$$V^{BM}(\beta,\gamma_t) = V^{FB}-q_B\Delta^{Over}(1-\phi_B+\beta(1-\gamma_P))-q_G\Delta^{Under}(1-\phi_G)-hK(\beta)-\delta\tau(\beta). \quad (4)$$

Lemma 1. *When earnings management is contractible, in equilibrium,*

1. *there is no earnings management, i.e.,* $\beta^{BM}=0$;
2. *the optimal verification requirement is* $\gamma_P^{BM}=\gamma_N^{BM}=0$. *Trivially, the optimal rule is neutral, i.e.,* $c^{BM}=0$.

Lemma 1 is straightforward from inspecting Eq. (4). The effect of the verification of $t=N$ on firm value is $\partial V^{BM}/\partial\gamma_N = -\delta(d\tau/d\gamma_N)<0$ for any β and γ_t. It consumes resources without any benefit, because $t=N$ is not manipulated by the manager, hence $\gamma_N^{BM}=0$. The effect of earnings management on firm value is captured by $\partial V^{BM}/\partial\beta = -hK'-q_B\Delta^{Over}(1-\gamma_P)-\delta q_B\gamma_P$. Earnings management consumes real resource (the first term). When it succeeds in generating $t=P$, it either enables the manager to take suboptimal action a_M in the *Bad* state (the second term) or invokes costly verification (the third term). Thus, the optimal earnings management is 0. With $\beta^{BM}=0$, the effect of the verification of $t=P$ on firm value is $\partial V^{BM}/\partial\gamma_P = -\delta(d\tau/d\gamma_P)<0$. Without earnings management, the verification of $t=P$ consumes resources without any benefit, just like the verification of $t=N$. Thus, $\gamma_P^{BM}=0$ and $c^{BM}=0$.

3.3. The design of ex ante accounting rule with non-contractible earnings management

In practice, earnings management is rarely contractible. Instead, the manager's choice of earnings management is governed only by his IC condition in Problem 2. In particular, the manager takes the interest rate D and accounting rule γ_t as given at the time of earnings management. The optimal earnings management β^* satisfies the following first-order condition:

$$q_B(1-\gamma_P)X_B = hK'(\beta^*). \quad (5)$$

From the manager's perspective, the left-hand side is the marginal benefit of earnings management at date $\frac{1}{2}$. By generating the positive transaction characteristic that is measured as *good*, earnings management allows the manager to retain the control right in the *Bad* state and receive the private benefit X_B. The right-hand side is the marginal cost of earnings management borne by the manager.

Lemma 2. *When earnings management is not contractible,*

1. *earnings management exists in equilibrium (i.e.,* $\beta^*>0$*) unless* $\gamma_P=1$;
2. *the verification of the positive transaction characteristic is more useful in mitigating earnings management than the verification of the negative transaction characteristic, i.e.,* $\partial\beta^*/\partial\gamma_P < \partial\beta^*/\partial\gamma_N = 0$.

Part 1 of Lemma 2 is proved by inspecting Eq. (5). It suggests that earnings management is ex post rational for the manager. After signing the contract (ex post), it is the accounting report r, not the state ω, that settles the covenant. The manager could keep out the external intervention as long as the state is *measured* as *good* by the pre-specified accounting rule. Thus, it is ex post rational for the manager to spend resources inflating transaction characteristics.

Part 2 of Lemma 2 is obtained by differentiating Eq. (5) with respect to γ_N and γ_P: $\partial\beta^*/\partial\gamma_N=0$ and $\partial\beta^*/\partial\gamma_P = -q_BX_B/hK''<0$. The verification of $t=N$ does not affect earnings management; in contrast, the verification of $t=P$ detects earnings management and prevents the manager from obtaining the preferred report, rendering earnings management less attractive to the manager. This asymmetry in the value of verification in deterring earnings management has immediate consequences for the design of the accounting rule.

Proposition 1. *If earnings management is not contractible and verification cost* δ *is sufficiently small, the optimal accounting rule is conservative.*

To see the intuition of Proposition 1, we verify that $\gamma_N^* = 0$ and $\gamma_P^* > 0$ for a sufficiently small δ. The effect of the verification of $t = N$ on firm value is $\partial V/\partial \gamma_N = -\delta(d\tau/d\gamma_N)$, which is negative for any β and γ_t. It is the same as in the benchmark case because γ_N does not affect earnings management. Thus, the optimal accounting rule sets $\gamma_N^* = 0$. Because $\gamma_N^* = 0$ holds for any β and γ_P, Problem 2 can be treated as a maximization problem with one choice variable γ_P. The first-order condition of γ_P could be expressed as

$$\frac{\partial V}{\partial \gamma_P} = q_B \Delta^{Over} \beta^* - (q_B \Delta^{Over}(1-\gamma_P) + hK')\frac{\partial \beta^*}{\partial \gamma_P} - \delta \frac{d\tau}{d\gamma_P}. \tag{6}$$

Eq. (6) reveals the effects of the verification of $t = P$ on firm value through its interaction with earnings management. First, given earnings management β^*, the verification of $t = P$ reduces the measurement error induced by earnings management (the first term). Second, the verification of $t = P$ reduces the manager's incentive to engage in earnings management in the first place, as captured by the term $\partial\beta^*/\partial\gamma_P < 0$. This reduction in earnings management improves firm value because it reduces the measurement error ($q_B \Delta^{Over}(1-\gamma_P)$) and saves the cost of earnings management (hK'). Finally, the total cost of verification also interacts with earnings management through τ, the probability that the verification of $t = P$ is triggered. This interaction is complex and analyzed in detail in Appendix A. Because the first two effects are positive, the verification of $t = P$ always occurs if it is not prohibitively costly. That is, for a sufficiently small δ, $\partial V/\partial \gamma_P|_{\gamma_P = 0} > 0$ and thus $\gamma_P^* > 0$. The combination of $\gamma_N^* = 0$ and $\gamma_P^* > 0$ proves Proposition 1 that $c^* \equiv \gamma_P^* - \gamma_N^* = \gamma_P^* > 0$. Further, this result of $c^* > 0$ is independent of the specifics of the underlying economic problem, namely, $q_G \Delta^{Under}$ and $q_B \Delta^{Over}$.

Proposition 1 is strikingly simple and general. While it might be straightforward after the accounting measurement process is articulated in the model, this result is at the heart of the heated debate on conservatism that has been influencing the accounting standard setting around the world. As discussed in the second paragraph of Introduction, much controversy about conservatism is predicated on the reduced-form representation that treats accounting measurement as a black box emanating a report with certain statistical properties. As a result, the property of an accounting report cannot be differentiated from the property of an accounting rule that generates the report. In the context of the model, the reasoning underlying the controversy could be understood as follows. One looks at the accounting report r, asks what are the optimal Q_B^g and Q_G^b if $Q_B^g + Q_G^b$ is constrained to be a constant, and arrives at the conclusion that $Q_G^{b*} > Q_B^{g*}$ if and only if $q_B \Delta^{Over} > q_G \Delta^{Under}$. Based on this exercise, one argues further that standard setters who serve a broad range of constituents should take an agnostic view of $q_B \Delta^{Over} = q_G \Delta^{Under}$. Therefore, the optimal accounting *report* is neutral. This conclusion is then further extrapolated as that the optimal accounting *rule* that generates the report is neutral.

While this reasoning is correct in describing the optimal property of accounting report r, it is misleading in describing the optimal property of the accounting rule that generates r. With the reduced-form representation of accounting measurement as an exogenous statistical process in the previous literature, conservatism is defined as a property of accounting report r, *i.e.*, $Q_G^b > Q_B^g$. In contrast, in this paper, the two-step representation of accounting measurement allows us to define conservatism explicitly as a property of an accounting rule that generates r. Conservatism requires more verification for *good* news ($t = P$) than for *bad* news ($t = N$), *i.e.*, $\gamma_P > \gamma_N$. Proposition 1 states that even if the economic problem calls for an accounting report r with the property of $Q_G^{b*} = Q_B^{g*}$, the optimal accounting rule that generates such a report is conservative. A conservative rule is the path to a neural accounting report in the presence of managers' opportunism. This simple shift of perspective, made possible by the articulation of the two-step representation of accounting measurement, clarifies the major controversy on conservatism.

We conduct comparative statics to derive empirical predictions about the determinants of conservatism. Proposition 1 relies only on $\gamma_P^* > 0$. In the Appendix, it is shown that γ_P^* is unique and interior under the following assumption, under which all the comparative statics are conducted.

Assumption 1. δ is sufficiently small and h is sufficiently large.

Corollary 1. *Under Assumption 1, the optimal accounting rule is more conservative if*

1. *it is easier for the manager to manipulate, e.g., h is smaller;*
2. *the manager's incentive to engage in earnings management is higher, e.g., q_B is larger;*
3. *the consequence of earnings management is more severe, e.g., Δ^{Over} is larger.*

Corollary 1 is proved by differentiating the first-order condition for γ_P with respect to relevant parameters. The optimal level of conservatism increases as the ex post earnings management becomes more severe a problem, either because it is cheaper or more attempting for the manager or more costly for the contracting parties as a whole. This heightens the contention of the paper that conservatism arises as an ex ante response to the manager's ex post opportunistic earnings management.

The effect of private benefit X_B on conservatism is ambiguous in the model. On one hand, an increase in X_B makes earnings management more attractive to the manager, which demands a more conservative rule as a counteraction. On the other hand, an increase in X_B reduces the inefficiency resulting from the manager obtaining the control right in the *Bad* state, which leads to a lower conservatism. The net effect of X_B on conservatism is thus determined by these two opposing effects.

3.4. Verifiability, reliability and relevance

One major benefit of opening the black box of accounting measurement is that it helps to formally define some commonly used concepts in accounting. In the model, the cost of verification δ might be interpreted as the verifiability of transaction characteristics. A smaller δ indicates that a transaction characteristic is more verifiable. Similarly, h could be interpreted as the reliability of a transaction characteristic and $\phi_i, i \in \{G,B\}$ as the relevance of a transaction characteristic. With these terminologies, we could ask the question how the verifiability, reliability and relevance of a transaction characteristic affects the firm value.

Corollary 2. *Under Assumption 1 and $K(\beta)=\beta^2/2$, the firm value increases in the verifiability, reliability, and relevance of a transaction characteristic, i.e., $dV^*/d\delta<0$, $dV^*/dh>0$ and $dV^*/d\phi_i>0$ for $i \in \{G,B\}$. Further, there is a trade-off between the reliability and relevance of a transaction characteristic, i.e., $dh/d\phi_i<0$, for $i \in \{G,B\}$.*

Corollary 2 is proved by the application of the envelop theorem. It formalizes some common intuition in accounting discourse. If a transaction characteristic becomes more verifiable, more reliable, or more relevant, the quality of accounting measurement improves and so does the firm value.[10] When two transaction characteristics differ in both their relevance and reliability, we obtain the classic trade-off between relevance and reliability.

3.5. Conservatism and price protection through interest rate

So far the analysis has not exploited the structure of the underlying financing problem except that it entails the use of a measurement-contingent covenant. This independence attests to the generality of the rationale for conservatism.

With the specifics of the financing problem, we could also examine the interaction of the accounting rule and other parts of the contract, in this case, the interest rate. We could rewrite the financier's break-even requirement at date 0 (binding IR condition in Problem 1) as

$$q_G\phi_G pD = I-A+\delta\tau-q_G(1-\phi_G)L-q_B(\phi_B-\hat{\beta}(1-\gamma_P))L. \tag{7}$$

Proposition 2. *Under Assumption 1, the face value D satisfies these properties:*

1. *ceteris paribus, it increases in the financier's conjecture about earnings management $\hat{\beta}$, i.e., $\partial D/\partial\hat{\beta}>0$;*
2. *in equilibrium, it is negatively associated with the level of conservatism, i.e., $dD^*/dc^*<0$.*

Part 1 captures the notion of ex ante price protection by the financier. If the financier believes that the manager is more likely to engage in earnings management after contracting, which enables the manager to pursue his own interest at the financier's expense, the financier demands a higher interest rate at date 0. As a result of the price protection, the manager bears the consequences of the ex post earnings management.

However, the ex ante price protection through the adjustment of interest rate does not eliminate the ex post opportunism. Because earnings management occurs *after* the interest rate is negotiated, the manager takes the interest rate as given when he chooses the level of earnings management. The first-order condition for the choice of earnings management (Eq. (5)) suggests that earnings management β^* does not directly depend on the interest rate D. Therefore, the interest rate in the contract alone does not perfectly align the contracting parties' preferences.

Part 2 of Proposition 2 states that conservatism and interest rate are imperfect substitutes for financier "protection" in the contract. The financier demands a lower interest rate when the accounting rule in the covenant is more conservative. The reason is because conservatism increases the chance that the control right is transferred to the financier, *i.e.*, $d\Pr(r=b)/d\gamma_P>0$. The control right at date 1 is valuable and thus the financier is willing to receive less cashflow in return for more control right. In other words, the financier can be "protected" by either a higher interest rate or a more conservative accounting rule in the covenant.

4. Extensions

The baseline model is deliberately simplified to highlight the general rationale for conservatism and contrast it to results in the previous literature. In this section, I extend the model in various ways to show the robustness of the general rationale for conservatism.

[10] The joint conceptual framework of FASB and IASB lists relevance and faithful representation (reliability) as two fundamental qualitative characteristics, and verifiability as one of the enhancing qualitative characteristics. Corollary 2 indicates that the three concepts should be at par with each other.

4.1. A broad view of verification as information production

The first extension considers a broad definition of verification. In the baseline model, verification is interpreted narrowly as the attestation to the authenticity of transaction characteristics. A broad definition equates verification with information production about the state ω.

In particular, I assume that when verification is not conducted, the transaction characteristic is accepted at its face value and that when verification is conducted, the state ω is revealed and measured perfectly. With information production, the linear cost $\delta\tau$ is not sufficient to guarantee an interior choice of γ_t. Thus, I assume that $\gamma_t, t \in \{P,N\}$ incurs a cost of $T(\gamma_t)$, with $T(0)=T'(0)=0$, $T' \geq 0$, $T'' > 0$ and $T'(1)=\infty$, and set $\delta=0$. The measurement errors under this new verification technology are

$$Q_G^b \equiv (1-\phi_G)(1-\gamma_N) = (1-\phi_G)-(1-\phi_G)\gamma_N,$$
$$Q_B^g \equiv (1-\phi_B+\beta)(1-\gamma_P) = (1-\phi_B+\beta(1-\gamma_P))-(1-\phi_B)\gamma_P.$$

The *Good* state generates $t=N$ with probability $1-\phi_G$. When it is not verified, $t=N$ is accepted as $r=b$, hence Q_G^b. Q_B^g has a similar interpretation except that $t=P$ could result additionally from earnings management β.

Compared with their counterparts in the baseline model (Eq. 1 and 2), Q_G^b and Q_B^g admit the additional components of $-(1-\phi_G)\gamma_N$ and $-(1-\phi_B)\gamma_P$. They reflect the information production of verification. In the baseline model, verification only mitigates the measurement bias introduced by earnings management; let us label it as the behavioral value of verification. With the broad definition, verification also reduces the measurement noise; let us label it as the technical value of verification. Conservatism is justified by the asymmetric behavioral value of verification in the baseline model, which is preserved in this extension. The technical value of verification depends on the specifics of the problem and is symmetric for $t=P$ and $t=N$. As a result, in a symmetric setting the optimal accounting rule is still strictly conservative.

Using the same procedure as in the baseline model, we could obtain the following results.

Proposition 3. *When verification generates information about ω,*

1. *with contractible earnings management, $\beta^{BM}=0$, $c^{BM} \equiv \gamma_P^{BM}-\gamma_N^{BM} > 0$ if and only if $q_B\Delta^{Over}(1-\phi_B) > q_G\Delta^{Under}(1-\phi_G)$. γ_P^{BM} and γ_N^{BM} are determined by*

$$\frac{\partial V^{BM}}{\partial \gamma_N^{BM}} = q_G\Delta^{Under}(1-\phi_G)-T'(\gamma_N^{BM})=0,$$
$$\frac{\partial V^{BM}}{\partial \gamma_P^{BM}} = q_B\Delta^{Over}(1-\phi_B)-T'(\gamma_P^{BM})=0.$$

2. *with non-contractible earnings management, $\beta^* > 0$, $\partial\beta^*/\partial\gamma_P < \partial\beta^*/\partial\gamma_N = 0$, $\gamma_P^* > \gamma_P^{BM}$, and $\gamma_N^* = \gamma_N^{BM}$. Thus, $c^* > c^{BM}$;*

3. *In a symmetric case with $q_B=q_G$, $\phi_G=\phi_B$, and $\Delta^{Over}=\Delta^{Under}$, $\gamma_P^* > \gamma_N^* = \gamma_P^{BM} = \gamma_N^{BM} > 0$. Thus $c^* > 0$.*

Proposition 3 mirrors Lemmas 1 and 2 and Proposition 1. The asymmetric behavioral value of verification is preserved, as confirmed by $\partial\beta^*/\partial\gamma_P < \partial\beta^*/\partial\gamma_N = 0$. The only difference is that with the additional technical value of verification, the base level of verification is elevated in the benchmark case and carried over to the setting with non-contractible earnings management. Even though the technical value of verification depends on the specifics of the problem, it is symmetric in the specifics of the problem. Therefore, its presence does not alter the asymmetry of the total value of verification. In the case with symmetric costs of measurement errors, the optimal accounting rule is strictly conservative.

4.2. Noisy verification technologies

So far, the verification technologies are assumed to be costly but perfect. In this extension, I show that the rationale for conservatism is robust to noisy verification technologies. This extension also generates a result consistent with the notion that accounting measurement involves a trade-off of different measurement errors.

The setting is the same as in the previous subsection except that verification now reveals the state ω imperfectly. Verification generates additional evidence (transaction characteristics) t' in the following way:

$$\Pr(t'=P|\omega=G) = \Pr(t'=N|\omega=B) = \pi, \quad \pi \in \left(\frac{1}{2},1\right).$$

To make verification not trivial, I assume that r is determined by t' when verification is conducted: $r(t'=P)=g$ and $r(t'=N)=b$. That is, π is sufficiently large. Note that the direct cost of verification is not necessary because verification is endogenously costly due to its imprecision. Subjecting a transaction characteristic to verification may result in its wrong measurement. As a result, we could set $\delta=0$ and $T=0$. For simplicity, I also assume that $\phi_G=\phi_B=1$ so that the technical value of verification is absent. In addition, I assume that earnings management in the absence of verification is sufficiently severe so that the corner solution of no verification at all is not optimal.

With this technology, the new measurement errors are

$$Q_G^b = \gamma_P(1-\pi),$$

$$Q_B^g = \beta(1-\gamma_P+\gamma_P(1-\pi))+(1-\beta)\gamma_N(1-\pi) = \gamma_N(1-\pi)+\beta(1-\pi\gamma_P-\gamma_N(1-\pi)).$$

When $t=P$ is subject to verification and fails to pass, Q_G^b occurs. Similarly, Q_B^g originates from two sources. First, with earnings management, the *Bad* state generates $t=P$, which could be measured as *good* with probability $1-\gamma_P+\gamma_P(1-\pi)$. Second, even if the *Bad* state generates $t=N$, it could still be measured as *good* when it is subject to verification but fails to pass, which occurs with probability $\gamma_N(1-\pi)$.

Using the same procedures in the baseline model, we obtain the following results.

Proposition 4. *When verification is noisy,*

1. *with contractible earnings management,* $\beta^{BM}=0$, *and* $\gamma_P^{BM}=\gamma_N^{BM}=0$;
2. *with non-contractible earnings management,* $\beta^*>0$, *and* $\partial\beta^*/\partial\gamma_P<\partial\beta^*/\partial\gamma_N<0$;
3. *in a symmetric case with* $q_G=q_B$ *and* $\Delta^{Under}=\Delta^{Over}$, $\gamma_P^*>\gamma_N^*=\gamma_P^{BM}=\gamma_N^{BM}=0$. *Thus* $c^*>0$.

Again, Proposition 4 mirrors Lemmas 1 and 2 and Proposition 1. The asymmetric behavioral value of verification is preserved ($\partial\beta^*/\partial\gamma_P<\partial\beta^*/\partial\gamma_N$) and so does the rationale for conservatism. The only difference is that with the noisy verification technology, the endogenous cost of verification is related to the specifics of the problem. For example, because the verification of $t=P$ could result in measurement error Q_G^b, the cost of γ_P depends on Δ^{Under}, the consequence of the measurement error Q_G^b. Moreover, this cost of verification is symmetric for γ_P and γ_N. As shown in the proof in the Appendix, the optimal verification requirement thus has two components, one for its asymmetric behavioral value and the other for its symmetric cost. Due to the asymmetric value of γ_P and γ_N in mitigating earnings management, the optimal accounting rule is still conservative when the costs associated with different measurement errors are symmetric.

4.3. Renegotiation

In the baseline model, the state-contingent covenant is not renegotiation proof but renegotiation is assumed away. Empirically, debt covenants are often renegotiated (e.g., Roberts and Sufi, 2009). Because at date 1 the financier and the manager may have information that is not captured by the accounting report used in the contract, a natural question is that whether the contracting parties could improve efficiency through renegotiation. Does the possibility of costless renegotiation after the settlement of the debt covenant preempt the value of using conservative accounting measurement rules? The answer is somewhat surprising: the possibility of ex post renegotiation intensifies earnings management and thus could make conservatism more attractive.

The only case in which renegotiation is possible is when the state is *Bad* but measured as *good*.[11] Without renegotiation, the manager would take action a_M, resulting in an ex post efficiency loss of Δ^{Over}. Thus, the financier could "bribe" the manager to take action a_F by sharing with the manager some surplus from the saving of Δ^{Over}. Denote the manager's bargaining power as $\mu\in[0,1]$ and consider a Nash bargaining solution. The manager's payoff in the *Bad* state with $r=g$ changes from X_B to $X_B+\mu\Delta^{Over}$. Anticipating the increased payoff in the *Bad* state with $r=g$, the manager's earnings management β^{**} is determined by the new first-order condition

$$q_B(X_B+\mu\Delta^{Over})(1-\gamma_P) = hK'(\beta^{**}) \tag{8}$$

Comparing it with its counterpart in the baseline model (Eq. (5)), it is straightforward that $\beta^{**}\geq\beta^*$. In addition to receiving the private benefit, the manager also receives a fraction of the surplus resulting from the renegotiation. As a result, $r=g$ becomes more valuable to the manager. As the marginal benefit of earnings management increases, the manager chooses a higher level of earnings management. Therefore, while renegotiation improves the ex post action taken at date 1, it intensifies ex ante earnings management. As a result, conservatism is even more attractive.[12]

[11] If the state is Good, there are two cases. In the case $r=g$ renegotiation is not necessary because the manager takes a_M efficiently. In the case of $r=b$ renegotiation is not feasible because the firm does not have any wealth to pay the financier and the private benefit is not pledgable. If the state is Bad and measured as bad, renegotiation is not necessary because the financier takes a_F efficiently.

[12] Another possible solution combines a non-contingent contract with renegotiation. The firm retains control right by default and the financier could bribe the firm to take a_F in the Bad state. While this arrangement implements socially optimal actions in both states without inducing the cost of earnings management and verification, it does have one drawback. It requires a face value higher than D^* in the baseline model. Thus, if the cash flow Y is limited, there is a region in which this arrangement is not feasible but the contract in the baseline model is still feasible. See Aghion and Bolton (1992) for more details of results in this line.

4.4. Two types of conservatism

One limitation of this paper is that it focuses only on one aspect of a conservative rule, namely, the differential verification requirement. As such, all the results in the paper are obtained under the assumption that it is optimal to recognize a given transaction characteristic. Therefore, the model describes the "interior" form of conservatism but does not directly address the "corner solution" form of conservatism. Revenue recognition is an example of the interior form of measurement in which r could be either g or b, depending on t.

Corollary 2 shows that the value of using a transaction characteristic depends on its quality in terms of verifiability, reliability and relevance. Thus, it could be optimal not to use a transaction characteristic when the quality of a transaction characteristic deteriorates, leading to a corner solution. The corner solution corresponds to the more extreme types of conservatism in practice, such as expensing R&D in which $r=b$ regardless of t. It might be argued that the transaction characteristics indicative of the economic substance of R&D are often difficult to verify (a high δ) and vulnerable to managers' influence (a low h). As a result, it could be optimal not to capitalize any R&D expenditure. That is, $r=b$ regardless of t and the verification of positive transaction characteristics that lead to $r=g$ is absent. This type of conservatism requires a model that focuses on the first instrument of the design of measurement rules and is left to future research. The classification of interior-form versus corner-solution-form conservatism also corresponds to the classification of conditional versus unconditional conservatism (e.g., Beaver and Ryan, 2005).

4.5. Does the value of conservatism reverse as the conservative bias for current contracts reverse in future?

One criticism of conservatism is that the conservative bias in current period leads to upward bias in future periods, as expressed by FASB: "Understating assets or overstating liabilities in one period frequently leads to overstating financial performance in later periods" (FASB 2010 BC3.28). It is interpreted that whatever value conservatism has in one period is inevitably reversed in others. This concern seems to be an important consideration when conservatism is eliminated from the FASB and IASB's joint conceptual framework (FASB, 2010). In this extension, I show that when a conservative bias exists and reverses in the future, it does not diminish the efficiency of conservatism for contracting.[13] The intuition relies on a careful differentiation of ex ante contractibility versus ex post observability of information.

To examine this issue, the model has to be extended to multiple periods. A simple way is to repeat the same stage game every period. Suppose every period the firm discovers a project that needs financing. All the payoffs of the projects across periods are independent and identically distributed. The firm enters into one new contract to finance the newly discovered project each period. The timeline could be depicted as follows:

date	$t-1$	t	$t+1$	$t+2$
Project t	Contract t signed	ω^t measured	ω^t realized	
Project $t+1$		Contract $t+1$ signed	ω^{t+1} measured	ω^{t+1} realized

Further, so far the state ω has been assumed to be not contractible at date 0. Now I also assume that it is observable ex post at date 1. This assumption is implicitly behind the above criticism. If ω is not observable at date 1, then we cannot ascertain the existence of the bias, rendering the criticism moot in the first place. Specifically, at date t, the state of project t, ω^t, is measured as $r^t(\omega^t)$. The bias of the accounting report for contract t is conservative if $r^t(\omega^t)-\omega^t<0$. Similarly, at date $t+1$, the state of project $t+1$, ω^{t+1}, is measured as $r^{t+1}(\omega^{t+1})$. In addition, ω^t is realized at date $t+1$. The realization of ω^t then reverses the bias in the previous measurement $r^t(\omega^t)$. That is, the reversal, $-(r^t(\omega^t)-\omega^t)$, is added to the accounting report at date $t+1$. The aggregate accounting report at date $t+1$ is

$$r^{t+1}(\omega^t,\omega^{t+1})=r^{t+1}(\omega^{t+1})+(\omega^t-r^t(\omega^t)).$$

$r^{t+1}(\omega^t,\omega^{t+1})$ has an upward bias $\omega^t-r^t(\omega^t)>0$ because contract t has a conservative bias, *i.e.*, $r^t(\omega^t)-\omega^t<0$. Under-measuring state ω^t at date t leads to the over-measurement of state ω^{t+1} at date $t+1$. In this sense, FASB's observation is correct.

Does contract $t+1$ have to use $r^{t+1}(\omega^t,\omega^{t+1})$ as it is? From the contracting perspective, recall that at date t when contract t is settled, ω^t is observed. In other words, the conservative bias $r^t(\omega^t)-\omega^t$ is transparent. Therefore, contract $t+1$ could use a modified accounting report $r^{t+1}_{Modified}(\omega^t,\omega^{t+1})=r^{t+1}(\omega^t,\omega^{t+1})-(\omega^t-r^t(\omega^t))=r^{t+1}(\omega^{t+1})$ to exclude the impact of the reversal of the conservative bias from contract t. As a result, the conservative bias used in contract t is not carried over to contract $t+1$. FASB's reason for eliminating conservatism from the conceptual framework is thus flawed from the contracting perspective.

Consider the example in which the outcome of R&D is not ex ante contractible but ex post observable. At the time the current contract was negotiated, it was excluded from measurement (or expensed) for contracting purpose because of its lack of reliability. However, one period later, after the state that determines the outcome of the R&D is observed but before

[13] I operate under the assumption that there exists a conservative bias when a conservative rule is in place. This assumption itself is nebulous in that the benchmark for the bias is not specified. Because a conservative rule mitigates the manager's aggressive influence, the direction of the net bias is not certain. See Section 4.4 for the discussion of the two different types of conservatism.

the actual benefit pays out, the contracting parties learn the magnitude of the conservative bias resulting from the expensing, and expect it to reverse when the actual benefit of the R&D pays out later. The key observation is that when the information that is not used in the previous contract due to its lack of reliability becomes observable ex post, it can be used for the *new* contract. That is, at the time of negotiating the new contract, the contracting parties could use the knowledge about the conservative bias from the previous contract to make appropriate adjustment to exclude the confounding effects of its expected reversal. As a result, due to the differential timing of the two contracts and the difference between ex ante contractibility and ex post observability of information, the conservative bias in the current contract does not affect the new contract.

5. Literature review

The two-step representation of accounting measurement, which separates the property of an accounting report from that of an accounting rule that generates the report, differentiates my paper from many models on conservatism. For example, Chen et al. (2007) also study the role of conservatism in dampening the insiders' earnings management. In their model, efforts lead to economic earnings, which in turn are converted to reported earnings. Both earnings management and conservatism are defined as direct influence on the second mapping from economic earnings to reported earnings. The two-step representation adds transaction characteristics between economic earnings (economic substance) and reported earnings (accounting report). This allows me to define earnings management as the influence on the first step from economic substance to transaction characteristics, and define conservatism as a property of an accounting rule that maps from transaction characteristics to reported earnings. As a result, the two models are substantially different.

As discussed in the Introduction, with a reduced-form representation of accounting measurement and conservatism, many models essentially turn the evaluation of conservatism into a comparison of decision costs associated with different measurement errors. For example, Gigler et al. (2009) show that for a project that has been financed already, a false negative error is more costly than a false positive error. As a result, conservatism, defined as trading a higher false negative error for a lower false positive error, reduces debt contracting efficiency. Similarly, other papers explore frictions that alter the relative costs in different settings. For example, by adding a non-contractible ex post asset substitution problem that raises the cost of a false positive signal, Caskey and Hughes (2012) show that conservatism could be efficient when the asset substitution problem is sufficiently severe. Li (2010) introduces costs of renegotiation and Jiang (2011) brings in non-accounting information to find regions where conservatism could be efficient. Lu et al. (2011) introduce a value-enhancing expansion opportunity that is traded off with an asset substitution problem. In Nan and Wen (2011), conservatism could be efficient if the proportion of bad firms is large, which makes a false positive signal more costly.

It is worth noting that there are two types of agency problems in this context. One is the agency problem in the economic setting that creates the demand for accounting information, and the other is the agency problem with the accounting measurement process that directly affects the design of accounting rules. The models above, except (Chen et al., 2007), focus exclusively on the first friction to evaluate conservatism. Antle and Gjesdal (2001) and Beyer (2012) define conservatism in an articulated context of accounting measurement, expense recognition in the former and lower of cost or market in the latter. That the conditions for conservatism to be valuable identified in both papers rely heavily on the specifics of their economic settings that is, on the comparison of the relative costs of measurement errors, seems to be related to the lack of managers' opportunistic influence on accounting measurement in their models. In Gox and Wagenhofer (2009, 2010) the main results are obtained without the second agency problem as well.

There are also models on conservatism in a principal-agent setting. Antle and Lambert (1988) motivate conservatism from the auditor's asymmetric loss function and Antle and Nalebuff (1991) further endogenize the auditor's preference from the strategic interaction between the auditor and the privately informed manager. In Kwon et al. (2001), conservatism loosens the limited liability of the agent and thus improves efficiency. Gigler and Hemmer (2001) model the link between the bias in accounting measurement and the incentives for the managers to issue voluntary disclosure. They argue that the concave earnings-return relation does not necessarily result from the conservatism in accounting. Bagnoli and Watts (2005) and Chen and Deng (2010) model conservatism as a signaling device to convey the manager's private information.

Defining conservatism as differential verification requirements also relates this paper to the literature on costly state verification and conditional investigation. In Townsend (1979) the firm tends to claim a low report in an attempt to extract concessions from lenders who then respond with more verification of the low report. In my model, the firm has incentive to inflate the report so as to prevent intervention from the lenders, inducing more verification of a high report. Thus, Townsend (1979) is more appropriate for a short-term debt contract in which the report is the same as cash payment, whereas my model focuses on a long-term debt contract that demands accounting reports (earnings) to settle the covenant in the interim.[14] As I argued in the introduction, as far as the use of accounting reports is concerned, users' concerns tend to be more about the inflation of earnings than about the opposite. Baiman and Demski (1980) and Dye (1986) study a principal-agent model and conclude the optimal investigation policy depends on the agent's utility function in general.

[14] In practice earnings and cash typically move in opposite directions. Empirical research finds firms that are doing well and expanding have reductions in cash and firms that are doing poorly and contracting have increases in cash (see, e.g., Dechow et al., 1998).

Christensen and Demski (2004) extend Baiman and Demski (1980) by allowing the agent to report the output. They highlight the asymmetric value of additional information in motivating agents' effort and truth-telling, but do not explicitly model the accounting measurement process and the design of accounting rules.

6. Empirical and policy implications

The large empirical literature has relied on the contracting explanation of conservatism in Watts (2003a). By formalizing it, my model provides a formal justification for many empirical findings in the literature. In particular, it substantiates empirical predictions about the consequences and determinants of conservatism. When conservatism is considered as an institutional parameter, the model predicts that conservatism constrains the manager's ex post opportunism and lowers the interest rate. When conservatism is viewed as a choice variable, the model predicts that conservatism level is higher if the reliability or hardness of a firm's transactions is lower or if the agency cost associated with the manager is higher. Further, the cost of earnings management h could also be broadly interpreted as the strength of other mechanisms that constrain the manager's earnings management, such as reputation, corporate governance, and legal regimes. Thus, the model predicts that conservatism could be a substitute for these mechanisms. These predictions are consistent with the existing evidence such as Ball et al. (2000), Watts (2003b), Zhang (2008), Watts and Zuo (2011), and Kim et al. (forthcoming).

Second, the model strengthens the contracting explanation of conservatism. For example, the efficiency of conservatism does not rely on the assumption that the cost of overinvestment is larger than that of underinvestment. For another example, the financier's posterior beliefs about the state do not play a direct role in the model, which has two important implications. First, earnings management in equilibrium could be observable ex post as long as it is not contractible ex ante. This equilibrium existence of transparent earnings management is empirically important. Many empirical studies of earnings management use direct proxies for earnings management and thus assume that earnings management is observable. These studies would be self-contradictory if they relied on a theory that requires earnings management be non-observable. Second, that the contracting parties' posterior beliefs do not affect the model directly implies that an accounting report is useful for contracting as long as it is *correlated* with the state; in particular, it *does not have to be* incrementally informative to contracting parities. This makes the contracting view of accounting measurement directly testable.

Finally, the model might have some implications for accounting standard setting. Arguably, one of the most difficult issues in standard setting is to deal with managers' ex post opportunistic response to standards, as evident in standards for such controversial issues as consolidation, securitization, and leases. In the presence of this difficulty (non-contractibility of earnings management) and managers' opportunistic incentives, my model shows that the optimal accounting rule is conservative even if the neutrality of accounting reports is the desirable goal. There is a difference between the properties of an accounting report and those of an accounting rule that generates the report. Even if it is agreed on that a neutral accounting report is desirable, the accounting rule, which is the domain of accounting standard setting, is conservative. This issues a cautionary note to the approach of pursing neutral accounting reports via neutral accounting rules.

7. Conclusion

This paper formalizes the long-lasting intuition in accounting that conservatism serves as an ex ante safeguard against managers' ex post opportunistic influence on accounting measurement. The key innovation is to use a two-step representation of accounting measurement. The representation features earnings management as the main friction and specifies instruments in the design of an accounting rule. With this framework articulated, it is easy to see that conservatism is optimal as long as the manager has the incentive and ability to inflate accounting reports. This rationale is more general than the requirement imposed on the comparison of the costs of measurement errors of the accounting report. Thus, the paper substantiates the generality of conservatism as measurement principle by shifting the focus from the properties of an accounting report to the properties of an accounting rule that generates the report.

In addition to its contribution to the debate on conservatism, this paper also illustrates the importance of opening the black box of accounting measurement. To understand institutional features of accounting practice, two questions could be asked. First, given a feature of accounting information, how is it used (optimally) and what are its economic consequences? Second, how is the accounting measurement process designed to generate accounting information with a targeted feature? The previous literature has devoted most attention to the first question and as a result dealt with the institutional features of accounting practice indirectly at most. This paper takes one step towards answering the second question and shows that the two-step representation of accounting measurement is a useful tool.

Finally, this paper focuses on contracting as the economic setting that calls for accounting measurement. Contracting setting has the nice feature that the contracting parties' posteriors about the state do not directly interfere with the ex post settlement of the contract. The model could be extended to other economic settings that demand accounting measurement, such as informing capital markets. Gao (2012) models a general setting of the demand for accounting information.

Acknowledgments

I have benefited from many discussions on this topic with Rick Antle, Anil Arya, Ray Ball, Mary Barth, Jeremy Bertomeu, Anne Beyer, Judson Caskey, Qi Chen, Douglas Diamond, Merle Erickson, Richard Frankel, Matthew Gentzkow, Frank Gigler, Jonathan Glover, Milt Harris, Zhiguo He, Thomas Hemmer (discussant), Jack Hughes, Chandra Kanodia, Mozaffar Khan, Pierre Liang, Christian Leuz, Tong Lu, Claudine Mangen, Xiumin Martin, Brian Mittendorf, Valeri Nikolaev, Mort Pincus, Raghuram Rajan, Karthik Ramanna, Haresh Sapra, Katherine Schipper, James Sinclair (discussant), Doug Skinner, Swaminathan Sridharan, Shyam Sunder, Tsahi Versano, Alfred Wagenhofer (the reviewer), Ross Watts (the editor), Regina Wittenberg-Moerman, Jing Wu (discussant), Joanna Wu, Yun Zhang, Luo Zuo, and participants of workshops and conferences at Carnegie Mellon University, Chinese University of Hong Kong, Ohio State University, Peking University, Tilburg University, UCLA, UC Irvine, University of Chicago Applied Theory Workshop, University of Chicago Accounting Workshop, University of Minnesota, Washington University in St. Louis, Yale University, 2011 HKUST Accounting Symposium, 2012 Financial Report Accounting Section Mid-Year Meeting, 2012 American Accounting Association Annual Meeting, and 2012 Utah Winter Accounting Conference. All errors are my own. I also acknowledge the generous financial support from University of Chicago Booth School of Business.

Appendix

Proof of Lemma 1 and 2, Proposition 1, and Corollary 1. By definition, the total probability of verification τ is

$$\tau(\beta,\gamma_t) \equiv \Pr(t=P)\gamma_P + \Pr(t=N)\gamma_N = (q_G\phi_G + q_B(1-\phi_B+\beta))\gamma_P + (q_G(1-\phi_G)+q_B(\phi_B-\beta))\gamma_N.$$

$$\frac{\partial\tau}{\partial\gamma_P} = (q_G\phi_G + q_B(1-\phi_B+\beta)) > 0,$$
$$\frac{\partial\tau}{\partial\gamma_N} = (q_G(1-\phi_G)+q_B(\phi_B-\beta)) > 0,$$
$$\frac{\partial\tau}{\partial\beta} = q_B(\gamma_P-\gamma_N).$$

For the benchmark case, β is a choice variable at date 0. Because $\partial V^{BM}/\partial\gamma_N = -\delta(d\tau/d\gamma_N) < 0$ for any β and γ_t, $\gamma_N^{BM}=0$ for any β and γ_P. Because $\partial V^{BM}/\partial\beta = -hK' - q_B\Delta^{Over}(1-\gamma_P) - \delta q_B\gamma_P < 0$, $\beta^{BM}=0$ for any γ_P. Because $\partial V^{BM}/\partial\gamma_P = -\delta(d\tau/d\gamma_P) < 0$, $\gamma_P^{BM}=0$. Thus, $c^{BM}=0$. This proves Lemma 1.

From Eq. (5), we have $\beta^* > 0$ if $\gamma_P < 1$. Because Eq. (5) is independent of γ_N, $\partial\beta^*/\partial\gamma_N = 0$. Differentiating Eq. (5) with respect to γ_P, we have $\partial\beta^*/\partial\gamma_P = -q_B X_B/hK'' < 0$. This proves Lemma 2.

For Proposition 1, I prove that $\gamma_N^* = 0$ and $\gamma_P^* > 0$ for a sufficiently small δ. It is a straightforward application of Kuhn–Tucker theorem except that the cost of verification $\delta\tau$ in the objective function does not behave well: it is neither always increasing nor always convex in γ_P. To see the possibility of non-increasing,

$$\frac{d\tau}{d\gamma_P} = \frac{\partial\tau}{\partial\gamma_P} + \frac{\partial\tau}{\partial\beta^*}\frac{\partial\beta^*}{\partial\gamma_P}.$$

$\partial\tau/\partial\gamma_P > 0$, $\partial\tau/\partial\beta^* > 0$, but $\partial\beta^*/\partial\gamma_P < 0$. That is, the marginal cost of verification could be negative. The intuition is that an increase in γ_P has both a direct and an indirect effect on τ. The direct effect is that it triggers verification more often, holding earnings management constant, *i.e.*, $\partial\tau/\partial\gamma_P > 0$. The indirect effect is that it reduces earnings management, which decreases the probability of $t=P$ being presented and thus of verification being triggered, *i.e.*, $\partial\beta^*/\partial\gamma_P < 0$. As a result, $d\tau/d\gamma_P$ could be negative. To see the possibility of non-convexity

$$\frac{d^2\tau}{d\gamma_P^2} = q_B\left(2+\gamma_P\frac{q_B X_B K'''}{h(K'')^2}\right)\frac{\partial\beta^*}{\partial\gamma_P}$$

could be clearly negative. A sufficiently small δ assures that the properties of the objective function are not dominated by $\delta\tau$.

With this, I proceed to prove $\gamma_N^* = 0$ and $\gamma_P^* > 0$. Because

$$\frac{\partial V}{\partial\gamma_N} = -\delta\frac{d\tau}{d\gamma_N} = -\delta(q_G(1-\phi_G)+q_B(\phi_B-\beta^*)) < 0,$$

$\gamma_N^* = 0$ for any γ_P and β^*. To prove $\gamma_P^* > 0$, I show that $\partial V/\partial\gamma_P$ evaluated at $\gamma_P = 0$ is strictly positive

$$\frac{\partial V}{\partial\gamma_P} = q_B\Delta^{Over}\beta^* - (q_B\Delta^{Over}(1-\gamma_P) + hK'(\beta^*))\frac{\partial\beta^*}{\partial\gamma_P} - \delta\frac{d\tau}{d\gamma_P} = q_B\left(\Delta^{Over}\beta^* + (\Delta^{Over}+X_B)\frac{K'}{K''}\right) - \delta\frac{d\tau}{d\gamma_P}. \tag{9}$$

The second equality utilizes the first-order condition for β^* (Eq. (5)) and the expression of $\partial\beta^*/\partial\gamma_P = -q_B X_B/hK''$. As mentioned in the text, the first term in Eq. (9) is the marginal benefit of γ_P through its interaction with earnings management. From $\partial\beta^*/\partial\gamma_P < 0$ and $(K'/K'')' > 0$, we know that β^* is maximized at $\gamma_P = 0$ and thus the first term in Eq. (9) is maximized at $\gamma_P = 0$. The second term is the marginal verification cost of γ_P, as analyzed above. Therefore, with a sufficiently small δ, $\partial V/\partial\gamma_P|_{\gamma_P=0} > 0$ and $\gamma_P^* > 0$, hence Proposition 1.

To conduct comparative statics in order to prove Corollary 1, I first prove that γ_P^* is unique and interior under Assumption 1: δ is sufficiently small and h is sufficiently high. At $\gamma_P = 1$, $\beta^* = 0$. Evaluating $\partial V/\partial\gamma_P$ at $\gamma_P = 1$, we have

$$\frac{\partial V}{\partial\gamma_P}\bigg|_{\gamma_P=1} = -\delta\frac{d\tau}{d\gamma_P}\bigg|_{\gamma_P=1} = -\delta\left(\frac{\partial\tau}{\partial\gamma_P}+\frac{\partial\tau}{\partial\beta^*}\frac{\partial\beta^*}{\partial\gamma_P}\right)\bigg|_{\gamma_P=1} = -\delta(\left(q_G\phi_G+q_B(1-\phi_B)-q_B\frac{q_BX_B}{hK''(0)}\right).$$

If h is sufficiently high, the indirect effect of γ_P on τ is mild. As a result, $d\tau/d\gamma_P|_{\gamma_P=1} > 0$ and $\partial V/\partial\gamma_P|_{\gamma_P=1} < 0$. Furthermore, a sufficiently small δ assures that the first-order condition is both necessary and sufficient (because $\gamma_N^* = 0$ for any γ_P, Problem 2 is effectively a single-variable maximization problem.) Together, Assumption 1 assures that γ_P^* satisfying $\partial V/\partial\gamma_P^* = 0$ is unique and interior. With the first-order condition $\partial V/\partial\gamma_P^* = 0$ and $\gamma_N^* = 0$ for any γ_P, the comparative statics for c^* are obtained by differentiating $\partial V/\partial\gamma_P^* = 0$ with respect to relevant parameters. That is, $dc^*/di = d\gamma_P^*/di$,i is a relevant parameter. For example, for $i = h$,

$$\frac{dc^*}{dh} = \frac{d\gamma_P^*}{dh} = -\frac{q_B\left(\Delta^{Over}+(\Delta^{Over}+X_B)\left(\frac{K'}{K''}\right)'\right)\frac{\partial\beta^*}{\partial h}-\delta\left(q_B\frac{\partial\beta^*}{\partial h}+q_B\gamma_P\frac{\partial^2\beta^*}{\partial\gamma_P^*\partial h}\right)}{\frac{d^2V}{d\gamma_P^{*2}}} < 0.$$

Other results could be obtained similarly. □

Proof of Corollary 2. The proof is by a straightforward application of the envelope theorem

$$\frac{dV^*}{dh} = \frac{\partial V}{\partial h}\bigg|_{\gamma_P=\gamma_P^*,\gamma_N=\gamma_N^*=0} = -q_B\Delta^{Over}(1-\gamma_P^*)\frac{\partial\beta^*}{\partial h}+\frac{\beta^{*2}}{2}-\delta q_B\gamma_P^*\frac{\partial\beta^*}{\partial h} > 0,$$

$$\frac{dV^*}{d\phi_G} = \frac{\partial V}{\partial\phi_G}\bigg|_{\gamma_P=\gamma_P^*,\gamma_N=\gamma_N^*=0} = q_G\Delta^{Under}-\delta(q_G\gamma_P^*) > 0,$$

$$\frac{dV^*}{d\phi_B} = \frac{\partial V}{\partial\phi_B}\bigg|_{\gamma_P=\gamma_P^*,\gamma_N=\gamma_N^*=0} = q_B\Delta^{Over}(1-\gamma_P^*)+\delta(q_B\gamma_P^*) > 0,$$

$$\frac{dV^*}{d\delta} = \frac{\partial V}{\partial\delta}\bigg|_{\gamma_P=\gamma_P^*,\gamma_N=\gamma_N^*=0} = -\tau < 0.$$

$dV^*/dh > 0$ utilizes $K(\beta) = \beta^2/2$ and $dV^*/d\phi_G > 0$ relies on δ being sufficiently small. Applying the total differentiation to V^* with respect to ϕ_i and h, we have $0 = dV^* = (dV^*/dh)\,dh+(dV^*/d\phi_G)\,d\phi_G+(dV^*/d\phi_B)\,d\phi_B$. Therefore, there is a trade-off between h and ϕ_i because

$$\frac{dh}{d\phi_G} = -\frac{dV^*/d\phi_G}{dV^*/dh} < 0, \quad \frac{dh}{d\phi_B} = -\frac{dV^*/d\phi_B}{dV^*/dh} < 0. \quad \square$$

Proof of Proposition 2. From Eq. (7), by treating γ_t and τ as constants, we have $q_G\phi_Gp(\partial D/\partial\hat{\beta}) = q_B(1-\gamma_P)L > 0$. In equilibrium, $\hat{\beta} = \beta^*$ and neither β^* nor γ_P^* cannot be treated as constant. Substituting $\gamma_N^* = 0$ in to Eq. (7) and differentiating it with respect to c^* or γ_P^*

$$q_G\phi_Gp\frac{dD}{dc^*} = q_G\phi_Gp\frac{dD}{d\gamma_P^*} = q_B(1-\gamma_P)L\frac{\partial\beta^*}{\partial\gamma_P}-q_B\beta^*L+\delta\frac{d\tau}{d\gamma_P} = \left(q_B(1-\gamma_P)\frac{\partial\beta^*}{\partial\gamma_P}-q_B\beta^*\right)L+q_B\left(\Delta^{Over}\beta^*+(\Delta^{Over}+X_B)\frac{K'}{K''}\right)$$

$$= -q_BX_B\beta^*+q_B\left((1-\gamma_P^*)\frac{\partial\beta^*}{\partial\gamma_P}+\frac{K'}{K''}\right)L = -q_BX_B\beta^* < 0.$$

The second step utilizes the first-order condition of $\partial V/\partial\gamma_P^* = 0$, the third the definition of $\Delta^{Over} = L-X_B$, and the last the expression of $\partial\beta^*/\partial\gamma_P$ and Eq. (5). □

Proof of Proposition 3. With the new Q_B^g and Q_G^b, Problem 2 could be rewritten as

$$\max_{(\gamma_P,\gamma_N)} V = V^{FB}-q_B\Delta^{Over}(1-\phi_B+\beta^*)(1-\gamma_P)-q_G\Delta^{Under}(1-\phi_G)(1-\gamma_N)-hK(\beta^*)-T$$

subject to

$$hK'(\beta^*) = q_BX_B(1-\gamma_P)$$
$$\gamma_t \in [0,1].$$

When earnings management is contractible, $\partial V^{BM}/\partial\beta = -q_B\Delta^{Over}(1-\gamma_P)-hK' < 0$ for any γ_t. Thus, $\beta^{BM} = 0$. The first-order conditions for γ_t are obtained accordingly

$$\frac{\partial V^{BM}}{\partial\gamma_N} = q_G\Delta^{Under}(1-\phi_G)-T'(\gamma_N) = 0,$$

$$\frac{\partial V^{BM}}{\partial \gamma_P} = q_B \Delta^{Over}(1-\phi_B) - T'(\gamma_P) = 0.$$

The Hessian matrix,

$$\begin{pmatrix} -T''(\gamma_N) & 0 \\ 0 & -T''(\gamma_P) \end{pmatrix}$$

is negative definite. Because $T'' > 0$, $\gamma_P^{BM} > \gamma_N^{BM}$ if and only if $q_B \Delta^{Over}(1-\phi_B) > q_G \Delta^{Under}(1-\phi_G)$.

When earnings management is not contractible, we have $\partial\beta^*/\partial\gamma_P < \partial\beta^*/\partial\gamma_N = 0$ by differentiating the IC condition. Thus, $\gamma_N^* = \gamma_N^{BM}$. In contrast,

$$\frac{\partial V}{\partial \gamma_P} = q_B \Delta^{Over}(1-\phi_B) + q_B\left(\Delta^{Over}\beta^* + (\Delta^{Over} + X_B)\frac{K'}{K''}\right) - T'(\gamma_P).$$

Because $\partial^2 V/\partial\gamma_P^2 = q_B(\Delta^{Over} + (\Delta^{Over} + X_B)(K'/K'')')(\partial\beta^*/\partial\gamma_P) - T'' < 0$, $\partial V/\partial\gamma_P$ is decreasing in γ_P. Evaluating $\partial V/\partial\gamma_P$ at $\gamma_P = \gamma_P^{BM}$, we have

$$\left.\frac{\partial V}{\partial \gamma_P}\right|_{\gamma_P = \gamma_P^{BM}} = q_B\left(\Delta^{Over}\beta^* + (\Delta^{Over} + X_B)\frac{K'}{K''}\right)\Bigg|_{\gamma_P = \gamma_P^{BM}} > 0.$$

Thus, $\gamma_P^* > \gamma_P^{BM}$ and $c^* > c^{BM}$. Further, in a symmetric case, it is easy to verify that $\gamma_P^* > \gamma_N^* = \gamma_P^{BM} = \gamma_N^{BM} > 0$ and thus $c^* > 0$. □

Proof of Proposition 4. With the newly defined Q_B^g and Q_G^b, Problem 2 could be rewritten as

$$\max_{(\gamma_P,\gamma_N)} V = V^{FB} - q_B \Delta^{Over}(\gamma_N(1-\pi) + \beta^*(1-\pi\gamma_P - \gamma_N(1-\pi))) - q_G \Delta^{Under}\gamma_P(1-\pi) - hK(\beta^*)$$

subject to

$$hK'(\beta^*) = q_B X_B(1-\pi\gamma_P - \gamma_N(1-\pi))$$
$$\gamma_t \in [0,1].$$

When earnings management is contractible, $\partial V^{BM}/\partial\beta = -q_B\Delta^{Over}(1-\pi\gamma_P - \gamma_N(1-\pi)) - hK' < 0$ for any γ_t. Thus, $\beta^{BM} = 0$. Because $\partial V^{BM}/\partial\gamma_P = -q_G\Delta^{Under}(1-\pi) < 0$ and $\partial V^{BM}/\partial\gamma_N = -q_B\Delta^{Over}(1-\pi) < 0$, $\gamma_N^{BM} = \gamma_P^{BM} = 0$.

When earnings management is not contractible, by differentiating the IC condition, we have $\partial\beta^*/\partial\gamma_P = -q_B X_B/hK''\pi$ and $\partial\beta^*/\partial\gamma_N = -q_B X_B/hK''(1-\pi)$. Because $\pi \in (\frac{1}{2},1)$, $\partial\beta^*/\partial\gamma_P < \partial\beta^*/\partial\gamma_N < 0$.

The effects of γ_t on firm value are

$$\frac{\partial V}{\partial \gamma_N} = q_B\left(\Delta^{Over}\beta^* + (\Delta^{Over} + X_B)\frac{K'}{K''}\right)(1-\pi) - q_B\Delta^{Over}(1-\pi),$$
$$\frac{\partial V}{\partial \gamma_P} = q_B\left(\Delta^{Over}\beta^* + (\Delta^{Over} + X_B)\frac{K'}{K''}\right)\pi - q_G\Delta^{Under}(1-\pi).$$

Suppose (γ_P^*, γ_N^*) are the optimal solutions and we prove that $\gamma_P^* > \gamma_N^*$ for the symmetric case of $q_G = q_B$ and $\Delta^{Under} = \Delta^{Over}$. We first prove $\gamma_P^*\gamma_N^* < 1$ by contradiction. If $\gamma_P^* = \gamma_N^* = 1$, then $(1-\pi\gamma_P^* - \gamma_N^*(1-\pi)) = 0$ and $\beta^* = 0$, which imply that $\partial V/\partial\gamma_N|_{\gamma_N = 1} = -q_B\Delta^{Over}(1-\pi) < 0$ and $\partial V/\partial\gamma_P|_{\gamma_P = 1} = -q_G\Delta^{Under}(1-\pi) < 0$, contradicting $\gamma_P^* = \gamma_N^* = 1$. Thus, $\gamma_P^*\gamma_N^* < 1$. This implies $\beta^* > 0$ and $(\partial V/\partial\gamma_P - \partial V/\partial\gamma_N)|_{\gamma_P = \gamma_P^*, \gamma_N = \gamma_N^*} = q_B(\Delta^{Over}\beta^* + (\Delta^{Over} + X_B)K'/K'')(2\pi - 1) > 0$. Second, we prove that $\gamma_P = \gamma_N = 0$ is not the optimal solution by contradiction. If $\gamma_P^* = \gamma_N^* = 0$, then $\beta^* = \beta^0 \equiv \arg\max hK'(\beta^*) - q_B X_B$ is maximized. By the assumption that earnings management is sufficiently important,

$$\left.\frac{\partial V}{\partial \gamma_N}\right|_{\gamma_N = 0, \gamma_P = 0} = q_B\left(\Delta^{Over}\beta^0 + (\Delta^{Over} + X_B)\frac{K'(\beta^0)}{K''(\beta^0)}\right)(1-\pi) - q_B\Delta^{Over}(1-\pi) > 0,$$

contradicting $\gamma_N^* = 0$. Finally, collecting $\gamma_P^*\gamma_N^* < 1$, $(\partial V/\partial\gamma_P - \partial V/\partial\gamma_N)|_{\gamma_P = \gamma_P^* \gamma_N = \gamma_N^*} > 0$, and $\gamma_P = \gamma_N = 0$ is not optimal, we have either $\partial V/\partial\gamma_P|_{\gamma_P = \gamma_P^*} \geq 0 > \partial V/\partial\gamma_N|_{\gamma_N = \gamma_N^*}$, which means that $\gamma_P^* > 0 = \gamma_N^*$ or $\partial V/\partial\gamma_P|_{\gamma_P = \gamma_P^*} > 0 \geq \partial V/\partial\gamma_N|_{\gamma_N = \gamma_N^*}$ which means that $\gamma_P^* = 1 > \gamma_N^*$. Thus, for the symmetric case, $c^* > 0$. □

Received January 15, 2013; Revised February 02, 2013; Accepted March 14, 2013

Abstract This study investigates the effects of ownership structure on the performance of the listed companies in the Tehran Stock Exchange (TSE). Consequently, a main hypothesis is presented, which states that there is a significant relationship between companies' ownership structures and their performances and then five sub-hypotheses are provided. For testing the hypotheses, the statistical "panel data" technique is employed. For testing each hypotheses, 4 accounting and economics performance evaluation variables models based on different ownership structures are established. The statistical population includes 66 companies in the period between 2003-2008. Based on the research results, all hypotheses except the fourth one, were confirmed. The findings revealed a significant negative relationship between the "institutional ownership" and companies' performances; and the relationship between "corporate ownership" and companies' performance generally was significantly positive. "Management ownership", however, would affect the performance significantly and negatively. For "foreign ownership", there was no information that would indicate ownership of the foreign investors in our samples companies. With respect to the "company ownership", just in the models based on the accounting variables (i.e., ROA and ROE) coefficients are significant and negative. But in the models based on the "market variables" (i.e., Q-Tobin and MBVR) coefficients are not significant. In general, there was a significant relationship between companies' ownership structures and their performances.

Keywords: *ownership structure, corporate governance, Tehran Stock Exchange (TSE), panel data, performance evaluation*

1. Introduction

In its primitive form, agency theory, [30] and [6], with respect to the owner- management relations, hypothesizes that firms consist of two individuals; the agent (management) and the principal (the owner). The principal delegates authority of the decision makings concerning utilization of the firms' scarce resources to the agent based upon a designated fee schedule. However, since the objectives of the agent may be incompatible with the principal's objectives and their incentives may not be congruent, the agent's performance evaluation must be appropriately exerted [43].

Recently, the concept and applications of the basic agency theory, however, has been extended to more realistic situations-i.e., the corporate governance situations [60] and [58] in that, the role of the board of directors, management and those who are responsible in governing the corporation, are being identified and their potential relationships with corporate performances are being sought. However, as it will be explained later, the findings are primitive and sometimes opposite. Additionally, in developing countries, this kind of studies is in its early stages and a solid empirical studies are limited. (see e.g., [23] and [40], Hence, no conclusive results in this vital area can be derived from the existing literature.

Consequently, the major objective of this study is providing an empirical evidence to respond to this inquiry: does different corporations', ownership structure would lead to different financial performances? If that is the case, which form of the ownership structures, is the most appropriate one for enhancing the firms' financial performances? In approaching these questions, data for the companies listed in the Tehran Stock Exchange (TSE) will be extracted for 5 year period (2003-2008).

The structure of the paper is as follow. Section 2 is devoted to explain theoretical foundation of the paper. Section 3 reviews the domestic and foreign literature regarding the kinds of the ownerships and their significance in the corporate governance domain. The research method ,including hypotheses, research variables ,model buildings, population and sample selection ,data collection method, and statistical test is provided in section 4. Section 5 reveals the findings of the study and hypotheses. The concluding remarks and discussion of the article is reported in section 6. Finally, section 7 offers suggestions for future studies.

2. Theoretical Structure

Theoretical framework of this study is centered on the concept of the "corporate governance". This concept is based upon governing corporations in such a manner to respond to the stockholders and other stakeholders' financial demands and performing managements' stewardship functions [28]. In essence, different groups have attempted to define corporate governance. One group defines it as an attempt to discover a structure in such a manner that the power of realizations and decision makings of the managers will be exerted for servicing the firm's stockholders by the best channel [58].

Another group emphasizes corporate governance from the economic realm and considers it as a means for making corporations more efficient by establishing appropriate infrastructures such as contracts and designing corporate rules and regulations. This view is focused on the principle of increasing the value (wealth) for the stockholders [37].

The Organization for Economic Cooperation and Development (OECD, 1998) also has defined corporate governance as an organizational structure among stockholders, board members and management which determines their responsibilities.

Recently, different corporate governance models have been introduced in the literature. [50] and [4], for example, identify two distinctive models:

English-American (Anglo.-Saxon), and

German-Japanese model.

In the first model, private ownership is the key matter and stock exchange is the major source for providing corporations' funds. In the second model, a corporation is viewed as a coalition of different groups with incompatible interests and thus the function of the top management is to reach to equilibrium among different stakeholders. [63] consider these two models as the "Control Originated" and "Arms-Length Financing" models.

Given the nature and objective of this study, the Arms-length financing model will be adopted.

3. Literature Review

Kumar [34] identifies two main ownership structures: 1) institutional ownership and 2) private ownership. The first kind of ownership is referred to as the percentage of the stocks from the whole stocks which is maintained by the public corporations. The corporations include insurance companies, financial institutions banks, public corporations and other government sections. The second structure consists of private ownership and is divided into the following sub-sections:

1) firm investors, 2) management investors and 3) foreign investors [13]

In Iran, until almost 5 years ago and before the emergence of the so called "The Principle 44", most businesses were under the ownership and control of the government. After promulgation of this principle", government was forced to follow privatization and offering public stocks to private individuals. Thus, institutional firms were reduced and private ownerships were increased. The first private ownership structure is "Corporate Shareholding" in that public ownership is transferred to private firms which are known as "corporate shareholding". These firms attempt to obtain more of the firms' stocks in order to control operations of the invested firms. Another significant group of this category is mainly "Investment Companies" that are striving to obtain other firms' stocks in an effort to optimize their profits.

The second private ownership structure is known as the "Managerial Shareholding" in that public stocks are offered to private individuals through the stock market mechanism. The separation of ownership and management has mostly occurred in this situation and some family firms are listed in this category.

The third type of the private ownership structure is via the foreign investments, which is based upon a particular laws and regulations. This type of ownership is very limited in Iran and thus, does not play a significant role in the TSE ownership structure [35] and [23]

Since in this study we would investigate two main variables- ownership structures and company's performance-in the TSE, merely those studies will be reviewed here which will support these two selected variables.

In Iran, limited empirical studies have been conducted in this domain directly. Thus, some researches in this field, which is somehow related to our study, will be reviewed. Furthermore, some of these studies are enunciated just to support employment of the selected variables and their selections in the performance evaluation realm.

3.1. Institutional Investors and Privatization

3.1.1. Foreign Studies

Tsaia and GU, [60] investigated the relationship between "institutional ownership" and "company performance" in the Casino Industry from 1999 to 2003. An institutional ownership was determined by the percentage of the stocks which public corporations maintained from the whole stocks. Corporations included insurance companies, financial institutions, banks, public corporations and other government sections. The study revealed that institutional ownership in Casinos could possibly help investors in this industry to reduce obstacles of separating management from ownership. In addition, financial institutions would prefer to invest in those Casinos which maintained lower financial leverages.

Fernando et al. [20], theoretically and experimentally, studied the difference in institutional ownerships and the level of stock prices among American companies in the NYSE and AMEX from 1985 to 2005. The findings showed that companies with higher values, did maintain more institutional ownerships and higher stock price levels and the positive relation between stock prices and the institutional ownership was independent of the liquidity consideration and sizes of the companies.

Cornett et al. [13] also investigated the relation between institutional investors' involvement and operational performances of the large firms. They found that there was a significant relationship between "operating cash flow returns" of the companies and the percentage of the institutional stock ownerships and institutional stockholders. However, this relationship was just observed for a sub-group of institutional investors that did have less business relations with the firms.

Elyasiani and Jia, [18] have also studied the dependence of the Bank Holding Company (BHC) and the "institutional ownership stability". The results of their study showed that first, the performance of the BHC Companies are related positively to institutional ownerships. Second, dependence, of the BHC Companies on returns is weaker than the dependence in the firms' industry. Third, this dependency is stronger in new deregulated years and for the BHC Companies, in which they have lower possibility of adjustments.

3.1.2. Domestic Studies

Ahmadzadeh et al. [2], studied the capital structure of the Bank Keshavarzi during ten years (1991-2000) and estimated its' cost of capital. The results of this study indicated that there was no relationship between capital structure and costs of the capital within this period and it showed that capital structure of this bank in 2000 was non-optimal.

Hasasyeganeh and Pouria Nasab [23] argued that the more active the shareholder is, the better supervision on the company's management performance could be exerted and the agency problems would be reduced. In addition, institutional investors, as the main owners, of the companies are responsible for effecting the company management to maintain a significant role in their investments.

Mahdavi and Maydari [35], after investigation of privatization experiments in socialist countries especially Czech, estimated the extent of the ownership focus in the stock exchanges and determined the profitability of different kinds of ownerships structures. The results demonstrated that in Czech and China, ownership focus has a positive effect on the company's' performance efficiency.

Rahchamani [52], also studied the role of the ownership structure and protection of the investors and shareholders' rights after privatization of the companies. The result exhibited that in countries which investors are supported less, the focus on the ownership is more and privatization and private ownership would cause a superior performance.

Mokarami [40] by presenting the modern structure in managing enterprises and creating values for all stakeholders, argued that the responsibility of the evaluation of the enterprise performance and existing managers are related to institutional stockholders.

3.2. Firm Investors

3.2.1. Foreign Studies

Cheung et al. [12] studied the relationship between market returns and accounting revenues for sample companies in Japan from 1975 to 1994. The results indicated that company's relationship between returns and revenues were negatively affected by the ownership level of the investment in real states, level of investments in other firms' stocks and financial leverages. However, the level of foreign ownership affects this relationship positively. The company ownership is the percentage of keeping stocks from all stock investments by the company and includes all kinds of the firms except those that are presented in the following sections.

Kapopoulos and Lazaretou [31] have also investigated the effects of ownership structure on the company's performance by studying 175 Greek companies. They concluded that more focus in ownership structure would be positively related to higher profitability of the firm; and for gaining a higher profitability, ownership with less scattering is required.

3.2.2. Domestic Studies

Rahman Seresht and Mazloomi [53] studied the relationship between companies' investors, management performance and their shares of ownerships for listed companies in the TSE. They investigated the role of the company's investors and attempted to reply to this question: Does the ownership structure of the organizations provide a convincing result for their different performances? The results revealed that different groups of the owners (real and legal person) did not maintain the same strength and congruencies to affect company's performances and generally the difference of ownership structures of the companies could explain some of the variations in the companies' performances.

Sinaie and Rezaian [57], by focusing on financial performances of the public corporations in TSE, attempted to review the capital structure and changes of the financial parameters within the companies in the kinds of ownership and industrial structures. They presented modern approaches in the development of the financial markets. Their findings illustrated that a strong relationship existed between companies' key variables –i.e. company size, profitability, development chances, tangible assets - and the capital structure of the companies.

Namazi and Shirzadeh [44] studied the effect of the capital structure on the profitability of the TSE companies in different industries. The results of their study exhibited that there was a positive relationship between capital structures and company's profitability; but this relationship was statistically weak and depended on the industry type and the definition of the profitability. In addition, optimal capital structure of different industries could be determined.

Nowravesh and Ebrahimi Kordlar [45] had also investigated the role of the company's investors in reducing informational asymmetry in the TSE. In this research, investment companies and other business institutions were defined as "investors companies". The results indicated that companies with higher percentages of the investors, would report more information concerning future profits and, as a result, one would observe more informational asymmetry in companies with lower investors.

3.3. Management Investors

3.3.1. Foreign Studies

Bhagat [9] studied the effects of the plans of sharing managers in the company's ownership and it's impacts on the shareholders' wealth. He concluded that this plan could increase share holders' wealth.

Murphy [42] and Jensen and Murphy [29] have also studied the relationship between managers' compensations and company's performances by expensing combinations of the measurable data and Black and Schools stock options models. The results of their studies indicated that there was a positive relationship between stock options and changes of the shareholders' possession.

Hill and Stevens [26] also investigated the relationship between the managers' rewards and accounting profits and stock prices in the New York Stock Exchange. They also studied the relationship between parts of the managers' rewards and low index annual stock revenues (the weak form of evaluating company's performances) and annual revenues without the relevant industry index (the strong form of evaluating company performances). Their study showed that there was a positive relationship between short-term reward managers' ownership and stock returns. And in those companies in which the manager had more stocks, a superior performance could be attained. In addition, the reward and ownership had more positive and significant relations with stock returns. In a time that managers' ownership was increased and most of his wealth was depended on the stock increase, managers' motivations for increasing stock returns would be enhanced as well.

Mishra et al. [39] have also investigated the firm values and its relationship with control structures. They studied a sample of 120 Norwegian companies and concluded that the relationship between family board of directors and company's values for newly established firms, companies with less board of director members and firms with one kind of stocks, is very strong.

Mcconaughy et al. [38] have also studied the effects of the family ownership on the company's capital structure and values. Their results indicated that firms which were governed by family structures had higher values and efficiency and also had fewer liabilities.

Anderson and Reeb [3] have also investigated the performance of the family companies. They found that the family companies had a superior performance in comparison with others. They also reported a non-liner relation between company's performance and percentages of the family ownerships; indicating that when family members are in the board of directors, a more favorable performance could be attained.

Enqvist [19] has investigated the relationship between management ownerships and shareholder's supervision with company's performance. By exerting the concept of "Q Tobin" for Swedish companies, he concluded that stockholders' supervision had negative impacts on the Q-Tobin.

Halpern et al. [24] studied the relation between management investors and company's values for the acquired firms. The results showed that there was a non-liner relation between moral hazard costs and management investors and they indicated that acquired firms could be divided based on management's investments. The division would be different according to the following criteria: 1) sources of the wealth gains, 2) managerial resistance, 3) persons who acquire the firms and 4) how shareholders' objectives are being achieved.

Mueller and Spitz-Oener [43] interpreted the relationship between management ownerships (includes keeping stocks by the board of directors members) and the medium and small German private companies' performance with incentive criteria. In their search, they focused on economic units which were the most important sections of the German economy. They extracted a sample of 356 companies in the service segment which were related to business from 1997 to 2000. Their findings showed that in companies in which management ownerships percentage were more than 40%, the performance was improved.

Wang [61] in investigating family companies' ownership and profit quality, showed that family ownership would increase the relationship between users of the financial statements and internal organizations' members. He also concluded that high quality of profits may be resulted from true combinations of the family members and shareholders' interests.

Khan et al. [32] have also studied the mathematical relationship between management's stock ownership and companies' performance for Austrian companies' form 2000 to 2003. They found no evidence of non-liner relations between management's stock ownerships and Q-Tobin ratio. However, a significant negative relations between management stock ownerships and Q-Tobin ratio was found.

3.3.2. Domestic Studies

Poorhaydari and Hematy [51] studied effects of the confounding factors on profit management in the TSE. Consequently, the effect of the debt contracts, political costs, bonus and ownership plans in management's manipulation were investigated. The results showed that: 1) there was no significant and positive relations between stockholders' equity and profit manipulation, 2) by increasing the company's size, motivations for more profit would increase, 3) in firms with more staffs, for decreasing political pressures, manager would decrease profit and 4) there was a insignificant relationship between bonuses and ownerships and profit manipulations.

Mashayekh and Esmaele [36] also studied the relationship between profit quality and some aspects of the managing capital structures including ownership percentages of the board of director's members and numbers of managers in 135 companies accepted in the TSE during 2002 to 2003. The results showed that with 95 percent probability, there was no relation between profit quality ownership percentages of the board of director's relationship and accrual items and ownership percentages of the board of director's members. In addition, the number of managers and ownership percentages of the board of directors' members did not exhibit a significant role in improving profit quality of the TSE companies.

Sinaie [56] investigated the effects of companies' internal factors on the formation of the capital structure of the TSE companies and concluded that particular characteristics of the companies would affect financial structure of the companies.

3.4. Foreign Investors

3.4.1. Foreign Studies

Foreign investments are the percentage of stocks by keeping the foreigners. This includes foreign partners, foreign financial institutions, foreign nations and Iranian non-residents. The results showed that positive effects existing between foreign ownerships of the company's performance, basically was related to the companies with bigger investments and higher commitment and longer investments.

Cheung et al. [12] studied the relationship between market returns and accounting revenues for a sample of Japanese companies from 1975 to 1995. Their findings indicated that the strength of the returns-relationships would negatively affect company's ownership level, level of investments in real estates, level of investments in other companies investments and financial leverages; but foreign ownerships' level would positively affect this relations.

Aydin et al. [5] studied whether Turkish companies with foreign ownerships did obtain a significantly superior performance. They employed T-test, operating margin variables, returns on assets, returns on equity and pertinent information relating to all companies in the Istanbul Stock Exchange for 2003 and 2004. The results showed that companies with foreign ownerships actually did experience superior returns on assets in comparison with the ones with domestic ownerships. These finding also supported the hypothesis that foreign ownerships would improve company's performance.

3.4.2. Domestic Studies

So far, there has been no empirical study concerning the effects of the foreign investors' ownership on the TSE Company's performances. The major reason for this situation could be related to the existence of a few numbers of these investors as the main owners in the TSE companies.

In sum, from the whole preceding internal and external literature reviews, the following tentative general conclusions may be inferred:

1). Firm's ownership structure affects the performance of the corporations. More specifically, there is a significant relationship between the institutional ownership structure and the performance of the companies.

2). Different ownership structures, (private or government) could lead to different corporate performances.

3). Private ownership structures would enhance corporate performances. This relationship is particularly holds for the family companies.

4. Research Method

In this study, the role of the different "ownership structures" on the performances of the TSE companies will be investigated for the first time. Hence this study's research plan is based upon the one shot ex-post plan [1] and [59]. This plan is exerted when the researcher attempts to study the subjects after its occurrence without any control group and furthermore the manipulation of the independent variables are impossible.

4.1. Research Hypotheses

The objective of this research is to identify financial effects of the various ownership structures on the performances of the TSE companies. Consequently, this study, is based upon the results of the domestic and foreign studies which were reviewed in previous sections. It posits one main hypothesis and five subs-hypotheses as follows:

4.1.1. The Main Hypothesis:

There is a significant relationship between "ownership structure" and the "performances" of the TSE companies.

4.1.2. Sub Hypothesis

1. There is a significant relationship between "institutional ownership" and the "performances" of the TSE companies.
2. There is a significant relationship between "company's ownership" and the "performances" of the TSE companies.
3. There is a significant relationship between "company's managerial ownership" and the "performances" of the TSE companies.
4. There is a significant relationship between "foreign ownership" and the "performances" of the TSE companies.
5. There is a significant relationship between "private ownership" and the "performances" of the TSE companies.

4.2. Research Variables

In this research, four independent variables were considered: 1) institutional investors, 2) corporate shareholding, 3) managerial shareholding and 4) foreign investors, shareholding. These variables are in fact representing current and various ownership structures in Iran, in that the first one is related to the government structure and the last three are demonstrating private ownerships. The measurement of these variables was based upon the following definitions:

Foreign: Foreigners' Share Holding is equity shares held by foreigners as the percentage of total equity shares. These include foreign collaborators, foreign financial institutions, foreign nationals and non-resident Iranians.

Institutional investors: Governments and financial institutions' share holding is equity shares held by the government companies which is measured by the percentage of total equity shares. These includes insurance companies, mutual funds, financial institutions, banks, central and state government firms, state financial corporations and other government bodies.

Corporate shareholding: corporate share holding is equity shares held by corporate bodies which is determined as a percentage of total equity shares. These include corporate bodies excluding institutional managerial and foreign investors.

Managerial shareholding: Managers' shareholding is equity shares held by directors of the firms and includes shares held by the family members of the directors (see e.g., [40] and [35]).

This classification has also been adopted by Kumar [34]. In addition, each of these variables has been extensively exerted in the literature including the following studies:

Institutional investors: Tsaia and GU, [60], Fernando et al. [20], Cornett et al. [13], Elyasiani and Jia, [18].

Corporate investors' shareholding: Imam and Malik, [28], Kapopoulos and Lazaretou [31] and Cornett et al. [13].

Managerial shareholding: Himmelberg, et al. [27], Enqvist [19], Chen [11], Rose [55], Halpern et al. [24], Mueller and Spitz-Oener [41], Khan et al. [32], Cornett et al.[14] .

Foreign investors' shareholding: Barbosa and Louri, [8], Douma et al. [16], Aydin et al. [5].

The dependent variable of this study is "the value of the firm" which is represented by the performances of the companies. The performance was measured by the following two traditional accounting variables: 1) Return on Assets (ROA) and 2) Return on Equity (ROE),

$$ROA = \frac{PBDIT}{TA} \quad (1)$$

PBDIT = Profit before depreciation, interest expense and taxes
TA = Total Assets
and 2) Return on Equity (ROE)

$$ROE = \frac{PBDIT}{EC} \quad (2)$$

EC = Equity Capital
And also by the two contemporary market variables-i.e. 1) Q-Tobin's average and 2) Market to Book Value Ratio (MBVR),

$$Q - Tobin = \frac{TB + MV}{TA} \quad (3)$$

TB = Total Borrowings
MV= Market Value (Equity)
TA = Total Assets

$$MBVR = \frac{TB + MV}{BV} \quad (4)$$

BV= Book Value

These variables have also been adopted by Kumar [34], among others.

The major reason for selecting preceding accounting variables is that they maintain a straight relationship with the firm's strategies and performances. For example, %80 of the studies that have identified the significant variables affecting company's performances, have utilized "ROA" as a profound variable [62]. However, in order to examine companies' performances, accurately and comprehensively, considering merely accounting performance evaluation variables is not sufficient since they are based upon historical cost basis and hence some market evaluation criteria, which determine the current situation and value of the firm's performances, should be expended. In addition, these variables have been exerted frequently in the related literature, including the followings: Return on Assets (ROA); Randoy and Goel [54], Enqvist [19], Chen [11], Douma et al. [16], Krivogorsky [33], Omran et al. [47], Cornett et al. [47] and Elyasiani and Jia, [18].

Return on Equity (ROE): Bianco and Casavola [10], Krivogorsky [33], Aydin et al [5] and Omran et al. [47].

Q-Tobin's Average: Randoy and Goel [54], Enqvist [19], Chen [11], Rose [55], Douma et al. [16], Tsaia and GU [60], Imam and Malik [28], Omran et al. [47], Fernando et al. [20], Cornett et al. [14] and Elyasiani and Jia, [18].

Market to Book Value Ratio (MBVR): Halpern et al. [18] and Krivogorsky [33].

In order to control the effects of extraneous variables on the performance of the companies, three control variables were also selected: 1) size of the company, 2) Debt Intensivity (Debt.Int) and 3) Capital Intensity (Cap.Int). These variables have also been utilized in various studies including Himmelberg, et al. [27] and Habib and Ljungquist [21] and [22]) and also were selected based upon the literature review made in section 2.

4.3. Model Buildings

In some research problems, especially the ones in which the researcher is seeking to predict the extent of a variable, determining the main variable (which is to be predicted) and the correlations and combination of predicting variables is extremely important. In essence, the method which combines the predicting variable is titled "multi- variant regression" [49].

The multivariate regression method consists of different forms and their difference is related to selecting the predicting variables. For determining the regression equation in this article, the following formula was extracted:

$$Y = a + b_1 x_1 + b_2 x_2 + \ldots + b_n x_n \quad (5)$$

Y: company's performance
a: Constant
$x_1, x_2, \ldots, x_n$: all independent variables used in this study
$b_1, b_2, \ldots, b_n$: coefficient of the achieved regressions for all variables in this study.

The statistical data could be managed via three ways: cross sectional, time series and panel approach. The panel data method is an approach for combining cross sectional observations within different time periods. In this study, considering the data type and analysis approach, the panel method [49] was exerted. By employing panel data a group of data which includes a great number of cross sectional variables (N) that is obtained during a time period (T) is collected. In this case, the number of observations are $N \times T$, that could be estimated by different models.

By exerting the panel data, efficient estimations could be determined. The general form of the panel model, which is based upon the "error components method", is obtained from the following formula [15]:

$$Y_{it} = \beta_1 + \sum_{j=2}^{k} \beta_j X_{jit} + \sum_{[=1}^{s} Y_p Z_{pi} + \delta_i + \varepsilon_{it} \quad (6)$$

In the above formula, Y is the dependent variable, X is the observed explanatory variable and Z is the unobservable explanatory variable which affects the dependent variable in each period. For a more unambiguous explanation of the panel method, these groups of variables are separated. In effect, t is the time duration and j and p are observed and unobserved variables. ε(it) shows estimated errors of the panel data, which holds for all different conditions relevant to error statements under the Gauss-Markov hypothesis and δt shows the changes of the fix statements during the time. This model is known as "two-sided panel data model" [15]. As Z variables are immeasurable, one could show the sum of them as α1. In this case, the above equation could be presented as follows:

$$Y_{it} = B_1 + \sum_{j=2}^{k} B_j X_{jit} + \alpha_i + \delta_t + \varepsilon_{it} \qquad (7)$$

In the above formula, $\alpha_i = \sum_{p=1}^{s} \gamma_p Z_{pi}$. If α_i is dependent on each of the X explanatory variables, estimation and analysis by this equation will be biased in relation to variables which are not estimated [15].

If the immeasurable variables are controlled by exerting Ordinary Least Squares (OLS) or Generalized Least Squares (GLS), then the variables have efficient estimations. One way for controlling is expending the fixed effects model. In the fixed effects model, the unobserved effects will enter into the fixed statement of the regression model. In this model, by employing virtual variables method or the deferential method, the effects of the unobserved variables could be controlled.

With different tests such as Hausman or the Breusch-Pagan Lagrange Multiplier (LM) test, one could select suitable estimates. After selecting a suitable model, the continuity of the time series and the reliability of the regression should be followed [7].

Based upon preceding explanations, this study's model is presented as below:

Performance$_{i\,t}$ = f (Foreign$_{it}$, Institutional$_{it}$, Corporate$_{it}$, Director$_{it}$, (4)

Ln Sale$_{it}$, DebtInt.$_{it}$, Cap.Int.$_{it}$) + α_i + δ_t + $\varepsilon_{\iota\tau}$

Performance$_{it}$ = α + β (Ownership)$_{it}$ + γX$_{it}$ + α_i + δ_ι + $\varepsilon_{\iota\tau}$ (5)

In this research, the followings were studied by the regression equation: 1) self correlations, 2) the amounts of determining coefficient, 3) the significance of the model and its coefficient.

For determining whether a regression model error statements were self correlated or not, the Durbin-Watson test was employed. In Durbin-Watson test the model hypotheses are [49]:

$H_0 : \rho = 0$

$H_1 : \rho \neq 0$

In this model, when ρ is positive, self correlation is positive and when ρ is negative, self correlation is negative and if ρ=0 there's no self correlation.

Determining coefficient is a criteria which explain the strength of the relationship between the dependent and independent variables. The amount of this coefficient, in fact, determines what percentages of changes of the dependent variables are explained by the independent variables.

The significance of the regression equation was determined by F-statistic and related hypothesis were as follows [49]:

$$H_0 : \beta_1 = \beta_2 = \cdots = \beta_k = 0$$

$$H_1 : \exists \beta_i \neq 0 : i = 1,2,\cdots,k$$

If H_0 is rejected (with 95 percent probability), the regression equation is significant. After implementing the regression significance test, the regressions of each of the coefficients should have been tested. The test hypotheses are presented below:

$H_0 : \beta_i = 0$ The population coefficient is zero

$H_1 : \beta_1 \neq 0$ The population coefficient is not zero

For testing these hypotheses, t test was employed. In this test (with 95 percent probability) if we couldn't reject H_0, it means that the considered coefficient isn't significant and its rejection means the opposite.

4.4. Population and Sample Selection

The population of this study includes all Tehran Stock Exchange (TSE) firms from 2003 to 2008 (5 years period. TSE was reopened in 1968. It is an open stock market which is controlled by the governmental organization. It is a member of World Federation of Exchanges and a founding member of the Federation of Euro-Asian Stock Exchanges. It is also one of the world's best performing stock exchanges and has been categorized as an emerging market. During the time period of the study, it encompassed about 430 companies in recent years the number of private ownership companies listed in TSE has been increased significantly. Due to the adoption of the so called "principle 44".

However, the following conditions were considered for selection of the firms based upon the nature of the TSE market and this study:

1. Firms listed in the TSE up to the end of 2008.
2. Their financial year ended in the end of each year.
3. Their book value of the stockholders equity was not negative in any year.
4. They had a continual activity during the study period and their stocks were traded actively.
5. They shouldn't have changed their financial year during the study's period.
6. They shouldn't have stopped their activities during the time period of the study.
7. Their financial information required for this study would be available from 2002 to 2008.
8. They should not be listed as an investment company.
9. They should be profitable throughout the period of the study.

Considering preceding limitations, 66 companies were identified. Consequently, their information were gathered from the TSE computer web and Dena-sahm, Sahra and Tadbirpardaz software's.-three main software which revealed data pertaining to the TSE companies.

4.5. Data Collection Method

In this study, for data and information collection, the library and archival method [59] was also employed. In the library section, theoretical basis were gathered from the Persian and English journals and books (see references). Research data were gathered by means of the sample company data with reference to their financial statements, notes to financial statements, weekly and monthly reports of the stock exchange and by employing Dena-Sahm, Sahra and Tadbirpardaz software.

4.6. Test of the Reliability

At first, reliability of the continuity of the dependent variables as well as control variables was studied. Reliability of the study variables showed that variables mean and variances during the time period of the study and the covariance of the variables during different years were stable. As a result of exerting these variables in this model, we did not have a spurious regression. For the final investigations, the unit root tests, Levin, Lin and Chu, Im, Pesaran and Shin and Philips Perron tests, were expended [48]. Each of this test variable was conducted under two different methods: 1) the fixed amount approach and 2) the trend amount approach.

5. Findings

Table 1 shows the descriptive statistics of the study.

Table 2 and Table 3 disclose necessary information concerning the reliability test of the ROA variable under the fixed amount approach and the trend amount approach respectively, just as a sample. Similar tests were conducted for ROE, Q-Tobin, MBVR, Size, debt and capital under the fixed amount approach and also the trend amount approach. The results of these tests indicated that their P-values were lower than 0.05 and hence, these variables were stable and their weighted average and standard deviations were also statistically stable during the period of the study.

For studying each hypothesis 4 different models based upon each of the dependent variables for performances- Return on Assets (ROA), Return on Equities (ROE), Q-Tobin and Market Book Value Return (MBVR) – were defined and estimated. Then, the results of these 4 models for each hypothesis were investigated separately and finally the overall outcome for each hypothesis was presented.

5.1. First Hypothesis

In testing the first hypothesis, at the beginning, the relationship between "institutional ownership" and ROA along with the designated control variables- size of the company, debt structure and the amount of capital- were examined. The results are shown in Table 4.

Then, the same procedure was followed for other dependent variables. A summary of the results are presented in Table 5.

Table 4. The Relationship between "Institutional, ROA and Control Variables

Table 5. The Results of the Relationship between "Institutional Ownership" and 4 Models of Performance

R-Squared	Durbin-Watson statistics	Coefficient symbol	Significance of coefficient (t)		Significance of all model (F)		Independent variable	Dependent variable
			P –Value	Accepted Or rejected	P –Value	Accepted Or rejected		
%78/8	1/80	negative	0/000	accepted	0/000	accepted	Institutional ownership	ROA
%84/9	1/82	negative	0/000	accepted	0/000	accepted	Institutional ownership	ROE
%73	1/82	negative	0/002	accepted	0/000	accepted	Institutional ownership	Q-Tobin
%79/9	1/90	negative	0/000	accepted	0/000	accepted	Institutional ownership	MBVR

From Table 5 with respect to 4 applied performance models, it can be inferred that because the independent variable of the institutional ownership coefficient in all 4 models is negative and significant, thus generally there is a negative relationship between institutional ownership and company's performance. This means that considering the high level of R^2 and the independent variable of the institution ownership coefficient in all 4 models, the higher the institutional ownership, the weaker is the company's performance – hence, the first hypothesis is accepted. This finding is similar to other studies (Ahmadzadeh et al. [2] and Mokarami [40] as far as the existence of the significant relationship; is concerned. However, in regard to the kind of the relationship, the finding is different from some studies such as Tsaia and GU [60], Cornett et al. [14] and Mahdavi and Maydari [35].

The reason for this finding that the institutional ownership and company's performance is significantly and negatively related, could be related to situations in which institutional investors don't expend enough motivations to attempt for improving firm's performances and gaining profits. Additionally, in most cases, the major objective of the institutional investors is not extracting profits and obtaining high profitability, rather their goal, is protecting society from foreign invasion, establishing disciplines and security in the society, offering public services and fundamental facilities. It is also possible that some of these companies have benefited from government's supports such as subsidiaries. Hence, it seems that for obtaining profit gains and a financial superior performance, one should pay attention to owners' viewpoints and thoughts. It means that if the company desires accessing to profitability and a favorable performance, it should move towards private investors' companies.

5.2. Second Hypothesis

In approaching the second hypothesis a similar procedure, just like the preceding approach for the first hypothesis, was adopted. Table 6 illustrates the results' summary.

Based upon information presented in Table 6, one could conclude that because company's ownership coefficient in all four models is significant and positive (at $\alpha = 0.5$), there is a positive relationship between company's ownership structure and performances. Since R^2 is high and the independent variable of the company's ownership coefficient is significant and positive, when company's ownership is increased, a superior company's performances would be attained. Thus, the second hypothesis is accepted. These results are in agreement with most of the previous studies [31,44,45,53] and is inconsistent with some other like Cheung et al. [12].

Table 6. The Results of the Relationship between "Company Ownership" and 4 Models of Performance

Dependent variable	Independent variable	Significance of F model		Significance of t coefficient		Coefficient symbol	Durbin-Watson Statistics	R- squared
		Accepted Or rejected	P-value	Accepted Or rejected	P-value			
ROA	Company ownership	accepted	0/000	accepted	0/000	positive	1/81	%81
ROE	Company ownership	accepted	0/000	accepted	0/003	positive	1/87	%83/1
Q-Tobin	Company ownership	accepted	0/000	accepted	0/000	positive	1/90	%72/3
MBVR	Company ownership	accepted	0/000	accepted	0/001	positive	1/96	%80/9

These groups of investors are potentially the sources of effects on external organization's strategies and firm's performance. This issue is also emphasized by Fifer and Salanisc [53]. They argued that ownership is a facility making power which is fundamental in the organization. From this viewpoint, ownership type of an organization, should affect companies' performances and strategies. Viewing relevant models presented by these two researchers, an organization is not only a collections of groups with different profits, but also are markets in which the power and control are exchanged and companies' power is focused around sensitive and rare resources in which capital is one of them [53]. Thus, institutions which have investments in other companies’ subjects such as capital structures and establishing strategy and performances of owned companies could be potentially effective and being in the board of directors could also be helpful. The ownership ratio has its own role as well. Hence, one could conclude that company's ownership maintains positive relations with firm's performance models.

By changing companies’ ownership structure and combining all ownership forms, one could expect that firms’ behavior and performance be reduced and changed as well. Considering this issue is important from different aspects. First, the board ownership and its characteristics, could affect the company's financial performance. Long-term focus on special subjects such as long-term investments period for research, market development and products are also very necessary for the economic life of the enterprises. And with this, one could gain the necessary quality and capability and thoughtful investors could think about short - term goals. This fact is also very important because of its effect on companies' investments on research, development and creativity.

Thus, with respect to the second hypothesis, which is in the field of private investors, the results of this study revealed that in entrance of the company's investors, the dominated thought on company's performance is profit gain and superior performance. The results revealed that company's ownership holds a significant and positive relationship with company's performances. This means that by effective presence of the company's ownership in the companies' ownership structure, the company's performance will be improved. Because this type of investors are following profits and obtaining superior performances, they gain from company’s ownership structure and they attempt to meet this goal. Another reason is that, in this case, the ownership structures are more focused and hence the goal of gaining profitability would cause more supervision on the company's performance. Also, in this condition, companies would report more information about their performance and future profits, because they have unambiguous and widespread necessities for reporting.

5.3. Third Hypothesis

In approaching the third hypothesis, a similar approach like preceding hypothesis was adopted. Table 7 reveals a summary of the results.

Table 7. The Results of the Relationship between "Managerial Ownership" and 4 Models of Performances

Dependent variable	Independent variable	Significance of F model		Significance of t coefficient		Coefficient symbol	Durbin-Watson Statistic	R-squared
		Accepted Or rejected	P-value	Accepted Or rejected	P-value			
ROA	managerial ownership	accepted	0/000	accepted	0/000	negative	1/81	%93/4
ROE	managerial ownership	accepted	0/000	accepted	0/000	negative	1/89	%86/8
Q-Tobin	managerial ownership	accepted	0/000	accepted	0/010	negative	1/96	%77/1
MBVR	managerial ownership	accepted	0/000	accepted	0/037	negative	1/87	%71/5

As Table 7 illustrates, generally one could conclude that the relationship between managerial ownership and company’s performance is negative, because by considering four models, the managerial ownership coefficient is negative and significant. Since R^2 is high and the independent variable of the managerial ownership coefficient is significant and negative in all four models, one could conclude that when managerial ownership is increased, the company's performance tend to get weaker. These results are consistent with Khan et al. [32]. However, they are inconsistent with the findings of Bhagat [9], Mcconaughy et al. [38], Anderson and Reeb [3] and Mueller and Spitz-Oener [41]. A reason for this finding could be the fact that all companies with managerial ownerships in our samples are family companies, indicating the main ownership of these firms are belong to one family or a group of family. Considering the congruency of this group of owners with each other, they don’t provide true and real results to externals and smoothing information may be attempted.

5.4. Fourth Hypothesis

With respect to the fourth hypothesis, since the number of foreign investors was very limited in the TSE and there was no information related to foreign investor's ownership in our study, no result was found. In effect, presenting a reliable performance evaluation model was not possible.

5.5. Fifth Hypothesis

For testing this hypothesis, the relationship between private ownership structure (consisting of "company ownership" and "managerial ownership") and control variables (size, debt and capital) were examined. A selected summary of the results are presented in Table 8.

Table 8. The Relationship between* "Private Ownership" Structure and 4 Performance Models of Performance

Dependent variable	Independent variable	Significance of F model		Significance of the coefficient		Coefficient symbol	Durbin-Watson Statistic	R-squared
		Accepted Or rejected	P-value	Accepted Or rejected	P-value			
ROA	Private ownership	accepted	0/000	accepted	0/000	negative	1/81	%85/4
ROE	Private ownership	accepted	0/000	accepted	0/000	negative	1/85	%85/6
Q-Tobin	Private ownership	accepted	0/000	accepted	0/755	negative	1/94	%72/9
MBVR	Private ownership	accepted	0/000	accepted	0/756	positive	1/87	%81/0

* Private Ownership Consists of the "Company Ownership" and "Managerial Ownership"

Based upon 4 presented models, the independent variable of "the company ownership" coefficient was positive and significant in all four models. Thus, the relationship between company's ownership and company's performance was positive. Since R^2 is high and the independent variable of the company's ownership coefficient is positive and significant, if this kind of ownership is increased, the company's performance will be improved. On the other hand, because the independent variable of the "managerial ownership" coefficient was significant and negative in all 4 models, generally there is a negative relationship between managerial ownership and company's performance. Since the amount of R^2 is high and the coefficient of the independent variable of the managerial ownership is negative and significant, one could ascertain that as managerial ownership increases, the company‘s performance gets weaker significantly.

Now, if one wants to conclude the general role of the "private ownership" as a whole, only in the fourth model, which is based upon the MBVR, the company‘s performance is enhanced. In the rest of the models, coefficients are, however, in such a way which indicate that company‘s performance tend to get weaker. But, this result is reached just by a quick overview and with a deeper consideration, one could not conclude the preceding point based upon positive and negative coefficients. For a valid conclusion, the number of companies should be equal for both arriving at a firm "company‘s ownership" and "managerial ownership"; otherwise one could not jump to a clear and straight forward results. Hence, it could be ascertained that in "private ownership", if the company‘s ownership increased, the result is favorable.

Table 9 indicates the findings for the "institutional ownerships" and "private ownerships". Considering Table 9 and four presented models, the coefficient of the "institutional ownership" in all four models is negative and significant. Hence, in can be inferred generally that the relationship between "institutional ownership" and company's performances is negative. As R^2 is high and the coefficient of the independent variable of the "institutional ownership" increases, the company’s performance gets significantly weaker. On the other hand, because the coefficient of the independent variable of the "managerial ownership" as a representative of "private ownership" in all models is also negative and significant, then generally, the relationship between "managerial ownership" and the company's performances is negative. R^2 is high and the coefficient of the independent variable of the "managerial ownership" is significant and negative in all four presented models. Thus, when managerial ownership increases, the company's performance get tends to significantly weaker. However, with respect to the “company ownership", just in the models based on the accounting variables (i.e., ROA, ROE) coefficients are significant and negative. And in the models based on the "market variables" (i.e., Q-Tobin and MBVR), the coefficient is not significant. These results disagree with the second hypothesis. However, generally speaking, the main hypothesis is accepted. This finding implies that there is a significant relationship between company's structure and their performances. This result agrees with almost all previous studies and disagrees with some studies like Mashayekh and Esmaele [36].

In sum, comparing the "institutional ownership" and "private ownership" (except for the ROE model), the weaknesses of the company's performance is stronger in the "institutional ownership". Hence, the fifth hypothesis is generally accepted. But, one could not ascertain whether private ownership increases or decreases the performance, because it just reveals that there is a significant relationship. This result agrees with the findings of the most previous studies; but from the type of relationship viewpoint, disagrees with the results of some studies like Earle [17], Omran et al. [47] and Rahchamani [52].

Although there are some similarities and shared views in activities of the private firms and governmental companies, the motivations and behaviors of the private firms are completely different from the governmental companies. According to the International Bank's research, the stock investment rate in governmental industries returns is one third of the private industries. In other words, private ownerships, overall, would lead to a higher performance from both aspects of the quality and economic variables compared to the governmental ownership [25].

Table 9. The Results of the Relationship between "Institutional and Private Ownership" Structure and 4 Models Performance

Dependent variable	Independent variable	Significance of F model		Significance of t coefficient		Coefficient symbol	Durbin-Watson Statistics	R-squared
		Accepted Or rejected	P-value	Accepted Or rejected	P-value			
ROA	Institutional and ownership	accepted	0/000	accepted	0/000 And 0/000	negative	1/81	%85/8
ROE	Institutional and ownership	accepted	0/000	accepted	0/000 And 0/000	negative	1/86	%85/1
Q-Tobin	Institutional and ownership	accepted	0/000	accepted	0/038 And 0/000	negative	1/92	%72/9
MBVR	Institutional and ownership	accepted	0/000	accepted	0/036 And 0/000	negative	1/95	%81/3

6. Concluding Remarks and Discussion

The results of this study demonstrated that different ownership structures of the firms would actually lead to different financial performances. In general, private structures would lead to significant performances. Thus, there is a significant relationship between company's ownerships structure and company's performance. In the setting, in which both "institutional ownership" and "private ownership" structures were presented, the results illustrated that when ownership is governed by the institutional investors' type, the firm's performance will tend to get weaker than the private ownerships structure. With respect to private ownerships, however, it could be ascertained that there is just a significant relationship; but one could not infer the type of the relationship. This means that generally, one cannot ascertain whether private ownerships would actually lead to a superior performance or not.

In settings in which private ownerships were divided into sub classes–company's managerial and company's ownership–the results need to be analyzed in more details. They revealed that the existence of the company's investors in the company's structure would lead to a superior performance. This means that the relationship between groups of investors and company's performance is significant. However, if one considers managerial investors in the company's structure, the company's performance would be weaker. Finally in terms of the statistical sampling of this study, we couldn't observe any information which demonstrate the existence of the foreign investors in the company's foreign companies in Iran.

In effect, the significance of this study are as follows:

1). It provided an ex-post empirical evidence concerning the relationship between the structure of the company and its performance. Thus, it extended current knowledge concerning contemporary issues of the corporate governance.

2). It extricated the role of the governmental and / or privatization in the firms' performance process. In effect, it unambiguously demonstrated the usefulness of the privatization empirically.

3). It identified the most effective and appropriate forms of the firms' structures, (private or institutional) which affect the corporations' performances, among different structures.

4). It provided valid empirical evidence concerning the role of the corporate governance in the TSE Market. Given the internal and external validity of this research, the results would also be useful at the international level and thus, it would contribute to extending current knowledge in the growing field of the corporate governance.

7. Suggestion for Future Studies

There are different subjects in this field that could be important for future studies. Therefore, we suggest, the following issues be studied in more depth:

1. The effect of the industry on the ownership structure and company's performance relationships.
2. The investigation of other dependant variables of the study-the ownership structure- and its effect on company's performances.
3. The employment of other performance evaluating variables.
4. Investigation of the effects of the main economic variables such as inflation, oil prices and currency exchange rates on the ownership structure and performance relationships.
5. Studying and testing the relationship between ownership structures and company's performances for short –term periods (less than a year).
6. Studying and testing the effects of the ownership structures on the performance of loss maker companies in comparison with profitable companies by deployment of virtual variables.
7. Analyzing the effect of political problems and elections' effects on the company's performances.

Earnings Persistence and Stock Prices: Empirical Evidence from an Emerging Market

1. Introduction

According to International Accounting Standards Board (IASB) (1989), the basic purpose of financial reporting is to provide capital market participants with accounting information that can be used for informed and efficient investment decision making. The area of study aimed at exploring the relationship between available accounting information and its consequent use in pricing of financial assets is broadly categorized as value relevance research. Ever since the publication of pioneering work of Ball & Brown (1968) and Beaver (1968) who demonstrated that the information content of accounting earnings is reflected in stock returns, relevance of accounting information as an indicator of market value has attracted considerable attention. Value relevance studies attempt to empirically investigate the relationship between disclosed accounting information and stock market values (or changes in value) so as to assess the usefulness of such information for pricing of assets by investors. According to *Holthausen and Watts* (2001), a variable is said to be value relevant if it exhibits the predicted association with a measure of market equity value.

Research on value relevance studies was further embraced in the revolutionary work of Ohlson (1995, 1999) and Feltham & Ohlson (1995, 1996) who devised a structured model of firm value linking it with accounting data. The model introduced the innovations of linear information dynamics (LIM) which postulated the mechanism of time series behavior and linked current information with future abnormal earnings. The work of Ohlson (1995,1999) and Feltham-Ohlson (1995,1996) had a profound effect on value relevance literature post 1990's with modified versions of the model been tested successfully in a number of studies and applied in varied markets with different characteristics in the last two decades. Although different empirical studies have produced varied results regarding the degree of association between accounting variables and firm value, the findings over the years have converged towards the belief that basic fundamental accounting variables (viz. earnings, book value and cash flow) approximate pricing of firm particularly well.

Although the prior literature examining the persistence of earnings and earnings components is immense in developed markets (US, UK, Canada etc.), little is empirically known about the same in emerging markets where accounting and institutional settings are entirely different from those of mature capital markets. Consequently, one would be cautious in generalizing research findings in developed markets to emerging markets given the extensive use of accrual accounting, weak investor protection and low share-ownership concentration (Pincus *et al.* 2007). India as one of emerging markets presents an interesting case where institutional and accounting structures justifies the need for empirical investigation of earnings persistence and value relevance to determine stock valuation. In the 1990s Indian Government has introduced the economic liberalization to move the economy to free market economy. Privatization program was initiated and in order to enhance the reliability of the market, the Indian government established the Securities and Exchange Board of India (SEBI) in 1992, a regulatory body resembling the Securities and Exchange Commission (SEC) in the United States, to protect the interest of investors and to promote the development of securities market. However, Indian stock exchange is characterized by low trading volumes and the prominence of unsophisticated investors. Financial statements remains the main source of information available to investors in Indian capital market as listed firms do not disclose earnings forecasts. Further the financial analysts industry is still at a developing stage with small presence of foreign fund houses and consequently most transactions in Indian stock markets are made based on accounting data, especially, aggregate earnings. Resultantly, earnings fixation tends to be high with investors failing to attend separately to the cash flow and accrual components of earnings. Till now, only a few empirical studies on value relevance of financial statements exist in India with no published study using the Ohlson model. This study contributes in filling the gap in the literature by examining the persistence ability of accounting variables, namely abnormal earnings, book value, accruals and cash flows over a period of time and their valuation relevance in Indian scenario using a set of Indian listed companies. The study further explore and analyze the links between the forecasting relevance (with respect to next-period abnormal earnings), persistence (stationary first degree Autoregressive (AR1) process) and valuation relevance of earning components (accruals and cash flows).

This study aims to extend and enrich the extant literature on value relevance studies in several ways. The study provides a theoretical valuation framework of Ohlson model, identify its key features in the context of other valuation models and review the numerous empirical studies based on it undertaken in developed markets. Using the emerging market setting of India, the study puts the theoretical model to empirical test so as to determine the relevance and persistence of accounting information using linear information dynamics framework pioneered by Ohlson. The findings of our study generally conclude that in case of India, only abnormal earnings and book value are relevant for explaining the market value of equity with earning components (accruals and cash flows) holding little value relevance for investors. The findings confirm that investors are fixated on earnings in India capital market and fail to attend separately to the cash flow and accrual components of earnings while undertaking their investment decisions. Consequently, this may create an incentive for managers in Indian-listed firms to engage in earnings management to meet or beat earnings thresholds in order to enjoy positive market performance.

The remainder of the paper is organized in the following way. Section 2 discusses the literature review; Section 3 describes the research design and hypothesis. Section 4 details the empirical result and Section 5 concludes with summary of findings.

2. Literature Review

Genesis of Value Relevance studies

Within the realms of accounting discipline research, capital market research has emerged as a significant discipline over past decades and attracted extensive academic research and interest. This area of research started gaining prominence in 1960's from the seminal works of Ball *et al.* (1968) and Beaver (1968) who were forefathers to the theory that accounting information impacts equity prices by providing information and are value relevant to financial investors in their pricing and asset allocation decisions. Ball *et al.* (1968) in their study of US firms over 1946-66 investigated the usefulness of existing accounting numbers by examining their information content and timeliness. The results of the study provide evidence that accounting income of a particular year captures one half or more of all information available about an individual firm. The evidence also suggests that annual accounting numbers is not a useful timely indicator as share prices reflect more prompt information. Beaver (1968) in his seminal research finds that both trading volume and return volatility tend to increase during the earnings announcement week thereby establishing the information content of earnings announcement. According to Beaver (1968), although earnings announcement allays uncertainty and bridges the gap between beliefs, it leads to increase in trading volumes from participants who have assumed position based on their pre-earnings announcement beliefs.

Post 1960's, after the seminal work of Ball *et al.* (1968) and Beaver (1968) which embraced an information view of value relevance, most of the studies during the next three decades were typically conducted and referred to as information content studies. However in 1990's after Ohlson (1995, 1999) came up with his breakthrough work, the interest in value relevance research intensified again with most of the studies distancing themselves from information view and adopting measurement view of value relevance. Unlike information view where return was the only metric, both price and returns were used as metrics under measurement view (Easton, 1999). While price based studies tested the ability of financial statements to summarize the events affecting the firm upto a specified date, return based studies looked at the ability of accounting information to capture events affecting the firm over the return interval. Most of the studies under measurement view examined the value relevance of earnings, book values or combinations of two. Beyond 1990's the literature indicates a number of value relevance studies using different forms of Ohlson model. The various studies, performed in different markets, although indicates conflicting results as to whether there is an increasing or decreasing trend in the value relevance of accounting data, none of the them disapprove that a relationship exists.

Valuation Theories and Models

Theoretically, the intrinsic value of an asset is a function of expected payoffs that are received over the holding period discounted at an appropriate opportunity cost. When we talk of equity valuation, these expected payoffs take the form of dividends or earnings and/or cash flows and the opportunity cost becomes cost of equity (or cost of capital) for the firm. The genesis of intrinsic approach to valuation was laid down by Williams (1938) which is one of the early texts on investment theory and is reminiscent of the NPV approach commonly used in capital evaluation techniques. In empirical literature we have seen a plethora of financial valuation models which talk about determinants of a firm's market value and helps in investment decision making.

Dividend Discount Model (DDM)

As discussed earlier, the theoretical value of a firm is the sum total of stream of payouts (in this case dividends) that are expected to be received in future and market value of equity at the end of the forecast horizon. Now if we make an assumption of infinite horizon, the dividend discount model can be theorized as the present value of expected future dividends (PVED) discounted at an appropriate rate of return. Mathematically:

$$V_t = \sum_{i=1}^{\infty} \frac{E_t[DIV_{t+i}]}{(1+r_{t+i})^i}$$

where V_t is the firm's intrinsic value of common equity at time t, $E_t(DIV_{t+i})$ is the expected future cash dividend in period $t+i$ conditional on information available at time t, and r is the cost of equity in period $t+i$.

Hence, looking at the above mathematical formula, firm value can be defined as a function of expected dividends and applicable discount rates. Now, the problem arises since estimating dividends for infinite periods have practicability issues. To do away with this problem, Gordon (1962) suggested a way wherein he simplified the model by making certain assumptions on dividends and discount rates. Under GGM (Gordon Growth Model), if the cost of equity remains constant through time and dividends grow geometrically at a constant rate g and g<r (r being cost of equity), the DDM equation can be reduced to

$$V_t = \frac{DIV_{t+i}}{r - g^D}$$

Although the above stated model did away with the practicability issues, it inherently suffered from some drawbacks. This model worked well for companies which were in mature stage or where growth rates were generally stable. For companies which are growing at high growth rates or where firms are in early growth stages and not paying dividends, the model fails to find the right market valuations. Generally the market value of such firms is usually higher than indicated by the above models. Also as shown by Miller & Modigliani (1961), under the assumption of no taxes and transaction cost, value of firm does not get affected by dividend payouts (dividend irrelevance theorem). As a result of these drawbacks, various other models began to emerge which did away with assumptions of dividend models.

Residual income (abnormal earnings) valuation model

Residual income valuation (RIV) model, which has its genesis in the dividend discount model, combines the dividend discount model with clean surplus relation and expresses the value of a firm as current book value plus the present value of infinite residual (abnormal) earnings. Mathematically:

$$V_t = BV_t + \sum_{i=1}^{\infty} \frac{E_t[x_{t+i}^a]}{(1+r)^i}$$

where V_t is the intrinsic value of common equity at time t, BV_t is the book value of common equity at time t, $E_t[x_t^a]$ is the expected future residual (abnormal) income in period $t+i$ conditional on information available at time t, and r is the cost of equity, indicated as a constant.

Residual income as defined by Ohlson (1995) is the amount of net income (profit) in excess of capital charge on the book value of equity. Mathematically:

$x_t^a = x_t - (r_t * BV_{t-1})$

where x_t^a is the residual income at time t, x_t denotes net income for the period ending at time t, r is the cost of equity, and BV is the book value of common equity at time $t-1$.

A basic assumption of residual income valuation (RIV) model is the clean surplus relation theory. According to clean surplus relation (CSR) theory, income for a period is equal to net dividends plus the change in book value of equity. Under clean surplus accounting, all revenues, expenses, gains and losses pass through the income statement thereby ensuring clean surplus. This basically means that all changes in the book value of equity during a fiscal period are reflected in that period's net income or dividends distributed to common shareholders. Mathematically:

$BV_t = BV_{t-1} + x_t - D_t$

Where BV_t is the book value of common equity at time t, x_t the net income for the period t, and D is the cash dividend paid for period t.

The Ohlson (1995) model

Ohlson (1995) model, which formalizes the relation between accounting variables and firm value, is basically an extension of residual income valuation (RIV) or abnormal earnings model. The model constitutes a solid theoretical framework for market valuation based on fundamental accounting variables (future earnings, dividends and book value). Using the assumption of the LIM , PVED and CSR, Ohlson (1995) allows the following closed-firm value relation to be stated:

$P_t = BV_t + \alpha_1 x_t^a + \alpha_2 \nu_t$

where: P_t = equity value of firm at time t

BV_t = book value at time t

x_t^a = abnormal earning at time t

v = 'other information' at time t

$\alpha_1 = \omega / (R_f - \omega) \geq 0$

$\alpha_2 = R_f / (R_f - \omega)(1 + R_f - \gamma) > 0$

The above equations of Ohlson (1995) thus expresses equity value as a function of three components i) Current Book value ii) capitalized current residual income, and (iii) capitalized value implied by other information. In his work, Ohlson (1995) considers the discount rate as risk neutral or risk free rate. Also one of the assumptions made is that of persistency or autocorrelation of abnormal earnings. Ohlson assumes that abnormal earnings follow a first-degree AR(1) process. The model also assumes that there is another variable v_t (other information) which impacts forecasting of future abnormal earnings.

The Ohlson (1999) model

Ohlson (1999) model (extension of Ohlson (1995) model) develops the concept of transitory earnings and contrasts the source of earnings to "core" (or recurring) earnings. According to Ohlson, transitory earnings possesses certain characteristics which distinguishes them from core or recurring earnings. The three major attributes of transitory earnings are : 1) Unpredictability: Transitory earnings are unpredictable in the sense that current transitory earnings are irrelevant with regards to influencing subsequent transitory earnings 2) Forecasting irrelevance: Current transitory earnings are irrelevant while forecasting earnings for next period or subsequent year 3) Value irrelevance: transitory earnings are not incrementally informational while estimating present value of firm's expected dividends.

Using the assumptions of present value of expected dividends, clean surplus relation and linear information dynamics, Ohlson (1999) presents a generalized version comprising following four equations:

$$x_{t+1}^{a} = \omega_{11}x_t^a + \omega_{12}x_{2t} + \gamma_1 .v_t + \varepsilon_{1t+1} \quad (1)$$

$$x_{2t+1} = \omega_{22}x_{2t} + \gamma_2 .v_t + \varepsilon_{2t+1} \quad (2)$$

$$v_{t+1} = G.v_t + \varepsilon_{3t+1} \quad (3)$$

$$P_t = b_t + \alpha_1 x_t^a + \alpha_2 x_{2t} + \beta.\ v_t \quad (4)$$

where x_t^a abnormal earnings is defined as earnings less a normal return on equity book value. x_2 in above model implies transitory earnings (the model applies to any component of earnings). P_t is market value of equity at time *t*. ω_{11} implies persistence of abnormal earnings, ω_{12} is the incremental effect of accruals or cash flows on abnormal earnings, ω_{22} implies persistence of accruals or cash flows; α_1 is the incremental effect of abnormal earnings on market value of equity and α_2 is incremental effect of transitory earnings on market value of equity. v_t represents vector of *K* random variables representing other information; γ_1 and γ_2 are two *K* dimensional vectors of fixed constants, and *G* is a square matrix of size *K* x *K*. In equation (4), β is a *K* dimensional factor. Also it can be shown that the parameters γ_1 and γ_2, *G* do not effect α_1 and α_2; they still are $\alpha_1 = \omega_{11}/ (R_f - \omega_{11})$ and $\alpha_2 = \omega_{12} R_f / (R_f\text{-}\omega_{22}) (R_f\text{-} \omega_{11})$.

Empirical Evidence of Value Relevance Studies

Beyond 1990's, the literature indicates a number of value relevance studies in both developed and emerging countries using different forms of Ohlson's model examining the relationship between accounting variables and firm value. For instance Hayn (1995) examines the value relevance of accounting earnings in explaining stock returns in US and finds positive association. Similarly Sloan (1996) in his study of a set of industrial firms in US finds that accrual component of earnings is less persistent than cash flow component of earnings in explaining earnings performance. However stock prices act as if investors are fixated on aggregate earnings and fail to distinguish between different levels of persistence of two components of earnings. Dechow *et al*. (1999) in a study involving US firms over a period of 20 years (1976-1995) finds that the linear information model (LIM) proposed by Ohlson (1995) is reasonably empirically descriptive and provides a useful framework highlighting the relationship between current accounting variables and future abnormal earnings. Similar evidence is reported by Frankel and Lee (1998) in their study involving 20 countries including Australia, Japan, South Korea and Thailand. Barth *et al.* (1999) examines the differential ability of accruals and cash flows components of earnings that affect their relation to firm value by using annual data from 1987-1996 using generalized version of Ohlson (1999) model and finds that accruals and cash flows are incrementally informative regarding future earnings and market values. Graham and King (2000) further examines the value relevance of book value per share and current residual income in Indonesia, Malaysia, Philippine, South Korea, Taiwan and Thailand and finds that coefficients of these variables are statistically significant for all the countries. Chen *et al.* (2001) examines the relationship between accounting information, earnings and book value, and stock price in the Chinese stock market from 1991-1998 and finds that accounting information as reflected in the income statement and the balance sheet is value-relevant to domestic investors (A-share market) in the Chinese stock market. Shamy and Kayed (2005) examines the value relevance of earnings and book values under the Kuwaiti accounting system (compliant with IFRS) using Ohlson (1995) framework and show that while earnings and book values jointly and individually are positively and significantly related to stock prices, incremental information content of earnings is greater than that of book values. Subramanyam and Venkatachalan (2007) examines the relative importance of earnings and operating cash flows in equity valuation and finds superiority of earnings in explaining security returns over cash flows. Similar evidence is reported by Habib (2008) who examines the relative information content of earnings and cash flows in New Zealand context. Pirie and Smith (2008) finds that both equity book value and earnings, summarizing the balance sheet and income statement respectively, have significant explanatory power with respect to market prices and managers are justified in using the accounting system as a primary source of information for monitoring financial performance in Malaysia. Vishnani and Shah (2008) examine the value relevance of financial statements of listed companies in India and find that financial statements have negligible value relevance as far as stock market reactions are concerned. Saeedi and Ebrahimi (2010), in contrast to earlier studies, do not find any value relevance for earnings and cash flows in explaining stock returns in Iranian context. Similarly, Akbar *et al.* (2011), in contrast to earlier studies, finds that cash flows have incremental value relevance compared to that of earnings and funds flow in UK. Ganguli (2011) in his study involving Indian companies tests empirical validity of Ohlson (1995) and Feltham and Ohlson (1995) models and finds value relevance of abnormal earnings and book value in explaining market value of equity with cash flows showing no such evidence.

In summary, while empirical studies regarding the relationship between accounting variables and firm value in developed countries provided mixed and contradictory evidence, there are a few studies which empirically examine this relationship in emerging (transition) economies such as India. It is, therefore, necessary to examine the relationship between accounting variables and firm value in India as an example of emerging economies.

The Indian Context

Post liberalization in 1990's, India financial system has evolved into a well developed and competitive structure with increased levels of financial intermediation, integration of domestic markets and further deepening of financial markets. Resultantly, the presence of multinational firms and foreign institutional investors has increased, as financial liberalization led to free movement of capital across the borders. Financial reporting in India is monitored by the provisions of the Companies Act, 1956, pronouncements of the Institute of Chartered Accountants of India (ICAI) and in some cases stock exchanges listing agreements. The accounting standards in India are formulated by Accounting Standard Board (ASB) constituted by ICAI in 1977. However, ASB is now a recommendatory body only and the ultimate authority of making accounting standards mandatory vests with the Ministry of Corporate Affairs (MCA) in consultation with the National Advisory Committee on Accounting Standards (NACAS). Till date, MCA has notified 35 IFRS converged Indian Accounting Standards (called Ind AS) without notifying the applicability date. For certain categories of companies like electricity companies and insurance companies etc., the accounting process and procedures including format of financial statements are laid down in the governing acts of such companies.

In order to enhance the reliability of the market, the Indian government established the Securities and Exchange Board of India (SEBI) in 1992, a regulatory body resembling the Securities and Exchange Commission in the United States, to protect the interest of investors and to promote the development of the securities market. Indian stock market today is comparable to the international benchmarks in terms of stocks listed, investor base and transaction costs. BSE (Bombay stock exchange), established in 1875, is Asia's first stock exchange and one of India's leading exchange groups. BSE is the world's largest exchange in terms of listed securities (over 6,000 stocks) and commands a total market capitalization of USD 1.32 trillion. According to world federation of exchanges, BSE is also the third largest exchange in terms of index options trading.

Given the increasing degree of globalization and integration of Indian stock market with the rest of the world, value relevance studies assumes significant importance as it can provide an insight into the relevance and reliability of financial statements in India.

3. Research Methodology and Hypotheses

Research Design

To develop the hypotheses for studying the persistence and valuation relevance of abnormal earnings, book values, cash flows and accruals, we utilize a generalized version of Ohlson model which comprises of following four equations. The basic structure of the model is analogous to the "other information" model of Ohlson (1995). One can interpret x_2 as Ohlson's other information, *v,* in those models.

:

$$x^a_{t+1} = \omega_{11}x^a_t + \omega_{12}x_{2t} + \omega_{13}BV_t + \varepsilon_{1t+1} \quad (1)$$

$$x_{2t+1} = \omega_{22}x_{2t} + \omega_{23}BV_t + \varepsilon_{2t+1} \quad (2)$$

$$BV_{t+1} = \omega_{33}BV_t + \varepsilon_{3t+1} \quad (3)$$

$$MV_t = BV_t + \alpha_1 x^a_t + \alpha_2 x_{2t} + u_t \quad (4)$$

where x^a_t (abnormal earnings) is defined as earnings less a normal return on equity book value. x_2 in above model implies transitory earnings (the model applies to any component of earnings and can be either accruals or cash flows). MV_t and BV_t are market value of equity and book value of equity respectively at time *t*. ω_{11} implies persistence of abnormal earnings; ω_{12} is the incremental effect of accruals or cash flows on abnormal earnings, ω_{13} is the incremental effect of lagged book value of equity on abnormal earnings; ω_{22} implies persistence of accruals or cash flows, ω_{23} is the effect of lagged book value of equity on accruals or cash flows; ω_{33} signifies persistence of book value of equity; α_1 is the incremental effect of abnormal earnings on market value of equity and α_2 is incremental effect of accruals or cash flows on market value of equity.

The Hypotheses

H1 – Abnormal earnings follow an AR (1) process. Accrual and cash flow components of earnings help in forecasting future abnormal earnings incremental to abnormal earnings and book value: Equation (1) in above Ohlson generalized model describes the autocorrelation or persistence of abnormal earnings. Abnormal earnings are said to be transitory if $\omega_{11} = 0$. If abnormal earnings are not entirely transitory, then higher the ω_{11}, the more shall be the persistence (or predictability) of abnormal earnings. Thus if abnormal earnings are positively autocorrelated, $\omega_{11} \neq 0$. Our null hypothesis is therefore $\omega_{11} = 0$.

In our model, x_2 is either accrual or cash flow from operations. The coefficient on the earnings component (x_2), ω_{12}, reflects the incremental effect that the earning component has on the forecast of next period abnormal earnings. Now if any component of earnings (accrual or cash flow) exhibit forecasting irrelevance i.e. it does not aid in forecasting next period abnormal earnings, ω_{12} shall equal zero. We therefore further test the null hypothesis that $\omega_{12} = 0$.

H2 – Accrual and Cash flow components of earnings follow an AR (1) process: Equation (2) in Ohlson generalized model describes the autocorrelation or persistence of that particular earning component (accrual or cash flow). Earning components (accrual or cash flow) are said to be transitory if $\omega_{22} = 0$. If earning components are not entirely transitory, then higher the ω_{22}, the more is the persistence (or predictability) of the earning component. Thus if earning components (accrual and cash flow) are positively autocorrelated, $\omega_{22} \neq 0$, separately, for each component (accrual and cash flow). Our null hypothesis is therefore $\omega_{22} = 0$. Equation (1) and (2) further includes book value of equity which allows for the effects of conservatism to manifest themselves (Feltham and Ohlson (1995, 1996)).

H3 – Book value of equity follow an AR (1) process: Equation 3 in Ohlson generalized model describes the persistence of book value of equity. Book value of equity is said to be transitory if $\omega_{33} = 0$. If book value of equity is not entirely transitory, then higher the ω_{33}, the more persistent (or predictable) is the book value. If book value is positively autocorrelated, $\omega_{33} \neq 0$. Thus our null hypothesis is $\omega_{33} = 0$. Equation (3) preserves the triangular information structure of the generalized version of Ohlson's model.

H4 – Accrual and Cash flow component of earnings enhances explanatory power for Market value of the equity incremental to Abnormal earnings and Book Value: Equation (4) is the valuation equation based on the information dynamics in equations (1) through (3). α_1 is the valuation multiple on abnormal earnings. If abnormal earnings have significant explanatory power of market value, then $\alpha_1 \neq 0$. We therefore test the null hypothesis that $\alpha_1 = 0$. Similarly i_1 is the valuation multiple on book value of equity. If book value of equity shows significant explanatory power of market value, then $i_1 \neq 0$. We therefore test the null hypothesis that $i_1 = 0$. α_2 is the valuation multiple on x_2, i.e., earning component in our model (accruals or cash flows). Similar to the interpretation of ω_{12} in equation (1), α_2 reflects the incremental effect that the earning component has on equity valuation. Now if an earning component (accrual or cash flow) does not have any significant explanatory power of market value incremental to abnormal earnings and book value, α_2 shall equal zero; otherwise $\alpha_2 \neq 0$. Thus we test the null hypothesis that $\alpha_2 = 0$.

Research Method – Panel Data Regression Estimation

The study uses fixed effect Panel data model which allows for intercept to vary across individual firms keeping the slope constant across. The study introduces two Linear Information Models, LIM 1 (Accrual system) and LIM 2 (Cash Flow system) for each earnings component separately (accruals and cash flows) using seemingly unrelated regression and permitting regression errors to be correlated across equations. The two systems of equations are:

LIM1: Accrual system

$$NI_{it}^{a} = \omega_{10,i} + \omega_{11}NI_{it-1}^{a} + \omega_{12}ACC_{it-1} + \omega_{13}BV_{it-1} + \varepsilon_{1it} \quad \textbf{(1a)}$$

$$ACC_{it} = \omega_{20,i} + \omega_{22}ACC_{it-1} + \omega_{23}BV_{it-1} + \varepsilon_{2it} \quad \textbf{(2a)}$$

$$BV_{it} = \omega_{30,i} + \omega_{33}BV_{it-1} + \varepsilon_{3it} \quad \textbf{(3a)}$$

$$MV_{it} = i_{0,\mathrm{i}} + i_1 BV_{it} + \alpha_1 NI_{it}^{a} + \alpha_2 ACC_{it} + u_{it} \quad \textbf{(4a)}$$

LIM2: Cash flow system

$$NI_{it}^{a} = \omega_{10,i} + \omega_{11}NI_{it-1}^{a} + \omega_{12}CFO_{it-1} + \omega_{13}BV_{it-1} + \varepsilon_{1it} \quad \textbf{(1b)}$$

$$CFO_{it} = \omega_{20,i} + \omega_{22}CFO_{it-1} + \omega_{23}BV_{it-1} + \varepsilon_{2it} \quad \textbf{(2b)}$$

$$BV_{it} = \omega_{30,i} + \omega_{33}BV_{it-1} + \varepsilon_{3it} \quad \textbf{(3b)}$$

$$MV_{it} = i_{0,\mathrm{i}} + i_1 BV_{it} + \alpha_1 NI_{it}^{a} + \alpha_2 CFO_{it} + u_{it} \quad \textbf{(4b)}$$

Variable Measurement and Definition

Abnormal earnings (NI^a) equals $NI_t - rBV_{t-1}$, where BV_{t-1} is equity book value for previous period and NI is net income before extraordinary items and discontinued operations for the current period. To calculate abnormal earnings (NI^a), we have set r (risk free rate) as 8%, which is consistent with average ten year treasury yield in India during the period studied. Accruals (ACC) is the difference between net income (NI) and cash flow from operations (CFO) i.e. ACC = NI-CFO.

Data and Sample

Source of Data

The underlying index of the empirical study is BSE (Bombay Stock Exchange) 30, which represent approximately 50 percent of the total market capitalization of Indian Equity Market thereby making it a reliable proxy of Indian market. The BSE index is based on free float market capitalization methodology and contains thirty largest stocks in the Indian equity market. To construct the data sample historical data have been taken from capitaline plus database. For our study, we have used the list of companies subsisting on 31 March, 2011 as BSE 30 is not a static index and new companies keep replacing older ones on the basis of market capitalization. The period of study is based on six year sample from fiscal year 2005-06 to 2010-11. A year for the purpose of sample classification starts from April of the year concerned and ends in March of the following year. For example, the fiscal year 2005-06 sample starts from April 1, 2005 and ends at March 31, 2006.

For a firm to qualify for inclusion in the sample, it must have (at the end of the fiscal year) all required data including, but not limited to, book values, prices, earnings and cash flows in the capitaline plus database. Cases with missing data have been eliminated. Further, following prior studies, all the variables of the study have been deflated by the number of outstanding ordinary shares at the end of the financial year. The number of outstanding shares has been obtained from capitaline plus database.

4. Empirical Results

Descriptive Statistics

Table I reports the characteristics for each of the variables used in this study. Panel A provides the descriptive statistics for the variables used in the models. Panel A reveals that, on average, market value of equity (MV) exceeds the book value of equity (BV), indicating that equity book value alone is insufficient to explain equity market value in India. The mean value of abnormal earnings (NI^a) is 32.32 with standard deviation of 28.60. Similarly cash flows from operations (CFO) have a mean value of 50.85 with a standard deviation of 80.79 and a median of 41.21. Panel A further reveals that, on median/mean basis, accruals

(ACC) are negative and cash flows are positive. This is consistent with depreciation expense being included in accruals but capital expenditures being included in investing cash flows. Also cash flow from operations (CFO) has a larger standard deviation than accruals (ACC).

Panel B shows the correlation matrix for the set of independent variables. Abnormal Earnings (NI^a) are significantly positively correlated with cash flow from operations (CFO). Cash flow from operations significantly positively correlates with book value per share (BV). On the other hand, accruals (ACC) are significantly negatively correlated with cash flow from operations (CFO).

Results of Panel Data Estimation

Abnormal Earnings Equation

Table II, Panel A and B, presents regression summary statistics corresponding to the abnormal earnings equations (1a) and (1b) under LIM 1 and LIM 2 for all firms (based on Panel data regression). The coefficient estimates, *t* statistics, and adjusted R^2 values are presented in each Panel of Table II.

With regards to our first research hypothesis, the results (Panel A) reveal that coefficient on lagged abnormal earnings, ω_{11}, is positive and significant for the dataset (0.53). The regression results implies that abnormal earnings exhibit persistence or stationary AR(1) process, as such abnormal earnings of a particular year is significantly related to previous period abnormal earnings. Thus we reject the null hypothesis that $\omega_{11} = 0$ in case of LIM 1. Panel A further shows that accruals are not incrementally informative regarding prediction of future abnormal earnings. Thus we reject forecasting relevance of accruals, i.e., we accept the null hypothesis that $\omega_{12} = 0$ in case of LIM 1.

Panel B reveals inference consistent with those of accruals in Panel A. Panel B reveals that coefficient on lagged abnormal earnings, ω_{11}, is positive and significant for the dataset (0.50). We therefore reject the null hypothesis that $\omega_{11} = 0$ in case of LIM 2. The results also reveal that cash flows are not significantly incremental informative regarding future abnormal earnings. Thus we accept the null hypothesis that $\omega_{12} = 0$ in case of LIM 2. This implies that inclusion of one year lagged cash flows as a variable does not help in forecasting future abnormal earnings incremental to abnormal earnings and book value thereby rejecting forecasting relevance of cash flows.

Finally the coefficient on lagged book value, $\omega_{13,}$ is significant both in case of accruals and cash flows thereby suggesting its incremental informative relevance in explaining future period abnormal earnings.

Accruals and Cash flows Autoregression results

Table III, Panel A and B, presents regression summary statistics corresponding to the earnings components (accruals and cash flows) equations (2a) and (2b) for all firms.

With regards to our second research hypothesis, the results in Table III (Panel A) reveals that for accruals, ω_{22}, AR(1) process is not stationary for the empirical dataset. The regression results imply that the accruals do not exhibit persistence; as such accrual of a particular year is not related to previous period accrual in a statistically significant manner. The estimated coefficient on lagged accrual, $\omega_{22,}$ is negative (-0.13) and insignificant (-0.38). Thus we accept the null hypothesis that $\omega_{22} = 0$ in case of LIM1.

Panel B reveals inference consistent with those of accruals in Panel A. Panel B reveals that for cash flows, ω_{22}, AR(1) process is not stationary for the empirical dataset; as such cash flow of a particular year is not related to previous period cash flow in a statistically significant manner. We therefore accept the null hypothesis that $\omega_{22} = 0$ in case of LIM 2 also.

Book value Equation

Table IV presents regression summary statistics corresponding to the book value of equity equations (3a) and (3b) for all firms. With regards to our third research hypothesis, the results reveal that for book value, ω_{33}, AR(1) process is stationary for the empirical dataset. The regression results imply that the book value of equity follows AR(1) process or exhibit persistence; as such book value of equity of a particular year is related to previous period book value in a statistically significant manner. Thus we reject the null hypothesis that $\omega_{33} = 0$ in case of LIM 1 and LIM 2.

Market Value Equations

Table V, Panel A and B, presents regression summary statistics corresponding to the valuation equations (4a) and (4b) for all firms. We address our fourth hypothesis by estimating the relation between equity market value and book value, abnormal earnings, and the earnings components (accruals and cash flows).

Regarding the fourth hypothesis, Table V, Panel A, reveals that coefficient on abnormal earnings, (α_1) and book value (i_1) is positive and significant i.e. they have significant explanatory power of market value in case of LIM 1. We therefore reject the null hypothesis that $\alpha_1 = 0$ and $i_1 = 0$ in case of LIM 1. Panel A further reveals that α_2, the coefficient on accruals, is not significantly different from zero for all firms. We therefore accept the null hypothesis that $\alpha_2 = 0$ in case of LIM 1. This implies that the accrual component of earnings do not enhance the explanatory power for market value of the equity incremental to abnormal earnings and book value in case of Indian dataset examined.

Panel B reveals inference consistent with those in Panel A. Panel B reveals that for LIM 2, coefficient on abnormal earnings and book value is positive and statistically significant. We therefore reject the null hypothesis that $\alpha_1 = 0$ and $i_1 = 0$ in case of LIM 2. The results further reveal that α_2, the coefficient on cash flows, is not significantly different from zero for all firms. This indicates that the cash flow component of earnings is incrementally valuation irrelevant. We therefore accept the null hypothesis that $\alpha_2 = 0$ in case of LIM 2. This implies that cash flow component of earnings do not enhances explanatory power for market value of the equity incremental to abnormal earnings and book value.

Overall the empirical findings provide us with evidence that in case of Indian markets, aggregate (or abnormal) earnings are the relevant earnings construct for valuation and the second earnings component (accrual and cash flow) is irrelevant. We further demonstrate that besides earnings, book value plays an important role in setting investment expectations of investors. Consistent with Sloan (1996), these results suggest that stock prices in Indian stock market act as if investors fixate on aggregate earnings, failing to distinguish fully between the different properties of the accrual and cash flow components of earnings. Consequently, firms with relatively higher (lower) levels of accruals can experience higher (lower) levels of stock returns.

5. Summary and Concluding Remarks

One of the main research areas in accounting and finance is so-called value relevance research that aims to determine empirically the relationship between disclosed accounting information and stock market values. Although prior literature examining the persistence of earnings and earnings components is immense in developed markets (US, UK, Canada etc.), little is empirically known about the same in emerging markets where accounting and institutional settings are entirely different from those of mature capital markets. This study contributes in filling the gap in the literature by examining the persistence of earnings (and earning components) and their valuation relevance in Indian scenario for a period of six years. Based on a sample of Indian listed firms, the findings provide evidence on the construct of persistence and value relevance of earnings and book value of equity in Indian context. This evidence is consistent with prior empirical findings on persistence and value relevance of earnings and book value reported in developed and emerging markets to date (Barth *et al.*, 1999; Dechow *et al.*, 1999; Ganguli, 2011). With regards to the forecasting relevance (with respect to next-period abnormal earnings), persistence and valuation relevance of earning components (accruals and cash flows), the evidence suggest that the earning components (accruals and cash flows) do not add to any value relevance over and above abnormal earnings and book value in explaining market value of equity. Further, both earnings components (accruals and cash flows) fail to show persistence and forecasting ability (or relevance) in explaining next period abnormal earnings in case of Indian dataset examined.

Overall, the findings confirm that investors are fixated on earnings in India capital market and fail to attend separately to the cash flow and accrual components of earnings while undertaking their investment decisions. Therefore, Indian investors who neglect this distinction are overly optimistic about the future prospects of firms with high accruals, and overly pessimistic about the future prospect of firms with low accruals. The results provide consistent evidence that accounting information, especially earnings, is value-relevant in the Indian capital market. These findings might indicate that competing information sources such as earnings forecasts, firm research by financial analysts, management conference calls, etc. are far less prevalent in India as compared to developed markets. The significant role of aggregate earnings in Indian capital market may create an incentive for managers in Indian-listed firms to engage in earnings management to meet or beat earnings thresholds in order to enjoy positive market performance. Accordingly a potential policy implication of above analysis is that stock markets in India needs complementary information sources other than published accounting reports to become more informationally efficient.

Avenues for further research could include analysis of various components of accruals (discretionary and non discretionary) and their association with cash flows and market values over historical period. Furthermore, the sub samples can be analyzed with respect to association of various individual components of accruals and market value. Also persistence of various accounting variables can be tested using more than 1 year lags.

Professional Biography: The author has worked extensively in Indian Equity and Debt Markets with companies like JPMorgan and Max Life Insurance. Before joining IMT (Institute of Management Technology) Ghaziabad as Assistant Professor, the author was managing funds of USD 100 million in the capacity of Portfolio Manager covering both Equity and Debt markets. The author is an MBA Finance and has recently submitted its doctorate in finance.

Table I: DESCRIPTIVE STATISTICS
(SAMPLE OF 805 OBSERVATIONS, FY 2005-06 to 2010-11)

Panel A: Descriptive Statistics

Description	Variable	Mean	Median	Std dev
Market value	**MV**	871.77	671.1	753.52
Book Value	**BV**	232.80	192.35	180.17
Cash Flow from Operations	**CFO**	50.85	41.21	80.79
Abnormal earnings	**NI^a**	32.32	26.21	28.60
Accruals	**ACC**	-2.04	-2.31	71.44

Panel B: Correlation Matrices Between Variables

VARIABLES	*Price*	*BV*	*CFO*	*NI^a*	*ACC*
Price	1.00				
BV	0.52	1.00			
CFO	0.28	0.33	1.00		
NI^a	0.69	0.54	0.45	1.00	
ACC	0.05	0.01	-0.89	-0.03	1.00

Table II: Summary Statistics from Panel Data Regressions of Abnormal Earnings on Lagged Abnormal Earnings and Earnings components (Accruals and Cash flows).

Panel A: Accruals: $NI_{it}^{a} = \omega_{10,i} + \omega_{11}NI_{it-1}^{a} + \omega_{12}ACC_{it-1} + \omega_{13}BV_{it-1} + \varepsilon_{1it}$

MANAGERIAL OWNERSHIP AND FIRM PERFORMANCE: THE INFLUENCE OF FAMILY DIRECTORS AND NON-FAMILY DIRECTORS

Hasnah Kamardin

ABSTRACT

Purpose – *The main purpose of the study is to examine the influence of family directors on the firm performance of public listed companies (PLCs) in Malaysia. This study provides empirical evidence on the agency problems between controlling shareholders and minority interests in the concentrated ownership setting.*

Design/methodology/approach – *Samples of the study are 112 PLCs in year 2006. Two measures of firm performance are used: return on assets (ROA) and Tobin's* Q. *Managerial ownership refers to the percentage shareholdings of executive directors with direct and indirect holdings. It was further categorized into family ownership and non-family ownership.*

Ethics, Governance and Corporate Crime: Challenges and Consequences
Developments in Corporate Governance and Responsibility, Volume 6, 47–83

ISSN: 2043-0523/doi:10.1108/S2043-052320140000006002

Findings – *In relation to ROA, managerial ownership is found positively significant. The results also show that the positive relationship between managerial ownership is contributed by the managerial-non-family ownership. In relation to Tobin's* Q*, the results show a U-shape with turning point at 31.38% for managerial ownership and 28.29% for the managerial-family ownership. The results found significant and positive relationships between managerial ownership and both measures of firm performance which indicates that managerial ownership and family ownership yield greater efficiency.*

Research implications – *The study highlights the effects of corporate governance on ROA and Tobin's* Q *are somewhat different. It provides some evidence on the need to use appropriate measure of firm performance. The significant relationship supports the argument of Chami (1999), Fama and Jensen (1983), and DeAngelo and DeAngelo (1985) and empirical evidence of Lee (2004) that family ownership enhances monitoring activities.*

Originality/value – *Differentiating the types of managerial ownership into family and non-family categories enriches our knowledge about who actually contributes to the improved performance.*

Keywords: Corporate governance; managerial ownership; firm performance; Malaysia

INTRODUCTION

Poor corporate governance is partially a cause of the Asian financial crisis in 1997 (Mitton, 2002; Thomas, 2002). Johnson, Boone, Breach, and Friedman (2000) found that during the crisis, corporate governance variables explained a greater proportion of the variation in exchange rates and stock market performance than did other economic variables. In Malaysia, weak corporate governance is found to be associated with corporate performance (Abdul Samad, 2004). In addition, Credit Lyonnais Securities Asia (CLSA) in the year 2000 ranked Malaysia as one of the 10 worst emerging countries in terms of corporate governance. Poor corporate governance is argued to be the result of poor implementation of corporate governance reforms. Indeed, a research by the Credit Lyonnais Securities Asia (CLSA) Emerging Market in collaboration with Asian Corporate Governance Association (ACGA) on corporate governance in Asian countries reported the inconsistency between law reforms and implementation. Comparatively, Malaysia had the highest score (9 out of 10) in law reforms but among the five lowest Asian countries (score 3.5 out of 10) in the implementation of corporate governance.

Malaysian regulators have taken various efforts to strengthen corporate governance (Susela, 2003) as a firm's performance is related to its corporate governance practices (Brown & Caylor, 2009; Durnev & Kim, 2005). These efforts are essentially taken to instil confidence and trust of the existing and potential investors to invest in good governance firms. Among the efforts is the launching of the code of corporate governance to listed companies by the Malaysian Institute of Corporate Governance (MICG) in 1999, which was then followed by the revamp of Listing Requirements by the Bursa Malaysia in 2001. The code puts heavy emphasis on board structure to make sure the board functions effectively. Among the recommended items in the code is that the Board of Directors (BOD) and Audit Committee (AC) should compose a majority of independent directors, as outside directors are said to play their roles in line with the interests of shareholders. The revamp of Listing Requirement (LR) by the Bursa Malaysia (formerly known by Kuala Lumpur Stock Exchange, KLSE) requires listed companies to adhere to the Listing Requirement and the Malaysian Code of Corporate Governance (MCCG). Whilst the changes in corporate governance are laudable, the mandatory requirements have however led companies to comply with the 'form' rather than the 'substance' of the corporate governance practices (Roberts, 2002; Sonnenfield, 2002).

Regulators have put heavy emphasis on companies to comply with the best practices of corporate governance after the Asian Financial Crisis in 1997. It is assumed that corporate governance mechanisms should provide sufficient fundamentals to lead to a better firm performance. The MCCG was revised in 2007, which among other amendments place importance on the board process (SC, 2007). BOD should implement a process to be carried out annually for assessing the effectiveness of BOD, of committees of the board and the contribution of each individual director. The revised code also provides criteria that should be considered by the nominating committee when recommending candidates of directorships. The proposed criteria include skills, knowledge, expertise and experience; professionalism; integrity; and candidate's ability to discharge such responsibilities.

Corporate governance is defined as 'a set of mechanisms through which outside investors protect themselves against expropriation by the insiders, managers and controlling shareholders' (La-Porta, De-Silanes, Shleifer, & Vishny, 2000, p. 4). The aim of good corporate governance is geared to enhance the long-term value of the company. Corporate governance mechanisms are designed to reduce agency costs associated with the separation of ownership and control (Fama, 1980; Fama & Jensen, 1983; Jensen & Meckling, 1976) in modern companies. Expropriation of wealth is related to agency problem which takes a variety of forms such as transfer pricing, asset stripping, investor dilution, overpaying executives, diversion of corporate opportunities from the firm and installing unqualified family members in managerial positions (Jensen & Meckling, 1976; Johnson et al., 2000). It occurs when insiders use the company's profits to benefit themselves rather than outside investors.

Corporate governance mechanisms can be categorized into internal and external controlling mechanisms. The key external controlling mechanisms are managerial labour markets, market for corporate control, debt and concentrated shareholding by blockholders (Ali & Sanda, 2001). Two important internal corporate governance mechanisms are BOD and directors' shareholding. Due to the weak market control in emerging countries, internal corporate governance mechanisms play a vital role in corporate governance of emerging markets (Lei & Song, 2004).

Other than the issues of board characteristics, ownership structure is also considered to have influence on the decisions made by the managers. Lemmons and Lins (2003) posit that firm's ownership structure is a primary determinant of the extent of agency problems between controlling insiders and outside investors. Managerial ownership is used as a means to enhance control in public listed companies (PLCs) in Malaysia (Claessens, Djankov, & Lang 2000; KLSE-PWC, 1999). In addition, family ownership is shown to be significantly correlated with managerial ownership. Given the scenario above the main objective of this study is to examine the influence of family directors on the firm performance of PLCs in Malaysia. It also intended to examine the influence of board attributes on firm performance.

CORPORATE GOVERNANCE CHARACTERISTICS IN MALAYSIA

Corporate governance in Malaysia is greatly influenced by ownership structure which has been found to have impact on board composition, board practices and board decisions (Tan, 2005). Shareholding in Malaysian PLCs is highly concentrated in the hands of a few numbers of shareholders (Abdul Samad, 2004; La-Porta et al., 2000). A majority of the companies have ultimate controlling owner, either individual or family (Ishak & Napier, 2006). As of December 1998, Abdul Samad (2004) reported that the mean of the first largest shareholding was 30.30% and that of the five largest shareholding was 58.84%, which accounted for more than half of the voting shares. About 71.4% of companies (Main Board and Second Board) were under majority ownership, having a shareholding of more than 50%, and were controlled by their five largest shareholders. The percentage shareholding by type of five largest shareholders is dominated by nominees followed by non-financial companies and government. It shows that Malaysian PLCs were dominated by large shareholders, and thus protection of minority shareholders may be a problem in Malaysia. In fact, minority shareholders are practically powerless to prevent large shareholders from implementing their plans for the company.

The significant means of enhancing control in Malaysia is through pyramid-holding, cross-holding and managerial ownership (Claessens et al., 2000). There is significant participation of owners in management with 33% of them involved in management (KLSE-PWC, 1999). The concentrated shareholding in PLCs is also dominated by family. Eighty-five per cent (85%) of the sample companies of Claessens et al. (2000) had their CEO, board chairman or vice-chairman from a controlling family. The percentage of family control is 57.5% and 67.2%, at 10% cut off and 20% cut off, respectively. Family also has the highest control in large companies (35%) and smaller companies (84%). Apart from that, there is an increase in the importance of shareholdings by the state holdings (Claessens et al., 2000), institutional holdings (Joher, Ali, & Nazrul, 2006) and foreign ownership (Suto, 2003) in Malaysian corporations.

CORPORATE GOVERNANCE AND FIRM PERFORMANCE

Agency theory is widely used to examine the relationship between internal corporate governance mechanisms and firm performance from the economic and finance perspective. The main concern is to protect the shareholders' interests by focusing on the role of outside directors to monitor top management (Fama, 1980; Fama & Jensen, 1983) and provide services to top management (Wan & Ong, 2005). Due to the potential agency problems from managers, having small board size, majority of independent outside directors in the BOD, independent board leadership (separate titles for Chairman and Chief Executive Officer [CEO]), and significant shareholding in managerial ownership (MOWN) are expected to provide better monitoring and better protection of shareholders' interests.

Empirical evidence on the effects of board composition and board leadership on firm performance shows contradicting findings. While some studies found no relationship between outside directors and firm performance (e.g. Abdullah, 2004; Baysinger & Hoskisson, 1990; Hermalin & Weishbach, 1988), negative relationships between outside directors and firm performance were also noted which contradict the assumption of the agency theory (e.g. Agrawal & Knoeber, 1996; Bhagat & Black, 1999; Weir & Laing, 2001; Yermack, 1996). Other studies, on the other hand reported positive relationships (e.g. Weir, Laing, & McKnight, 2002). Interestingly, Haniffa and Hudaib (2006) found that the relationship between board composition and board leadership on firm performance depends on the type of firm performance measures used (accounting measures vs. market-based measures). Studies on the relationship between ownership structure and firm performance also note conflicting results. There is evidence of non-linear relationship between managerial ownership (MOWN) and firm performance (Ali & Sanda, 2001; Chee & Md Taib, 2005; Faccio & Lasfer, 1999; Hermalin & Weishbach, 1991; Mat Nor, Mohd Said, & Redzuan 1999; McConnell & Servaes, 1990; Morck, Shleifer, & Vishny, 1988; Short & Keasey, 1999). But most findings show that managerial ownership (MOWN) is related to firm performance which entrenches at higher percentage of managerial ownership. An exception is noted in the findings of Chee and Md Taib (2005) who found that managerial ownership at the higher percentage aligned with the interests of outside shareholders. In the East Asian countries characterized by concentrated ownership, previous studies have shown that controlling shareholders and family controlled firms were found to be associated with higher performance (Joh, 2003; Wiwattanakantang, 2001; Yammeesri, Lodh, & Herath, 2006). These findings are somehow contradicting with the findings in the western countries (characterized by diffused ownership) where the alignment of interests occurs at the lower percentage of managerial ownership. Several reasons are cited for the differences such as the studies were conducted in different institutional governance (diffused vs. concentrated ownership) and different shareholders' protection (low vs. high protection).

It has been suggested that a study on the relationship beyond board composition and board structure should be conducted in order to better understand firm performance (Finkelstein & Mooney, 2003; Leblanc, 2004; Wan & Ong, 2005). Considering these recommendations, this study includes other board attributes (board characteristics and board process) as suggested by Zahra and Pearce (1989).

ATTRIBUTES OF BOD

Zahra and Pearce (1989) identify four attributes of BOD which lead to good performance of firms: board composition, characteristics, structure, and process. The board composition refers to the board size and the mix of director types (insiders vs. outsiders). The emphasis on board composition proxied by independent directors has shown contradicting results. With highly concentrated ownership in Malaysia, independent directors might not be able to play their roles effectively as they might be under management control. Outside directors having interests in the companies (non-independent non-executive directors [NINE]) would have more incentives to enhance firm performance. Board characteristics consist of two components which are directors' background (age, educational background, values and experience) and board personality. Multiple directorships and board knowledge are used as proxies of board characteristics, and frequency of board meetings or percentage of meeting's attendance are used as a proxy of board process in this study. Board structure refers to the dimensions of board's organization which include types of committees, committee membership, flow of information and board leadership. Board process is referred to the approach the board takes in making decisions. Vafeas (1999) used frequency of board meeting to proxy the board process.

The current study adapts all the board attributes suggested by Zahra and Pearce (1989). Table 1 provides summary of the board attributes used in the study.

Board Size

According to Section (S) 122 of the Malaysia's Companies Act, 1965, a company should have at least two directors. The act does not specify the maximum numbers of directors in a company. However, according to the MCCG, size of board should reflect the interests of other shareholders other than the significant shareholders. The subjective condition often

Table 1. Conceptualization of Board Attributes.

Attributes	Explanations
Composition	Board size and types of directors (outside directors)
Characteristics	Directors' background (board experience/knowledge)
Structure	Dimensions of board's organization (board leadership)
Process	Approach the board takes in making decisions (frequency of board meetings)

requires the BOD to exercise judgement in determining the appropriate board size.

Board size is used as a proxy of CEO domination on BOD. Larger board makes domination by the CEO becomes more difficult and directors are able to exercise their power in governing the corporation, thus larger board is preferable. However, as board size increases, it may be difficult to reach decisions timely because of the existence of rival factions and cliques that may slow the proceedings. Thus, large boards are less likely to function effectively because CEOs have sufficient power to control operations and decisions (Jensen, 1993). Board size of more than 10 directors is considered as excessive (Lipton & Lorsch, 1992) which may lead to negative effect on firm performance. Empirical studies on the influence of board size on corporate governance found mixed results. Yermack (1996) studies of the U.S. companies found an improved return on assets (ROA) and is related to small board size. Conyon and Peck (1998) also found a negative association between board size and firm performance. Mak and Li's (2001) study of Singaporean companies found that Tobin's *Q* was associated with small board size. Empirical evidence on the earnings management studies has shown a mixed result on the effectiveness of board size in monitoring the earning management activities. Abdul Rahman and Mohamed Ali (2006) found smaller boards were effective in monitoring earnings management in Malaysian companies whilst Peasnell, Pope, and Young (2001) and Xie, Davidson, and DaDalt (2003) found larger boards were associated with less earnings management activities. Abdullah (2004), on the other hand, found no association between board size and accounting profits. Following agency theory, small board size is predicted to lead to enhanced performance.

H1. There is a negative relationship between board size and firm performance.

Board Leadership

There have been concerns about the role duality or the 'dominant personality', where the CEO is also the chairman of the board. The concern is that no one individual should have unfettered powers. For the PLCs in Malaysia, the MCCG recommends a separate role for the CEO and chairman. If the combined roles are opted, there should be a strong independent element on the board. Companies can still pursue the role duality of CEO;

however, they have to disclose the information and reasons for adopting it in the annual reports. The role duality is common in small companies and in family controlled companies.

From an agency theory perspective, independent board leadership is necessary to prevent managerial entrenchment. Given that one of the board's central functions is to monitor the performance of top management, allowing the CEO to fulfil both roles would compromise the system of checks and balances. Moreover, if the purpose of the board is to represent the interests of the shareholders, CEO holding both roles would have conflict of interests. Fama and Jensen (1983) point out that the board is not an effective device for decision control unless it limits the decision discretion of individual top managers. Thus, independent board leadership would enhance the monitoring ability of the board (Jensen, 1993). Having independent leadership would reduce agency problems and thus enhance firm value (Fama & Jensen, 1983; Lei & Song, 2004; Rechner & Dalton, 1991). Rechner and Dalton (1991) examined the relationship between independent board leadership and organizational performance (ROE, ROI, profit margin). They found that firms with independent leadership consistently outperformed the CEO duality firms.

Brickley, Coles, and Jarrell (1997) argue that the separation of the roles has larger costs (agency costs of controlling the behaviour of outside chairman, information costs, cost of changing the succession process, etc.) than the benefits (separating decision management from decision control) for most large firms. They found that almost no major firm in their study (1988 data) had an independent outsider as chairman. Rather, in almost all cases the chairman is either the former employee or a person with special ties to the firm. In case of independent leadership, chairmen are people with detailed knowledge of the company and have relatively high shareholdings. They did not find evidence that CEO duality structure is associated with inferior performance. Thus, they argue that the combining titles of CEO and chairman (CEO duality) is indeed efficient and generally consistent with shareholders' interests for the typical large U.S. companies.

In the Asian countries, studies on the relationship between board leadership and firm performance produced mixed results. In Singapore, Wong and Yek (1991) found significant positive relationship between CEO duality and modified Tobin's *Q*. They also found that on average the modified Tobin's *Q* of firms with CEO duality is higher than those firms with independent leadership. They suggested that one possible explanation for the finding is that CEO duality is often associated with high shareholdings.

A similar finding is also found in Tan et al.'s study (2001) which shows that CEO duality had positive relationship with Tobin's *Q* during the crisis (1997 financial crisis). Their findings highlight the influence of environment the firm is operating in. The benefits of CEO duality during crisis by having more unified corporate responses and strong and decisive leadership style outweighed the potential agency problems. Haniffa and Hudaib (2006) found the relationship between board leadership and firm performance depends on the type of measurement used for the firm performance. They found CEO duality was not significantly related to Tobin's *Q* but had a significant negative relationship to ROA. The result supports the argument that giving too much power to one person is detrimental to the firm.

H2. There is a positive relationship between independent board leadership and firm performance.

Board Composition

Within corporate governance structure, non-executive directors (NEDs) have an important position to monitor the management and executive directors. NEDs are seen as the check and balance mechanism to enhance board's effectiveness. NEDs are expected to bring independence into the board and add to the diversity of skills and expertise of the directors (Abdullah, 2004). The role of outside directors (NEDs) in the BOD is vital as business adviser and 'watchdog' to ensure managers act in the interests of outside shareholders.

NEDs consist of independent directors (INE) and non-independent directors (NINE), and they are not full-time directors. The non-independent non-executive directors (NINE) is not independent as they could have business and management arrangements with the company or other relationships including family relationships with other directors (Cheah, 2003). They might have more incentives to monitor management decisions as underperformed firm performance would hurt them directly (Lorsch, 1995).

Previous studies on the relationship between NEDs and firm performance are not supporting the agency theory. A special report on NEDs by The Economist (20 March 2003, pp. 71–73) cautions that the independent directors alone may not behave independently and thus compromise their objectivity and loyalty to the shareholders. The report further highlights a special breed of NEDs who are non-independent, the so-called 'gray' or affiliated directors. Apart from being non-executive, an affiliated director is usually an ex-employee, related to the firm's controlling family, an interlocking director, or a professional with significant business or family ties with the firm (Klien, 1998). As most of the gray or affiliated directors owns significant shares in the companies, their incentives to get involved and engaged in corporate governance are higher (Roberts, McNulty, & Stiles, 2005). In addition, since affiliated directors have prior associations with the firm, they often have deeper knowledge of the firm and its industry than independent directors, and thus shareholders may feel affiliated directors instead of independent directors are better serving them.

Studies in the United States by Hermalin and Weisbach (1988) and Baysinger and Hoskisson (1990) found no association between NEDs and firm performance. Agrawal and Knoeber (1996) highlighted the persistent negative significant relationship between independent directors (INE) and firm performance for both analyses using Ordinary Least Square (OLS) and Two Stage Least Square (2SLS) regression. Yermack (1996) also found negative association between INE and firm performance. Bhagat and Black (1999) examined the effect of different types of BOD (inside[1] directors, affiliated[2] directors, independent directors) on firm performance to see whether there are differences of performance between firms with INE majority compared to firms with non-majority. Based on the board composition they measured majority independent board (INDEP) as proportion of INE minus proportion of inside directors. They found that INE has significant negative relationship to firm performance. They also found no evidence that boards with majority independent directors performed better than boards with more insiders than independent directors. In addition, they also found that firms with supermajority independent boards were less profitable than other firms. Studies in the United Kingdom also reveal inconclusive results where no significant relationship was found between the NEDs and firm performance (Baysinger & Hoskisson, 1990; Weir & Laing, 2001).

Evidence in the Asian countries also reveals inconclusive results on the relationship between board composition and firm performance. The NEDs had a negative significant relationship to firm value. Abdullah (2004) found no significant relationship between NEDs and accounting performance measured in ROA, ROE, EPS and profit margin.

In summary, most findings of the relationship between independent directors and firm performance found either a negative (significant) relationship or insignificant relationship. The non-independent non-executive directors (NINE), having interests in a company, would have more incentives to enhance firm performance compared to the independent directors. The need to explore the other potential contribution of NEDs, which are the non-independent non-executive directors (NINE), as proxy for the affiliated directors is also addressed by Klein (1998), Roberts et al. (2005) and Wan Hussin, Che Adam, Lode, and Kamardin (2005).

H3. There is a positive relationship between the proportion of non-independent non-executive directors (NINE) and firm performance.

Multiple Directorships

Haniffa and Hudaib (2006) define multiple directorships as directors sitting on more than one board. In the United States, a director holding less than three multiple directorships is often considered as the best practice. 'Busy directors' are defined as directors holding three or more directorships (Ferris, Jagannathan, & Pritchard, 2003; Sarkar & Sarkar, 2005).

In Malaysia, multiple directorships are found to be common among listed firms in Malaysia (Haniffa & Cooke, 2002). This practice is not surprising given the high limit of directorships allowable to directors. According to the Bursa Malaysia Listing Requirement, BOD are allowed to have a maximum of ten (10) directorships in PLCs and fifteen (15) directorships in non-listed companies.

Previous studies have shown that directors of larger firms have more multiple directorships as larger firms have wider contracting environments, thus requiring negotiations with more parties (Booth & Deli, 1996). Directors of larger firms are perceived to have more skills because of the size and complexity of the operations they oversee (Ferris et al., 2003). Differences in higher permissible limits on multiple directorships between developed countries and developing countries are driven by various factors such as supply constraints in managerial labour markets of many developing countries, lesser nature of tasks required in the developing countries and smaller company sizes (Sarkar & Sarkar, 2005).

Ferris et al. (2003) using various measures of multiple directorships (directorship per director; maximum number of directorships held by any one member of a firm's board; percentage directors having three or more directorships; average directorships held by outside directors; and maximum numbers of directorships held by any executive director to examine the impact of busy directors on firm performance) found that directorship per director had a significant and positive relationship to market-to-book value. Sarkar and Sarkar (2005) used median of directorship of independent directors and executive directors in India and found a positive and significant relationship between multiple directorships by independent directors and Tobin's Q but negative and significant relationship between multiple directorships by executive directors and firm performance (Tobin's Q and market-to-book value).

Studies of multiple directorships in Malaysia are limited and can be found in Tan (2005) and Haniffa and Hudaib (2006). Both studies measured multiple directorships as percentage of directors having more than one directorship in public companies. Tan (2005) found multiple directorships to be positively correlated with ownership concentration and to have a significant and positive relationship to ROA. Haniffa and Hudaib (2006) found no significant relationship to ROA but a significant and negative relationship to Tobin's Q. The negative relationship to Tobin's Q suggests that having directors sitting on more than one directorship is detrimental to the firm's performance.

H4. There is a negative relationship between multiple directorships and firm performance.

Director Knowledge

Nicholson and Kiel (2004) view a board as '… a bundle of intellectual capital that enables it to enact a role set …' (p. 449), which is fundamental to transform inputs into organizational performance. The knowledge acquired by BOD is assumed to improve the quality of actions taken. Previous studies in management associate relevant experience and knowledge on certain tasks (Carpenter & Westphal, 2001; Spliker & Prawitt, 1995). Zander (1994) found CEO age and tenure are associated with CEO experience. In terms of manager characteristics, CEO age and CEO tenure are commonly associated with experience, not the entrance scores or graduate degrees. Carpenter and Westphal (2001) provide evidence that BOD, having experience in a particular situation or having specific expertise, would be likely to affect their roles in monitoring managers.

From another perspective, long tenure tends to foster 'cohorts' within an organization (Pfeffer, 1983). For a board, long tenure among directors can mean increased social cohesion and the ability to reach consensus quickly based on shared experience. The factors that create consensus produce obstacles to independent thinking. Long tenure is likely to be associated with higher commitment to status quo. The high social cohesion is expected to lead to a reluctance to challenge the status quo (Wiersema & Bantel, 1992).

Wiersema and Bantel (1992) examined the relationship between top management teams and corporate strategic change. Their findings showed higher team tenure is associated with changes in corporate strategy. Bantel and Jackson (1989), on the other hand, examined the relationship between social composition (age, tenure, educational background and functional background) of the top management teams and innovation adoptions in the United States. They found an average tenure and innovation adoptions are not significant.

H5. There is a relationship between director knowledge and firm performance.

Board Process

Board process refers to decision-making activities of the board (Kula, 2005). It is assumed that the approaches taken by the board in making decisions are influenced by the frequency of board meetings (Vafeas, 1999). All major issues and decisions are discussed and made at formal board meetings. It is argued that the relationship between frequency of board meetings and firm performance is not clear. There are costs associated with board meetings such as managerial time, travel expenses and directors' meeting fees. Benefits associated with board meetings include more time for directors to confer, set strategy and monitor management.

As BODs hold other directorships in other companies, frequency of board meetings is considered important in improving the effectiveness of a board. Vafeas (1999) found larger boards and boards of firms with many standing committees had more meetings. In relation to firm value, he found that firms that meet more frequently are valued less by the market. The frequency of board meetings was higher during poor firm performance, and firms having more frequent meetings are followed by improvement in operating performance in the following years.

H6. There is a relationship between the board process and the firm performance.

Managerial Ownership (MOWN)

MOWN is considered an important governance mechanism to help control agency problem (Jensen & Meckling, 1976) and place greater effort to enhance firm wealth. MOWN works as direct incentives for managers to act in line with shareholders' interests (Weisbach, 1988). The greater the percentage of stocks owned by top managers, the more likely managers will make decisions consistent with maximizing shareholders' wealth. Singh and Davidson (2003) found that larger MOWN aligns the interests of shareholders and management which is positively related to higher asset utilization efficiency that reflects lower agency costs. Other empirical evidence on the role of MOWN in reducing agency problem has shown that the relationship between MOWN and firm performance is non-linear (Ali & Sanda, 2001; Mat Nor et al., 1999; McConnell & Servaes, 1990; Morck et al., 1988; Short & Keasey, 1999; Wong & Yek, 1991). These studies found that above certain level of ownership, managers may get entrenched, which may result in decreased firm performance. Morck et al. (1988) found positive relationship between MOWN and Tobin's *Q* occurs for MOWN 0% to 5% and beyond 25% ownership. Negative relationship occurs for MOWN 5–25% ownership. They suggest that the negative relationship is the effect of wealth constraints on MOWN. The entrenchment effect is supported by the presence of a founding family in an older firm.

Malaysian studies on the relationship between board ownership and firm performance are found in Ali and Sanda (2001), Chee and Md Taib (2005), and Mat Nor et al. (1999). Mat Nor et al. (1999) findings were consistent with Morck et al. (1988). Ali and Sanda (2001) found higher turning points (curvilinear relationship), positive relation for MOWN less than 36.7% and negative relation when MOWN exceeds 36.7%. Chee and Md Taib (2005) also found a curvilinear relationship but a U-shaped curvilinear. They found positive relation when MOWN is higher which supports the convergence-of-interest hypothesis.

Family ownership refers to the percentage of company's shares held by family members out of the total shares outstanding (Anderson, Mansi, & Reeb, 2003; Villalonga & Amit, 2006). La-Porta et al. (2000) defines family controlled firms based on a threshold of 20% and at least two members are on the board. Chen and Jaggi (2000) and Mishra, Randoy, and Jenssen (2001) use a threshold of 10% to determine family controlled firms. Villalonga and Amit (2006) use a smaller threshold of 5% to determine family controlled firms. Family ownership exceeding certain threshold would qualify it to gain family control over a firm. However, a family can also gain control even having less ownership in a firm. This is achieved through pyramidal structure (voting right) (La-Porta et al., 2000). Thus, family ownership is related to family controlled firms and non-family controlled firms.

Family controlled firms are governed differently from non-family controlled firms (Chami, 1999; Lee, 2004; McConaughy, Walker, Henderson, & Mishra, 1998; Mishra et al., 2001). Family controlled firms are fundamentally different than public corporations which tend to use different strategies and rely on control systems compared to non-family controlled firms. Family controlled firms are very much governed by family traits which do not exist in non-family controlled firms. Chami (1999) develop a theory of family business which explains the dynamics of family. He shows that family values (e.g. trust and altruism) can create 'an atmosphere of love for the business and a sense of commitment'. Nepotism and favouritism are held in check by the need for the family business to compete and succeed in the product and capital market. McConaughy et al. (1998) found that both founders and their descendants run their firms more efficiently than CEOs without family ties as founding family firms are characterized by transparent economic conditions and strong social relationship between owners and managers which lead to higher firm performance.

Family controlled firms are argued to pursue maximization of sales and shareholder's value well (Thomsen & Pedersen, 2000). Mishra et al. (2001) found a positive association between founding family controlled and firm value, which is consistent with a study in Singapore by Tan, Chng, and Tan (2001). The association between founding family CEOs and firm value is stronger among younger firms and firms with smaller boards. They suggest that founding family CEOs can enhance firm performance when family influence does not create shareholder entrenchment. In terms of board structure, they found that outside director representation does not improve corporate governance in founding family controlled firms. They argue that '… once the commitment is in place, the need for outside board monitoring is diminished and the inside directors who know the marketplace may be more valuable to these firms …' (p. 255). In Asian countries, Wiwattanakantang (2001) found controlling shareholder and family controlled firms are associated with higher performance in Thailand.

H7. There is a positive relationship between managerial ownership (MOWN) with firm performance.

H7a. There is a positive relationship between managerial-family ownership (MFOWN) and firm performance.

H7b. There is a positive relationship between managerial-non-family ownership (MNFOWN) and firm performance.

RESEARCH METHODOLOGY

Operational Definition and Measurement of Variables

Data for the internal corporate governance, ROA and control variables were gathered from the annual reports (KLSE, 2004–2006). Share prices of companies were searched in the Thomson database. Details of data search and measurements used are explained in the following paragraphs.

Information on the board size, board composition, board leadership, directors' tenure and multiple directorships were searched in the sections of company information and directors' profiles of the companies' annual reports.

Change of directors during the financial year required the researcher to determine which director to be considered as in most cases, a new director is also nominated in the same financial year. In determining which director to be considered, as this would also affect the directors' tenure and multiple directorships, this study adopted the requirement by the Bursa Malaysia Listing Requirement to have directors attending at least 50% of the companies' meetings. Following that requirement, the cut-off period a director should be on the board in the financial year was determined to be at least six months. Director stays of less than six months on the board in the financial year were not considered.

For multiple directorships, only directorships in the PLCs were considered. This is due to the Bursa Malaysia Listing Requirement to disclose only multiple directorships in PLCs. In addition, not all companies voluntarily disclose directorships in private companies.

Information on the frequency of board meetings and percentage of meeting attendance was gathered from the Company's Corporate Governance Statement in the annual reports. Instead of considering only the quantity (frequency of meetings), this study also considered the quality of board process proxy by the percentage of directors' meeting attendance. The average percentage of directors' meeting attendance was determined based on the average frequency of meetings attended by the directors.

Managerial ownership refers to the percentage shareholdings of executive directors at year end with direct and indirect holdings. Managerial ownership was further categorized into the ownership that belongs to family members (MFOWN) and non-family members (MNFOWN). In determining type of managerial ownership either MFOWN or MNFOWN, first the researcher identified family members connected with the directors based on the directors' information in the Director Profile. A member of a director's family includes the spouse, parent, child (including adopted child or step child), brother, sister and the spouse of his child and spouse of his brother or sister (Section 122A of Malaysia's Companies Act 1965). Then the family shareholdings in the company are determined based on direct and indirect holdings. Non-linearity in the managerial ownership structure was addressed by using the quadratic terms in the function. For example, in this study, analyses of curve estimations for the quadratic terms on both ROA and Tobin's *Q* were conducted for managerial ownership (MOWN) and managerial-family ownership (MFOWN) as previous studies have indicated the presence of non-linear relationship. The significance of ANOVA table from the curve estimation would determine the use of quadratic terms. From the regression output, the turning point for each curvilinear was computed based on the coefficients ($-\beta_1/2\beta_2$), where β_1 is the coefficient of linear term and β_2 is the coefficient of non-linear term, quadratic term (Koh, 2003; McConnell & Servaes, 1990).

This study uses both measures of objective firm performance, Accounting-based performance (ABP) (ROA) and Market-based performance (MBP) (Tobin's *Q*), to see whether there are different effects (opposite directions) in the relationships between internal corporate governance and ROA and Tobin's *Q*. ROA was measured by earnings before interests and tax (EBIT) divided by the book value of total assets (ROA = EBIT/TA). EBIT is used to avoid the effect of firms' discretion choices of capital structure (Wiwattanakantang, 2001). The approximate Tobin's *Q* by Chung and Pruitt (1994) was adopted. The definition of debt includes short-term debt, related loans and long-term debt as suggested by the Bursa Malaysia. Thus, this study used book value of liabilities instead of debts as this definition was also used by Himmelberg, Hubbard, and Palia (1999) and Wiwattanakantang (2001). Differences of calculating Tobin's *Q* are as follows:

$$\text{Approximate Tobin's Q (Chung \& Pruitt,}\quad 1994) = (\text{MVE} + \text{PS} + \text{Debt})/\text{BVTA}$$

where

MVE = market value of equity, firm's share price × number of common stock outstanding,

PS = liquidity value of the firm's outstanding preferred stocks,
Debt = book value of long-term debt + Book value of current liabilities,
BVTA = book value of total assets.

Measurement for the approximation of Tobin's *Q* for this study is as follows:

$$\text{Tobin's Q} = (\text{MVE} + \text{BVLiabilities})/\text{BVTA}$$

In calculating the MVE, firm's share price is referred to the share price at the financial year end.

Firm size, leverage (debt ratio) and growth were used as control variables because firm performance may be affected directly or indirectly by factors related to the nature of the firm. Firm size was measured as the natural logarithm of book value of total assets. Leverage was measured as a ratio of total debt to total assets. Leverage was used to control risk associated with the firm. Growth referred to the sales growth measured by the percentage change of sales, averaged over the period 2004–2006. Table 2 summarizes the measurements used in the present study.

Standard or robust multiple regression was used in this study (Hair, Black, Babin, Anderson, & Tatham, 2006). The regression function for the study is as follows:

$$\begin{aligned}\text{FP} = \text{a}_0 + \text{a}_1(\text{BSIZE}) + \text{a}_2(\text{BLEAD}) + \text{a}_3(\text{NINE}) + \text{a}_4(\text{MDIR}) + \text{a}_5(\text{TEN})\\ + \text{a}_6(\text{BPROS}) + \text{a}_7(\text{MOWN}) + \text{a}_8(\text{Control Variables}) + \varepsilon\end{aligned}$$

where

FP firm performance, ROA or Tobin's *Q*,
BSIZE number of board members,
BLEAD independent board leadership, dummy '1' for CEO ≠ Chairman, '0' otherwise,
NINE proportion of non-independent non-executive directors,
MDIR percentage of directors having at least additional one directorship in another PLC or directorships per director,
TEN average of directors' tenure,
BPROS frequency of board meetings or percentage of meeting attendance,
MOWN percentage of executive directors' shareholdings; or MFOWN and MNFOWN.

Table 2. A Summary of Measurements of Firm Performance, Board Attributes, Managerial Ownership, Control Variables and Sources of Measures.

Variables	Definitions	Sources
FP	Firm performance is measured by ROA and Tobin's Q ROA = EBIT/TA Tobin's Q = (MVE + BVLiabilities)/BVTA	Pearce and Zahra (1991); Wiwattanakantang (2001)
BSIZE	Board size is the number of board members in a company	Bhagat and Black (1999)
BLEAD	Independent board leadership, dummy '1' if CEO ≠ chairman, '0' otherwise	Abdullah (2004)
NINE	Board composition is measured by the proportion of non-independent non-executive directors (NINE)	Bhagat and Black (1999); Klien (1998)
MDIR	Multiple directorships are: 1. the percentage (%) of directors having more than one directorship in public companies 2. directorships per director	Haniffa and Hudaib (2006); Tan (2005); Ferris et al. (2003)
TEN	Board tenure is a proxy for board knowledge which is measured as the average of board of directors' tenure in a company	Gottesman and Morey (2006)
BPROS	Board process is: 1. the frequency of board meetings, or 2. the percentage of BOD meetings attendance	Vafeas (1999); Ishak and Napier (2006)
MOWN	Managerial ownership structure: 1. MOWN, percentage (%) of executive directors' shareholdings, direct and indirect 2. MFOWN, percentage (%) of executive directors' shareholdings (MOWN) belongs to family members, at least two family members 3. MNFOWN, percentage (%) of executive directors' shareholdings (MOWN) belongs to non-family members 4. MOWN using piecewise method	McConnell and Serveas (1990); Morck et al. (1988); Wong and Yek (1991); Yammeesri et al. (2006)
FSIZE	Firm size is the logarithm of total assets	Agrawal and Knoeber (1996)
DEBR	Debt ratio is total debt to total assets	Wiwattanakantang (2001)
GROWTH	Growth is the sales growth measured by the percentage change of sales, averaged over the period 2004–2006	Wiwattanakantang (2001)

Sample Profile

The population of this study is companies listed on the main board of Bursa Malaysia for the year 2006. There was around 520 (excluding finance companies, PN4, PN17, companies listed after 2004) companies. 112 samples of the companies were randomly selected. Only the main board companies were selected in order to control for other factors that might influence performance of companies in other boards such as size differences and risks.

RESULTS OF THE STUDY

Sample Profile

Table 3 reports the sample profile of the study. With respect to sector, almost all sectors are covered in this study. Nearly 80% of the respondents come from four sectors namely Industrial Product (IP), Trading and Services (TS), Construction (CONST) and Property (PROP). Following Mishra et al. (2001) for the definition of family companies (at the cut-off 10% of family ownership), 42 companies fall under family controlled companies and 70 companies under non-family controlled companies.

Table 3. Sample Profile.

	Frequency	Percentage (%)
Industry type		
Consumer product (CP)	9	8.00
Industrial product (IP)	28	25.00
Trading and services (TS)	28	25.00
Technology (TECH)	3	2.70
Infrastructure (INFRA)	1	0.90
Construction (CONST)	17	15.20
Property (PROP)	15	13.40
Plantation (PLT)	11	9.80
Types of control companies		
Family control companies	42	37.50
Non-family control companies	70	62.50

Descriptive Statistics of Variables

Table 4 presents descriptive statistics of the categorical variable. About 83.9% of the sample companies have different persons acting as CEO/MD and chairman of the companies. Even though the MCCG recommends companies to have independent leadership, some companies (about 16.1%) still choose to opt the combined leadership structure.

Table 5 presents descriptive statistics of the continuous variables. The average of board size (BSIZE) is 7.66. Board size of the sample companies in this study is not much different from that in the study by KLSE-PWC (2002) of eight directors. The average proportion of non-independent non-executive directors (NINE) in a company is 0.24. The proportion of NINE

Table 4. Descriptive Statistics for Categorical Variable.

	Frequency	Percentage (%)
BLEAD		
CEO = Chairman (0)	18	16.1
CEO ≠ Chairman (1)	94	83.9

Note: $N = 112$. BLEAD is independent board leadership given '1' for CEO and chairman are different persons, '0' otherwise.

Table 5. Descriptive Statistics for Continuous Variables.

Variables	Mean	SD	Skewness	Kurtosis	Min	Max
BSIZE	7.66	1.79	0.47	−0.22	4	13
NINE	0.24	0.18	0.27	−0.93	0.00	0.67
FMEET	5.79	2.20	1.90	4.15	4	15
PMEET (%)	93.70	5.48	−1.15	1.35	75.00	100.00
TEN	7.79	4.87	1.56	3.11	1.25	26.33
PMDIR (%)	48.43	27.82	0.11	−0.98	0.00	100.00
MMDIR	1.43	1.15	0.94	−0.05	0.00	4.67
MOWN (%)	23.80	23.06	0.34	−1.32	0.00	79.10
MFOWN (%)	15.40	22.41	1.03	−0.47	0.00	78.77
MNFOWN (%)	7.71	15.44	2.00	2.86	0.00	60.58
LGTA	20.40	1.25	0.70	0.26	17.93	24.46
DEBR	0.41	0.21	0.44	−0.26	0.02	1.00
GROWTH	21.18	56.48	7.34	65.54	−25.47	540.71
ROA	0.07	0.05	0.11	−0.47	−0.05	0.17
Q	0.92	0.38	1.60	3.36	0.27	2.45

Note: $N = 112$.

in this study is quite low compared to that in the study by PWC (2002) of average three NINE in a PLC.

Frequency meeting (FMEET) conducted is about 5.79 times per year with a minimum of four times to a maximum of fifteen times. The percentage meeting attendance of directors (PMEET) is quite high with the average of 93.70% and with the minimum of 75% and the maximum of 100%. By company, the average tenure (TEN) of directors serving on the board is about 7.79 years with a minimum serving of 1.25 year and maximum of 26.33 years. For multiple directorships (PMDIR), on average about 50% (48.43%) of the directors in a company have at least one additional directorship in other PLCs. This is quite high compared to Tan's finding (2005) of 31.41% with a sample year of 2001. The multiple directorships per director (MMDIR) in a company is 1.43. For managerial ownership (MOWN), on average executive directors hold 23.80% shareholdings with a minimum holding of 0% and a maximum holding of 79.10%. The average shareholdings are not much different from Chee and Md Taib (2005) of 24.96%. In terms of total assets (LGTA), on average the LGTA is at 20.40. The average debt ratio (DEBR) and growth (GROWTH) is 0.41% and 21.18%, respectively. For performance measures, the average ROA is 0.07 whilst the average Tobin's Q is 0.92.

Correlations among Variables

Table 6 presents the Pearson correlation matrix between corporate governance variables, control variables and firm performance. In general, all correlations are less than 0.80, thus there is no issue of multicollinerity between independent variables. Board size (BSIZE) is found positively correlated with firm size (LGTA) and the proportion of non-independent non-executive directors (NINE). However, board size is negatively correlated with the percentage of meeting attendance (PMEET), which means that companies with larger board size tend to have lower percentage of board meeting attendance. For board leadership (BLEAD), there is a positive correlation between board leadership and the proportion of non-independent non-executive directors (NINE) but a negative correlation between board leadership and the percentage of meeting attendance (PMEET). This means that companies with independent leadership tend to have more proportion of non-independent non-executive directors (NINE) but less percentage of meeting attendance (PMEET).

Table 6. Pearson Correlations between Corporate Governance Variables, Control Variables and Firm Performance.

	BSIZE	BLEAD	NINE	LGFMET	PMEET	LGTEN	PMDIR	MOWN	MFOWN	MNFOWN	LGTA	DEBR	GROWTH	ROA	*Q*

*$p < 0.10$; **$p < 0.05$; ***$p < 0.01$.

The proportion of non-independent non-executive directors (NINE) is found negatively correlated with all ownership structure, managerial ownership (MOWN), managerial-family ownership (MFOWN) and managerial-non-family ownership (MNFOWN), but positively correlated with frequency of meetings (LGFMET). Having more meetings would suggest more expertise of NINE is required in the companies. Frequency of meetings tends to be more when more directors have multiple directorships (PMDIR). Directors with multiple directorships are more attached to larger companies. Higher managerial ownership (MOWN) tends to have higher managerial-family ownership (MFOWN) and higher managerial-non-family ownership (MNFOWN). However, there is a negative correlation between managerial-family ownership (MFOWN) and managerial-non-family ownership (MNFOWN). The results indicate that MFOWN and MNFOWN are substitute for each other.

Smaller companies tend to have higher managerial ownership (MOWN). The more complex the companies, the more frequency meetings will be held as suggested by the positive correlation between frequency meetings (LGFMET) and firm size (LGTA), debt ratio (DEBR) and growth (GROWTH). However, less frequency of meetings is held when there are more directors with longer tenure, more managerial ownership and more family ownership.

In relation to firm performance, ROA is found to be negatively correlated with multiple directorships (MDIR) and independent board leadership (BLEAD). This means that companies having more multiple directorships and separate leadership tend to have lower ROA. Tobin's Q is found to be positively correlated with board size, the proportion of non-independent non-executive directors (NINE) on the board, debt ratio and ROA.

Results of Regression Analysis

Table 7 presents the result of multiple regression analysis between corporate governance variables and ROA. Curve estimation is used to decide whether to use squared term of managerial ownership or not as previous studies have shown the presence of non-linearity relationship between managerial ownership and firm performance. The quadratic term of managerial ownership (MOWN) is used in regression analysis between corporate governance and Tobin's Q whilst the linear term of MOWN is used in the relationship with ROA.

Table 7. Multiple Regression Results between Corporate Governance and ROA.

*$p < 0.10$; **$p < 0.05$; ***$p < 0.01$.

The results in both models show that the proportion of non-independent non-executive directors (NINE) is positively significant ($p < 0.01$). Board leadership (BLEAD) is significant in both models but with negative directions. This suggests that having different CEO and chairman leads to lower ROA. The multiple directorships (PMDIR) are significant ($p < 0.05$) with negative directions. For ownership variable, MOWN is found to be positively significant ($p < 0.10$) in Model 1. By differentiating managerial ownership into managerial-family ownership (MFOWN) and managerial-non-family ownership (MNFOWN) as in Model 2, the results show that the positive relationship between managerial ownership is contributed by the managerial-non-family ownership (MNFOWN) as shown by the positive and significant relationship ($p < 0.10$) between MNFOWN and ROA.

The results of the regression analyses between corporate governance and Tobin's *Q* are presented in Table 8, after excluding two outlier cases. In Model 1 the squared managerial ownership is used to measure the impact of managerial ownership on Tobin's *Q*. Curve estimation for quadratic forms shows a very weak U-shape with turning point at MOWN 31.38%.

*$p < 0.10$; **$p < 0.05$; ***$p < 0.01$.

The results show a decreasing value of Tobin's *Q* if MOWN is less than 31.38% and an increasing value when MOWN is more than 31.38%. MOWN is found to be significantly related to Tobin's *Q* ($p < 0.10$). The frequency of meetings (LGFMET) is also found to be significant with a negative direction ($p < 0.05$). Board size (BSIZE) is significant and positively related to Tobin's *Q* ($p < 0.10$). The proportion of non-independent non-executive directors (NINE) is positively related to Tobin's *Q* but the relationship is not significant.

In Model 2, the curve estimation shows that MFOWN has a significant U-shape ($p < 0.01$). There is a decreasing value in Tobin's *Q* for MFOWN less than 28.29% but an increasing value for MOWN more than 28.29%. Other significant variables in Model 1 are also found significant in Model 2. However, the proportion of non-independent non-executive directors (NINE) is found to be strongly significant in Model 2 ($p < 0.05$).

In both models, it is found that multiple directorships (PMDIR), independent board leadership (BLEAD) and board tenure (LGTEN) are not significantly related to Tobin's *Q*. For control variables, debt ratio is found to be very strongly significant ($p < 0.01$) with positive directions for all models. Growth is also significant ($p < 0.05$) with positive directions.

DISCUSSIONS AND CONCLUSIONS

In summary, the corporate governance variables that are significant to ROA are board leadership, non-independent non-executive directors, multiple directorships, percentage of meetings attended and managerial ownership. For Tobin's *Q*, the significant corporate governance variables are board size, non-independent non-executive directors, frequency of meetings and managerial ownership.

The findings indicate that the impact of corporate governance on ROA and Tobin's *Q* are somewhat different for multiple directorships, board size, board process, board leadership and types of managerial ownership. The impact is similar for the proportion of non-independent non-executive directors. Managerial ownership is found to be positively related to ROA and Tobin's *Q*. Use of quadratic terms shows that managerial ownership is significantly related at higher percentage of ownership. When managerial ownership is further classified into family owned and non-family owned, it is found that managerial-family ownership is positively related to Tobin's *Q* at higher percentage whilst managerial-non-family ownership is positively related to ROA.

The insignificant relationship between board size and ROA indicates that board size does not have any influence on ROA. However, the positive and significant relationship with Tobin's *Q* means that the market reacts positively with large board size indicating the benefits of larger board size to firm performance. Larger board size means more outside directors' representatives to foster careful decision-making and is conducive for effective monitoring by the BOD which leads to improved Tobin's *Q*. This suboptimal board size (about eight members) enhances communication and coordination between board members (Lipton & Lorsch, 1992).

The results of independent board leadership are negative and significantly related to ROA, but not significantly related to Tobin's *Q*. The negative and significant relationship with ROA shows that CEO duality does not deteriorate firm performance. The insignificant relationship with Tobin's *Q* is consistent with the result of Weir et al. (2002). Further analysis of the t-test indicates that CEO duality is more preferable to provide improved ROA as indicated by the higher mean of ROA for companies adopting CEO duality compared to companies adopting independent leadership. The results may be attributed to several reasons. In this study, the percentage of companies adopting CEO duality is 16.0% which is smaller than that in Haniffa and Hudaib (2006) who reported it at 25.7%. However, when additional analysis is done by measuring CEO duality as CEO and chairman are the same person or different persons but from the same family, it is found that the percentage of CEO duality increases to 27.7%. This indicates that PLCs have moved towards complying with the MCCG of having independent leadership and the nature of CEO duality practices may be higher. The positive and significant relationship between CEO duality and ROA indicates that benefits of having CEO duality practices outweigh the agency problems created as separation of roles contributes to larger costs to the companies such as information costs (Brickley et al., 1997). CEO duality practices would lead to more unified corporate responses and strong and decisive leadership style (Tan et al., 2001). In fact the market for corporate control and managerial labour market would have adequately disciplined the CEO to work for firm value. In addition, the positive correlation between CEO duality practices and managerial ownership indicates that companies with CEO duality tend to have higher managerial ownership. Thus, the incentives of CEO duality toward company sustainability would be more enhanced.

The results of NINE with both ROA and Tobin's *Q* support the agency theory of the role of outside directors to provide effective monitoring of the management and supplement resources needed to the management. The strength of the relationship is more evident with the ROA. The market also perceives that non-independent non-executive directors are capable of bringing improved performance to companies. The results of the present study are consistent with those of Klien (1998), Roberts et al. (2005) and Wan Hussin et al. (2005). The positive contribution of non-independent non-executive directors might be due to them having shareholdings in the companies (Klien, 1998; Roberts et al., 2005). Having interests in the companies provides incentives for them to work towards high performance. The results show that NINE are effective persons to monitor management actions and provide strategic tasks to the management. In addition, the high correlation between non-independent non-executive directors and frequency of meetings may suggest the greater involvement of non-independent non-executive directors in the process of company's decision making.

The result of the relationship between multiple directorships and ROA is significant in a negative direction whilst the result with Tobin's *Q* is insignificant. The result with ROA supports the busyness hypothesis which relates multiple directorships with overcommitted work. Findings with ROA support the argument that directors with multiple directorships have less time and attention to a firm (Ferris et al., 2003). The results of this study are in contrast to those of Haniffa and Hudaib (2006) and Tan (2005) who found positive relationship between multiple directorships and firm performance of PLCs in Malaysia. The results have practical implications to the current practices which allow directors to have up to 25 directorships (10 for public companies and 15 for non-public companies). The negative relationship between multiple directorships and firm performance highlights the serious concern of multiple directorships in the Malaysian PLCs. This finding is in line with the concern of Minority Shareholder Watchdog Group (MSWG) to limit the number of directorships of the independent directors (MSWG, 2009).

The insignificant relationship between board tenure as a proxy for director experience shows that board tenure does not matter for firm performance. The insignificant relationship is consistent with the finding of Wiersema and Bantel (1992), but contradicts Carpenter and Westphal's (2001). The results indicate that having longer tenure does not guarantee higher firm performance. Previous studies which show positive relationships investigated top management team's knowledge on certain tasks (Wiersema & Bantel, 1992) do not hold for directors.

The negative relationship between frequency of board meetings and Tobin's *Q* is consistent with Vafeas's (1999) finding. The results show that when more meetings are conducted the market would perceive the companies may be having problems and the BOD with the management team is working to solve them through frequent meetings (Vafeas, 1999). Frequent board meetings are found associated with information costs to directors with multiple directorships. Given the time constraint, frequent board meetings would lead to fewer meetings attended by directors, thus making meetings less effective and productive.

The results between board tenure and frequency of meetings with firm performance do not support the requirement of the revised MCCG to consider criteria such as skills, knowledge, expertise and experience when recommending candidates for directorships. As the criteria stated in the revised code are very general, thus further studies need to consider other measurements to represent skills, knowledge, expertise and experience of BOD.

The results with managerial ownership show that quadratic form of managerial ownership is more applicable to Tobin's *Q* while the linear form is more applicable to ROA. The significant and positive relationships between managerial ownership and both measures of firm performance (ROA and Tobin's *Q*) are supported. In this study, linear and non-linear forms of managerial ownership are significant with ROA and Tobin's *Q*, respectively, which indicates that the benefits of managerial ownership outweigh the costs of it. The results show that managerial ownership and family ownership yield greater efficiency. The significant relationship between managerial-family ownership and firm performance supports the argument of Chami (1999), Fama and Jensen (1983), and DeAngelo and DeAngelo (1985) and empirical evidence of Lee (2004) that family ownership enhances monitoring activities. The U-shaped curvilinear relationship of managerial ownership with Tobin's *Q* is consistent with Chee and Md Taib's (2005) finding which supports the convergence-of-interest hypothesis but inconsistent with other studies (e.g. Ali & Sanda, 2001; Mat Nor et al., 1999; McConnell & Servaes, 1990; Morck et al., 1988; Short & Keasey, 1999; Wong & Yek, 1991) which found a downturn curvilinear relationship. The entrenchment effect of managerial ownership at the high level of ownership is not supported.

For the quadratic forms of managerial ownership and managerial-family ownership with Tobin's *Q*, the U-shaped curvilinear relationship supports the convergence-of-interest hypothesis. This means that high managerial ownership and high family ownership would act as an effective mechanism for managers to maximize the shareholders' wealth considering their high ownership in the company's shares. However, precaution should be taken as managerial ownership and managerial-family ownership are not effective in enhancing firm performance at all levels of ownership. The results show that shareholdings below certain percentage of ownership (i.e. 31.38% for managerial ownership and 28.29% for managerial-family ownership) would result in decreasing value as managers have less incentive and this will lead them to shirk their responsibilities and engage in excessive use of company's assets (Jensen & Meckling, 1976). The significant results of managerial-family ownership are consistent with Tan et al. (2001), Thomsen and Pedersen (2000), and Wiwattanakantang (2001).

In terms of theoretical perspectives, results of the study highlights the use of non-independent non-executive directors as a measure of board composition has extended the understanding of the impact of the type of NEDs on firm performance and board performance. A positive significant relationship is in fact supportive of the role of outside directors in protecting the shareholders' interests.

This study also highlights that the effects of corporate governance on ROA and Tobin's *Q* are somewhat different. This study provides some evidence on the need to use appropriate measure of firm performance as argued by Haniffa and Hudaib (2006). That is, when studying firm performance, various measures of firm performance should not be considered as one variable. This study also uses two approaches to capture the effect of managerial ownership on firm performance. Differentiating the types of managerial ownership into family and non-family categories enrich our knowledge about who actually contributes to the improved performance. The results of the study consistently highlight the significant contribution of managerial-family ownership to Tobin's Q. The linear and quadratic forms of managerial ownership are also able to capture the effect of managerial ownership on firm performance.

NOTES

1. Refers to persons who are currently officers of the company.
2. Refers to former company officers, relatives of company officers and persons who are likely to have business relationship with the company.

Keywords: Sarbanes-Oxley, Foreign private issuer, Deregistration, Corporate governance, Law and finance, Cross-listing, ADR

I am grateful for suggestions from Bill Christie, Art Durnev, Larry Fauver, Zhigang Feng, Reinier Kraakman, Jennifer Marietta-Westberg, Ronald Masulis, Giovanna Nicodano, Jordan Siegel, Jeff Sutthoff, Tracy Wang, T. J. Wong, seminar participants at the Chinese University of Hong Kong, Clark University, the Federal Reserve Board, Rutgers University, the Hong Kong University of Science and Technology, Singapore Management University, the University of Hong Kong, the 22nd Annual Conference on Finance, Economics, and Accounting, the European Corporate Governance Institute Conference at the University of Sheffield, the Finlawmetrics Conference at Bocconi University, the 2007 China International Finance Conference in Chengdu, the 2007 Conference of the Chinese Finance Association, the 2007 Conference on Empirical Legal Studies at New York University, and the University of Miami, and especially Tracy CarMichael at the British Columbia Securities Commission, Elliot Staffin at the Securities and Exchange Commission, Gennaro Bernile, Mingyi Hung, Guochang Zhang, Robert Holthausen (the editor), and an anonymous referee for helpful comments. Any errors are my responsibility.

The Sarbanes-Oxley Act and cross-listed foreign private issuers

I examine the short- and long-term impact of the 2002 Sarbanes-Oxley Act (SOX) on cross-listed foreign private issuers. Both short- and long-term test results suggest that the costs of SOX compliance significantly exceed its benefits and reduce the net benefits of cross-listings.

1. Introduction

In 2002, in the wake of a series of corporate scandals, the U.S. Congress by an overwhelming majority passed the Sarbanes-Oxley Act (SOX) to strengthen corporate governance and financial reporting. SOX aims to restore investor confidence in U.S. markets, which include U.S. companies, as well as the more than 1,300 foreign private issuers (FPIs) that have reporting obligations to the Securities and Exchange Commission (SEC). Hailed as the single most important piece of legislation on corporate governance, financial disclosure, and the practice of public accounting since the Great Depression (Hitt, 2002), SOX is also one of the most controversial business laws in U.S. history. Critics deplore it as a rushed political response to high profile corporate malfeasance that creates substantial net costs for issuers (Perino, 2003).[1]

My paper examines the short- and long-term impact of SOX on shareholders of cross-listed FPIs. FPIs are an important component of U.S. markets, accounting for about 20 percent of the common stocks listed on the NYSE. By cross-listing in the U.S., FPIs generally gain increased visibility, prestige, and trading liquidity. At the same time, their presence enhances the status of U.S. markets as the world's financial center. Because FPIs are usually of higher quality than other issuers in home markets, cross-listings provide an easy and inexpensive way for U.S. investors to diversify geographically. SOX appears, however, to drive FPIs away from U.S. markets.[2]

To assess the short-term impact of SOX, I compare the U.S. and home market stock returns of a comprehensive sample of cross-listed FPIs with the FPI-free home country index returns around 23 events related to the passage and implementation of SOX. Because SOX affects all U.S. listed issuers, U.S. stock market indexes are contaminated benchmarks for both cross-listed FPIs and U.S. issuers. To

[1] Various surveys of public companies indicate that the costs of compliance exceed the benefits. In addition to direct costs such as auditor expenses, indirect costs are likely to be much greater. Examples of indirect costs are distraction due to SOX compliance, exposure of proprietary information, reduction in the flexibility critical to robust growth, and overly risk-averse managers and independent directors.

[2] FPIs' varying backgrounds and potentially different mix of agency problems (as compared with diversely owned U.S. firms) likely make their compliance especially costly. Citing higher compliance costs, more FPIs go public only on home markets in the post-SOX period and many FPIs exit U.S. markets (Karmin and Lucchetti, 2006).

construct cleaner benchmarks, I create FPI-free home country indexes using all the firms in each foreign market, which are not affected by SOX. I also exclude the home market returns of FPIs with SEC reporting obligations for the period during which they are cross-listed or over-the-counter (OTC) traded in the U.S., as these returns are highly correlated with their U.S. returns, which are affected by SOX. I find aggregate abnormal returns for cross-listed FPIs of -10% on average in the U.S. and home markets, which suggests substantial destruction in the market value of FPIs during these events. The similar results in the U.S. and home markets that differ in market structure, investor sophistication and protection, and liquidity suggest that these differences and issues such as asynchronous trading cannot explain my results.

However, concerns could arise that these negative short-term market reactions are due to differences between FPIs that access U.S. markets and those that do not (e.g., size or growth opportunities), cross-sectional correlation and clustering of events, the measure of abnormal returns, or benchmark weighting schemes. Because all these concerns should affect both the event and non-event abnormal returns of a given FPI, to address them, I base my inferences on the empirical distributions and related bootstrapped *p*-values obtained by bootstrapping abnormal returns on non-event days during the 2002–2003 period. I find that these negative short-term reactions are significant at the 1% level.

To further ensure that these reactions are due to SOX, I conduct two additional short-term tests. First, I examine the event period reactions of both a sample of OTC-traded FPIs with SOX compliance and a sample of OTC-traded FPIs exempt from SOX compliance. If the reactions of cross-listed FPIs are due to SOX, only the former type of OTC-traded FPIs should react to SOX-related events. Given that OTC-traded FPIs may have less liquid trading in the U.S., I examine both their U.S. and home market reactions. These two types of FPIs differ from cross-listed FPIs and from each other. Therefore, different reactions may not prove that the reactions of cross-listed FPIs are due to SOX. Thus, I base my inferences for both types of FPIs on their own bootstrapped abnormal returns on non-event days. I find, in both markets, significantly negative event period reactions for OTC-complying FPIs and insignificant reactions for OTC-exempt FPIs.

Second, in cross-sectional analysis of the event period reactions of cross-listed FPIs, the reactions generally vary negatively with FPIs' governance quality (i.e., country-level corporate and securities laws and firm-level institutional monitoring). Given SOX's far-reaching impact on governance, this variation is expected and it provides further support that these reactions are due to SOX. Combined with the negative aggregate reactions, the generally negative relation suggests that SOX compliance is especially detrimental to better-governed FPIs. The reactions are also less negative if FPIs are more likely to go dark in the U.S.; that is, voluntarily delist and deregister to eliminate the SEC reporting obligations and in turn SOX compliance, suggesting that investors view escaping from SOX compliance favorably. Taken together, the short-term results suggest that SOX creates substantial net costs for cross-listed FPIs.

As for the long-term impact of SOX, I document three results using a comprehensive sample of going-dark FPIs during the 1995–2006 period.[3] First, many more FPIs go dark after the passage of SOX than in the pre-SOX period. Second, going-dark returns (i.e., abnormal returns around delisting and deregistration announcements) are negative before the passage of SOX but positive after its passage, with the difference being highly significant. Third, for the average FPI that goes dark in the post-SOX period, all FPI characteristics (e.g, governance quality and growth potentials) improve from the pre- to the post-dark phase, a finding not observed in the pre-SOX period. Although the first result is not a clear test of SOX as it may be explained by reduced growth potentials, increased agency problems, or increased compliance costs due to SOX, the last two results can only be consistent with the average FPI going dark in the post-SOX period to escape costly compliance. Otherwise, I should observe lower going-dark returns as shareholders vote with their feet to escape FPIs with increased agency problems and reduced growth potentials, as well as deterioration of governance quality and growth potentials from the pre- to the post-dark phase. The last two results indicate that the net costs created by SOX may have offset the net cross-listing benefits for the average going-dark FPI.

[3] For brevity, unless otherwise stated, I define "going dark" as going dark in the U.S. while maintaining home market listings and reporting obligations.

Short-term uncertainty or biases associated with short-term tests cannot explain either the long-term results or the combined results of the several short-term tests, whereas long-term global trends such as improved stock returns, liquidity, and governance in foreign markets are less likely to explain the short-term results. Overall, my short- and long-term results are consistent with each other and corroborate that SOX induces significant net costs, especially for better-governed FPIs.

My paper contributes to the long-standing fundamental debate on the impact of regulation (Landis, 1938; Coase, 1960; Stigler, 1964; Becker, 1968).[4] It also complements studies of SOX's impact on U.S. issuers by examining the law's impact on FPIs and by exploring SOX-related issues pertinent to several unique features of FPIs. In addition, it complements a few related studies of SOX's impact on cross-listed FPIs by providing more unambiguous and consistent evidence of SOX's negative effect. Its stronger inferences are attributable to more comprehensive and precise samples, a more thorough understanding of SEC rules on listings and registrations, and a broader set of unique features related to the impact of SOX. Further, I show that less than 20% of cross-listed FPIs have controlling shareholders. Although the broad literature on FPIs focuses on the controlling shareholder agency problems in firms with concentrated ownership, this finding suggests that future studies of FPIs should also examine the managerial agency problems in diversely owned firms.

The remainder of the paper is organized as follows. Section 2 provides a comparison with the literature. Section 3 describes the data, Section 4 presents the results, and Section 5 concludes.

2. Relation to the literature

Several contemporaneous studies examine SOX's impact on cross-listed FPIs. However, their evidence yields inconclusive inferences about the impact of SOX. For short-term impact, Litvak (2007) finds significantly negative event period reactions for a sample of cross-listed FPIs during mostly pre-SOX events. However, Litvak finds only a weak relation between these reactions and governance

[4] Evidence about the value of regulation is inconclusive. For example, evidence on the impact of mandatory disclosure requirements is mixed (see Healy and Palepu, 2001 for a review), resulting in calls to significantly modify or repeal U.S. securities market regulation (e.g., Palmiter, 1999).

characteristics. In addition, she finds significantly negative event period reactions for her sample of OTC-exempt FPIs. The last two results make it difficult to attribute the short-term reactions of cross-listed FPIs to SOX. As for long-term impact, Marosi and Massoud (2008) find a greater number of going-dark FPIs in the post-SOX period, but no difference in going-dark returns between the pre- and post-SOX periods, making it difficult to conclude that SOX has an impact. Hostak et al. (2013) focus on the pre-dark characteristics of non-Canadian FPIs voluntarily delisted in the post-SOX period. However, the lack of comparison between pre- and post-SOX periods makes it difficult to infer SOX's impact.

My paper provides more unambiguous evidence of the detrimental impact of SOX for two reasons. The first reason is the more comprehensive and precise nature of my analysis. For the short-term impact, my sample of cross-listed FPIs for event period reactions is 36% greater than that of Litvak (2007). In addition, Litvak (2007) includes few post-SOX implementation events in her analysis of short-term impact. My paper includes all of the major post-SOX implementation events (12 out of 23 SOX-related events), as well as a more comprehensive sample of pre-SOX events, as prior research emphasizes the importance of considering how law and regulation are implemented and enforced (Holthausen, 2009). In addition, my paper examines the prevalence of controlling shareholders in cross-listed and going-dark FPIs. For the long-term impact, I use evidence gathered after FPIs go dark in the U.S. and compares their pre- and post-dark characteristics to see how their behavior changes. Further, I find that more than half of the potential going-dark sample FPIs delist in home countries, become private, are acquired, or are financially distressed or liquidated within a year of U.S. delisting or deregistration. Unlike the other long-term studies, I eliminate these FPIs to obtain a more "pure" going-dark sample. If an FPI's motivation to go dark is only to escape U.S. compliance, it does not need to take such actions in home markets so soon. However, given the proximity in time of delistings or deregistrations in the U.S. and home markets, it is difficult to tell whether the going-dark effects are due to the removal of the U.S. or home listings and registrations. Also, financial hardship may have forced FPIs to quit doing almost everything inessential to survival, including listing and registration in the U.S., and exchanges often force distressed firms to delist, making these delistings unlikely to be voluntary. Distressed FPIs also have few filings by the time of U.S. deregistration, making it difficult to determine whether deregistration was voluntary.

The second reason is my more complete reliance on SEC rules on registrations and deregistrations in the research design. For example, the broad literature on FPIs treats all OTC-traded FPIs as exempt from SOX compliance. In reality, however, a large number of OTC-traded FPIs have to comply with SEC regulation. For example, about 35% of FPIs with SEC reporting and SOX compliance obligations are OTC-traded in 2001.[5] This more nuanced understanding of SEC rules may explain the insignificant reactions that Litvak (2007) finds for OTC-traded FPIs. As mentioned earlier, the insignificant reactions for OTC-traded FPIs make it difficult to attribute the short-term reactions of cross-listed FPIs to SOX.[6]

My paper complements the literature that finds mixed evidence about the impact of SOX on U.S. issuers (Jain and Rezaee, 2006; Zhang, 2007; Li et al., 2008; Chhaochharia and Grinstein, 2007; Marosi and Massoud, 2007; Leuz et al., 2008). FPIs are an important component of U.S. markets. However, conclusions in the literature about U.S. issuers may not be directly applicable to FPIs because the more concentrated ownership structure of FPIs means that they may face a different mix of agency problems. Further, several distinct features of FPIs make them a unique entity to examine the impact of SOX: cleaner benchmarks such as FPI-free home country indexes, the availability of two more comparable OTC control samples (OTC-traded U.S. issuers are tiny in size compared with listed U.S. issuers, whereas OTC-traded FPIs are relatively more comparable in size to listed FPIs), greater precision in identifying going-dark FPIs, the availability of the U.S. and home market reactions and of post-dark data, and a richer set of cross-sectional characteristics at both firm and country levels.

[5] A lesser-known fact by the broad literature on FPIs is that OTC-traded FPIs do not really have U.S. listings.

[6] I find significant reactions to SOX-related events on the part of all OTC-traded FPIs, similar to the results of Litvak (2007), if I pool my samples of OTC-traded FPIs with and without SOX compliance. Also, given that OTC complying FPIs are likely to be among the largest non-cross-listed FPIs, the size-matched samples for exchange-listed FPIs in Litvak (2007) are likely to include these FPIs, which should produce smaller event period reactions in magnitude for cross-listed FPIs as in her paper.

3. Data

3.1. The short-term impact of SOX: Abnormal returns around SOX-related events

The first part of my analysis examines the abnormal returns of all cross-listed FPIs around SOX-related events. I compile all legislative events before final passage of SOX from the Library of Congress' Bill Summary & Status for the 107th Congress on H.R. 3763 and S.2673. I collect all SEC rulemaking events related to implementation of SOX provisions in the post-SOX period from the SEC website on Sarbanes-Oxley rulemaking and reports (http://www.sec.gov/spotlight/sarbanes-oxley.htm). [7] The selection of events does not involve subjective judgments. I exclude SEC rules exclusively related to auditors, lawyers, and investment companies, as well as SOX provisions for which the SEC is not required to implement rules. Table 1 provides a complete list of events and summarizes each SEC rule and the exemptions applicable to FPIs. The final sample consists of 23 events, for a total of 82 trading days. The pre-SOX event sample is similar to those used in other studies of U.S. and foreign issuers.[8]

[Insert Table 1 near here]

I identify Level II and Level III American Depositary Receipts (ADRs) between January 1, 1999 and December 31, 2003 with share codes between 30 and 39 from the Center for Research in Security Prices (CRSP). I identify Canadian and Israeli firms directly listed in the U.S. with Compustat country codes 9 and 49. Combining the two samples produces the sample of cross-listed FPIs. I obtain information on country of incorporation from the Bank of New York Depositary Receipt Services and Compustat. Cross-checking with the SEC website yields corrections for several FPIs that incorporate in tax havens such as Bermuda. I identify OTC-complying FPIs from the SEC website. I also obtain the list

[7] The SEC usually first solicits comments on a proposed rule and then issues a final rule after the commenting period ends. The SEC also typically issues a press release, with a brief summary of the proposed or final rule, a few days before the official releases. Consultations with SEC staff indicate that detailed information about rules is unavailable until the official release dates. Thus, I include the dates of the press releases and official releases for both proposed and final rules. To the extent that final rules closely resemble proposed rules, or official release does not change investor expectations much relative to the press release, inclusion of all these dates only biases against finding any significant abnormal returns.

[8] I include event days (0, +1) for each event. The results are similar for alternative event windows.

of all OTC-traded FPIs from the Bank of New York Depositary Receipt Services, the OTC Bulletin Board, and the National Quotation Bureau's Pink Sheets.

For cross-listed FPIs, I obtain accounting data from Compustat, U.S. stock returns from CRSP, and home country stock returns from Datastream. For OTC-traded FPIs, I get U.S. and home country stock returns from Datastream. Specifically, I download data in U.S. dollars from Datastream for all the companies for which I can calculate at least one daily return from any country for the period between January 1, 1999 and December 31, 2003. I create an equal-weighted FPI-free home country index for each country.

A total of 658 FPIs are listed in the U.S. on January 1, 2002. I require sample FPIs to have returns on all 82 event days to maintain consistency in the cross-sectional regressions. I further require that FPIs be selected from the 49 countries examined by La Porta et al. (1998) to ensure availability of country-level governance variables. This yields a final sample of 524 cross-listed FPIs with U.S. return data.[9] Matching these FPIs by company name and country produces a final sample of 376 cross-listed FPIs with home country return data. Using similar requirements, I generate a final sample of 96 OTC-complying FPIs with U.S. return data and 164 with home country return data, as well as a final sample of 603 OTC-exempt FPIs with U.S. return data and 523 with home country return data. The differences between the U.S. and home samples are due to data availability.

3.2. The short-term impact of SOX: Variables used for cross-sectional analysis

The second part of the analysis examines cross-sectional variation in the event period reactions of cross-listed FPIs. The focus here is on country- and firm-level governance characteristics. I use four country-level corporate law measures from La Porta et al. (1998): *Shareholder rights*, which measures protection from corporate laws; *Judicial efficiency*, which is produced by Business International Corp. and measures law enforcement quality; *Rule of law*, which is produced by International Country Risk and assesses the law and order tradition; and *Accounting standard*, which is produced by the Center for

[9] I adopt these restrictions to generate a consistent sample. The results are stronger without the restrictions.

International Financial Analysis and Research (CIFAR) and measures disclosure quality via corporate financial reports. I take two securities law measures from La Porta et al. (2006): *Public enforcement*, which is an index of the characteristics and power of the main government agency supervising stock exchanges; and *Disclosure standard*, which is an index of disclosure requirements related to insider compensation and ownership, irregular contracts, major shareholders, prospectuses, and related-party transactions. I include two firm-level variables related to institutional monitoring: *II block* represents institutional blockholdings at the end of 2001 obtained from Form 20-F and proxy filings, and *Analyst coverage* is the number of analysts covering each issuer in 2001 from the Institutional Brokers' Estimate System (I/B/E/S).[10] For each of these variables, the larger the variable, the better the investor protection.

In addition to governance characteristics, I include several control variables. *Log (GDP)*, a common measure of country-level financial development, is the natural logarithm of average per capita gross domestic product (GDP) between 1999 and 2001 obtained from the World Bank's World Development Indicators database (www.worldbank.org). FPIs from countries with more developed financial markets should find raising capital in home markets easier. Thus, such FPIs should be less adversely affected if SOX compliance forces them to exit U.S. markets. *Non-II block* is the percentage of non-institutional blockholdings, obtained from Form 20-F and proxy filings.[11] *Log (TA)* is the natural logarithm of total assets and controls for firm size. SOX compliance is more costly for small firms if it entails a significant fixed cost. However, given the generally large size of cross-listed FPIs, this effect may not be pronounced. *PPEPCT* is property, plant, and equipment as a percentage of total assets, and it controls for information asymmetry. For example, a negative impact of SOX should be exacerbated by higher information asymmetry as measured by lower *PPEPCT*. *Sales growth,* one-year sales growth,

[10] Because I hand-collect shareholdings from Form 20-F and proxy filings, and these filings generally do not report owners of less than 5% and sometimes less than 10% of total shareholdings (especially for many Canadian issuers), the reported holdings in this paper are blockholdings. The holdings include cases in which related parties jointly possess blockholdings even if each individually owns less than 5%.

[11] *Non-II Block* represents the control rights of both insiders and outsiders such as management, family, and multinational corporations. Using cash flow rights or excluding outsiders without board representation does not change the conclusion but would result in a lower level of reported non-institutional blockholdings.

controls for growth opportunities. SOX compliance is likely to hurt high-growth firms by constraining financial and operational flexibility.

I also include four market friction measures. *Short sale*, which comes from Bris et al. (2007), is an indicator variable that takes the value of one when investors cannot sell shares short in a particular country and zero otherwise. Short-sale constraints are likely to reduce negative reactions. *Time zone,* the absolute number of time zones separating a country's main stock exchange from New York, controls for asynchronous trading. *Illiquidity*, the Amihud (2002) firm-level illiquidity measure for the U.S. market, is the average ratio of daily absolute returns to dollar trading volume on a given day (multiplied by 10^6). *Synchronicity,* a measure of information-based barriers proposed by Morck et al. (2000), assesses the extent to which stocks in a given country move together. No clear prediction can be made about *Illiquidity* or *Synchronicity*. For example, *Illiquidity* may deter large investors from investing and, therefore, hinder investor sentiment from being reflected in stock prices. However, it may also enable investors to influence stock price with less trading.

Part of the cross-sectional analysis also includes the going-dark probability obtained from a probit model that I describe in Subsection 4.2. The corporate and securities law measures are independent variables. If better-governed FPIs are more likely to go dark, that would suggest that SOX is excessively costly and may be forcing out better-governed FPIs. I also include non-institutional blockholdings. If SOX is detrimental to controlling shareholders, FPIs with such shareholders would be more likely and more easily to go dark, suggesting a positive coefficient estimate for this variable. I include four additional variables, *Cross-listing market cap, U.S. volume*, *Sales growth,* and *Log (TA)*, and expect negative coefficient estimates for all of them. *Cross-listing market cap* is the market value of equity from CRSP, which represents the market value of FPIs in the form of cross-listed shares in the U.S. divided by company market value from Compustat. Missing data are supplemented with data hand-collected from Form 20-F or proxy filings. *U.S. volume* is U.S. dollar trading volume as a proportion of FPIs' total trading volume in 2001. Negative coefficient estimates on the first three of the four variables would underscore the importance of U.S. markets to cross-listed FPIs. Because smaller firms can more easily go dark according to the SEC deregistration regulation, I expect a negative coefficient estimate on *Log (TA)*.

3.3. The long-term impact of SOX: The going-dark sample

To obtain the list of cross-listed FPIs that went dark over the 12-year sample period (1995–2006), I first compile all cross-listed FPIs between January 1995 and December 2005 using CRSP and Compustat.[12] The sample ends in 2005 to allow time for FPIs to deregister, because meeting the asset and shareholder requirements for deregistration usually takes some time after delisting even if FPIs intend to deregister sooner. In addition, an investigation of post-dark FPI characteristics requires several post-dark years. After I exclude cross-listed FPIs that delist due to mergers, bankruptcies, or liquidations according to CRSP delisting codes, I identify 141 FPIs that could have delisted voluntarily. Requiring sample FPIs to have filed Form 15 to deregister by the end of 2006 eliminates 12 FPIs.[13] I determine the earliest dates of delisting and deregistration announcements from press releases and newswire announcements, as documented by ProQuest and Factiva, or from SEC filings such as Form 6K and proxy statements. Examination of these documents reveals that many FPIs announce their intention to delist and deregister before the official delisting and deregistration dates. Examining these documents also eliminates 67 FPIs that delist in home countries, become private, are acquired, or are liquidated within a year of either official U.S. delisting or deregistration. I further eliminate six FPIs whose stock price is less than one unit of the home country currency at the time of announcement due to likely financial distress. These 73 eliminations (67 + 6) are an important distinction from Hostak et al. (2013) and Leuz et al. (2008). I exclude four more FPIs due to lack of return data. I obtain the home market stock returns for the final sample of 52 going-dark FPIs from Datastream.[14]

[12] Although OTC-complying FPIs can also go dark, I focus on the FPIs once listed on U.S. stock exchanges, due to data availability.

[13] For FPIs that filed multiple Form 15s, I use the date of first filing.

[14] The relatively small number of going-dark FPIs is consistent with the claim that exiting from U.S. reporting obligations is difficult for FPIs.

Going-dark FPIs are unique in that they continue to report to home country securities authorities, which allows me to obtain and compare their pre- and post-dark characteristics. I include five variables based on company financials in the six fiscal years around the going-dark fiscal year, from Worldscope, Form 20-F, or annual report filings.[15] *Tobin's Q,* a common measure of valuation, is the sum of total assets and market value of equity minus book equity, divided by total assets. *Sales growth* is the most recent year's sales growth and proxies for growth opportunities. *ROA* is earnings before interest, taxes, depreciation, and amortization (EBITDA) divided by total assets, and *ROE* is EBITDA net of interest expenses and preferred dividends and then divided by book equity. Both proxy for operating performance. Following Leuz et al. (2008), *Earnings management*, a measure of earnings quality, is the absolute value of accruals divided by the absolute value of operating cash flows. I also include three board characteristics and three blockholder variables obtained from Form 20-F or proxy filings, all drawn from the year before and the third year after going dark. *Board size* is the number of directors; *Non-executive directors* is the proportion of non-executive directors; and *Independent chairman* is an indicator for FPIs whose chairman is not also the chief executive officer (CEO). I also include *Largest holding*, the holding by the largest blockholder, as well as *II block* and *Non-II block*.

I include four analyst forecast-related characteristics from I/B/E/S, based on the 24 months of data around the going-dark months. *Forecast dispersion* is the 12-month average of the standard deviation of analysts' earnings forecasts. *Forecast error* is the absolute value of the 12-month average of actual earnings minus the median analyst forecast. *Forecast dispersion* and *Forecast error* are both deflated by the stock price at the beginning of the fiscal year. *Revision volatility* is the standard deviation of 12 monthly forecast revisions. Revisions are the current-month median forecast minus the previous-month median forecast. *Analyst coverage* is the number of analysts covering a given FPI. Following Lesmond et al. (1999), *Liquidity* is the proportion of days with zero returns during the 24 months surrounding the going-dark months. The data requirements for company financials and governance

[15] I use fiscal years 2005–2007 (2006–2007) as the post-dark years for FPIs that deregister in 2005 (2006) due to sample size concerns.

quality over several years further reduce the sample by three FPIs, which disappear from home country registrations less than two years after going dark.

3.4. Summary statistics

Table 2 reports summary statistics by country for the sample of cross-listed FPIs in the analysis of SOX's short-term impact. Panel A of Table 2 reports the mean and standard deviation of the measures of corporate and securities laws from La Porta et al. (1998, 2006) across all sample FPIs. For brevity, I do not reproduce these measures by country here. Panel B reports the mean of the rest of the variables across the firms within a country and for the whole sample. The sample FPIs are from 36 countries. Canada (139 FPIs), Israel (69), and the United Kingdom (66) have far more FPIs than any other country, as the country with the fourth-highest number of FPIs is France (23 FPIs). The sample FPIs are geographically diverse and somewhat diverse in legal origin, according to the classifications of La Porta et al. (1998). Prior studies have used some of these variables, but a few summary statistics are worth noting. Although approximately 17% (6 out of 36) of the sample countries have short-sale constraints, few sample FPIs (3%) are from those countries. About 44% of the total market cap and 31% of the total trading volume of sample FPIs are in the U.S., underscoring the importance of U.S. markets to these FPIs. Although controlling shareholders is prevalent in some foreign countries, average *Non-II block* for cross-listed FPIs is only about 9%.

[Insert Table 2 near here]

Given the paucity of comprehensive studies of the presence of controlling shareholders in FPIs after cross-listings, Panel C presents the distribution of non-institutional (non-II) blockholdings for all cross-listed FPIs in 2001 and for going-dark FPIs in the 1995–2006 period. The first two columns break down the distribution of non-II blockholdings for the 490 cross-listed FPIs used in cross-sectional analysis. Non-II blockholders are absent in 387 FPIs, and they own more than 20% in only 63, or 12.9% (= 63 / 490), of my sample FPIs. Although prior studies of FPIs in general have focused only on the controlling shareholder agency problem in firms with concentrated ownership, these results suggest that future studies of FPIs should also consider the managerial agency problem in diversely owned firms. Thus, I use agency problems to refer to both managerial and controlling shareholder agency problems throughout the rest of the paper unless otherwise specified. La Porta et al. (1998), by contrast, document an average ownership share of more than 45% on the part of the three largest owners in the ten largest non-financial domestic firms across 49 countries. The difference between my findings and theirs could be due to different sample periods or self-selection of FPIs (i.e., more diversely owned FPIs are more likely to cross-list, and FPIs reduce ownership concentration after cross-listing).

Columns 3–6 present the distribution of non-II blockholdings for the FPIs that go dark in the pre- and post-SOX periods. About 36% and 21% of going-dark FPIs have no non-II blockholdings in the pre- and post-SOX period, respectively, whereas about 55% and 63% of going-dark FPIs have total non-II blockholdings of greater than 20%. The higher proportion of going-dark FPIs with sizable non-II blockholdings than in the all-FPI sample suggests that controlling shareholders may play a significant role in going-dark decisions, as FPIs with large non-II blockholdings are unlikely to have gone dark without these blockholders' consent. The proportion of going-dark FPIs with controlling shareholders is not significantly different in the pre- and post-SOX periods at conventional levels. Further, the lack of substantial non-II blockholdings in many going-dark FPIs suggests that escaping from minority shareholder protections, even if sometimes present, may not be the only reason FPIs go dark.

4. Tests and results

4.1. The short-term impact of SOX: Abnormal returns around SOX-related events

This subsection examines the aggregate abnormal returns of a sample of cross-listed FPIs surrounding SOX-related events. Following Brown and Warner (1985), I measure abnormal returns with market model adjusted returns as follows:

$$A_{i,t} = R_{i,t} - \alpha_i - \beta_i R_{m,t}, \tag{1}$$

where $R_{m,t}$ is the day t return on the benchmark index, and α_i and β_i are ordinary least squares estimates of the market model estimation for the period between January 1, 1999 and December 31, 2001. Also, following the suggestion of Brown and Warner (1985), I use equal-weighted FPI-free home country indexes as benchmarks. While I provide the Brown and Warner (1985) *t*-statistic, I use bootstrapped *p*-values for inferences following Lo (2003) and Zhang (2007). Specifically, I draw non-event days over the 2002–2003 period equal in number to the duration of each event and calculate the cumulative abnormal returns on these non-event days. I repeat the drawing with replacement 10,000 times to obtain an empirical distribution for the event period abnormal returns. The one-tailed *p*-values are the proportion of the 10,000 abnormal returns drawn from non-event days that are greater than the event period abnormal returns. I double these proportions to obtain two-tailed *p*-values.

To track the development of SOX-related events, I divide them into three groups: pre-SOX events (Events 111), SEC proposed rule events (Events 12, 13, and 15–18), and SEC final rule events (Events 14 and 19–23). For brevity, the following discussion focuses on the aggregate abnormal returns and on the abnormal returns of the three groups of events.[16]

The trading periods for the U.S. and home markets are asynchronous for many FPIs. For example, when a SOX-related event is announced in the U.S., markets outside of the Americas are likely to respond to the news the next trading day, given their brief overlap in hours of operation, if at all, with U.S. markets. Asynchronous trading can be a problem in calculating U.S. abnormal returns for FPIs from countries outside of the Americas because the benchmark is FPI-free home country index. Thus, I match the U.S. returns of FPIs from the Americas on a given day with same-day FPI-free home country index returns and those of FPIs from other regions with next-day home country index returns.[17]

[16] I do not interpret the abnormal return of each event for two reasons. First, because the reaction to any event is likely to build on reactions to previous events, which in turn represents accumulated investor expectations up to the previous event, the reaction to any event says nothing about SOX-related legislation and implementation associated with the event. Second, selecting and interpreting events on the basis of anecdotal evidence can be arbitrary and controversial, and aggregate abnormal returns are much more important.

[17] Matching in different ways or adding up to three-day leading and lagging benchmark returns to Eq. (1) yields similar results.

Table 3 reports cumulative abnormal returns around SOX-related events for cross-listed FPIs in both the U.S. and home markets. It suggests a large and negative impact of SOX on cross-listed FPIs. The aggregate abnormal return is -9.63% for the U.S. sample of 524 cross-listed FPIs and -12.97% for the home sample of 376 cross-listed FPIs. Tracking the development of SOX-related events, the abnormal returns for pre-SOX legislative events are -9.55% and -11.05% in the U.S. and home markets, respectively, which suggests extreme investor pessimism about the significant costs imposed on FPIs by SOX. The abnormal returns for events related to the SEC's proposed rules are 3.59% and 2.11% in the U.S. and home market, respectively. The modest price rebounds in both markets indicate that the rules proposed by the SEC to implement SOX provisions raised some hope among investors that the SEC would be able to reduce certain costly SOX compliance requirements, moderating the damage caused by the passage of SOX. Most of the optimism fizzled, however, as the final releases of SEC rules yield abnormal returns of -3.67% and -4.04% in the U.S. and home market, respectively. The abnormal returns are all significant at the 1% level, according to both Brown and Warner *t*-statistics and the bootstrapped abnormal returns from the non-event period.[18] The proportion of the sample with negative reactions suggests that the results are not due to outliers.[19]

[Insert Table 3 near here]

These results are in line with the large negative abnormal returns for U.S. companies during events mostly leading up to the passage of SOX documented in Zhang (2007). Her sample events with significant reactions for U.S. issuers are roughly equivalent to Events 8–10 in my sample. Except for the insignificant reaction of Event 10, Events 8 and 9 are among my sample events with the largest reactions.

[18] In untabulated results, signed tests and signed rank tests on median abnormal returns, as well as binomial tests with the null hypothesis that the proportion of negative abnormal returns is 0.5, yield similar results.

[19] Including only proposed rule events or only press release events for the post-SOX implementation events yields similar results. Although the U.S. stock market indexes are contaminated benchmarks, I include them in the market model estimation in addition to the FPI-free home country indexes, given that they are likely to affect the stock returns of cross-listed FPIs to some extent. Either way, the conclusions are the same in untabulated results.

Unlike Zhang's results, however, the large number of events with large and significant abnormal returns suggests that the impact of SOX on cross-listed FPIs is not driven by a small number of events.[20]

The signs and significance are similar for the abnormal returns in the U.S. and home markets across most individual events, with only Event 1 having different signs for its insignificant reactions. At first glance, the aggregate abnormal returns in the U.S. markets seem to be smaller in magnitude. This difference is due to the relatively less negative reactions of U.S. sample FPIs without home market returns. In untabulated results, the aggregate U.S. abnormal return of these FPIs is -4.45%, whereas that of the other FPIs is -11.67%.[21] The magnitude of aggregate U.S. abnormal returns for the 376 FPIs with both U.S. and home market returns is only 1.30% smaller [= -12.97% – (-11.67%)], and this difference is statistically insignificant.

Because OTC-traded FPIs with SEC reporting obligations must comply with SOX and the OTC-traded FPIs without SEC reporting obligations are exempt from SOX compliance, SOX-related events should affect the returns of the first group in ways consistent with those of cross-listed FPIs but should not affect the returns of the second group. I therefore examine OTC-complying FPIs and OTC-exempt FPIs. Panel A of Table 4 shows the abnormal returns of OTC-complying FPIs as -5.45% and -5.17% in the U.S. and home market, respectively, both statistically significant at the 1% level according to bootstrapped *p*-values. In addition, the abnormal returns of FPIs without SOX compliance are -1.02% and -1.26% in the U.S. and home market, respectively, both statistically insignificant. The significantly negative reactions of OTC-complying FPIs and the little reactions of OTC-exempt FPIs to SOX-related events both support the conclusion that the significantly negative abnormal returns of cross-listed FPIs are due to SOX compliance.[22]

[20] Zhang (2007) finds four events with large and significant abnormal returns among her 17 sample events spanning from January to July 2002.

[21] Compared with other cross-listed FPIs, the FPIs that are in the U.S. but not the home country sample are much smaller. Their average total assets are $212 million, compared with $2.3 billion for other cross-listed FPIs.

[22] The abnormal return differences between cross-listed and OTC-exempt FPIs, and between OTC-complying and OTC-exempt FPIs, are significant at the 1% level. The much smaller magnitude of abnormal returns for OTC-complying FPIs in comparison with cross-listed FPIs may be due to the smaller firm size of OTC-complying FPIs. It would be much easier for the smaller OTC-complying FPIs to go dark as stipulated by the SEC deregistration

[Insert Table 4 near here]

4.1.1.Additional tests on abnormal returns around SOX-related events

I conduct robustness tests of inferences about the event period reactions of cross-listed FPIs. For brevity, I report only the aggregate abnormal returns across all 23 events. First, I create 36 equal-weighted country portfolios, using sample FPIs within each country, and evaluate their abnormal returns. This approach adjusts for within-country cross-sectional correlation. The first row of Table 4, Panel B shows that these abnormal returns are negative and significant at the 1% level in both the U.S. and home markets.[23] The second row of Panel B reports the results after excluding any Datastream daily return for cross-listed FPIs that exceeds 25% in absolute value, following Morck et al. (2000). I recreate the FPI-free home country index returns by trimming all the returns from Datastream. For consistency, because CRSP data also contain large daily returns, I trim the U.S. stock returns of cross-listed FPIs from CRSP. The results are similar to those in Table 3. Using other trimming thresholds does not affect the results. Thus, return outliers are unlikely to drive the results.

Directly listed Canadian and Israeli FPIs account for about 40% of the sample. Such FPIs could behave differently from ADRs (e.g., the SEC historically has given more exemptions to Canadian FPIs). The third row shows that my conclusions are robust to excluding these FPIs. I also use Morgan Stanley Capital International (MSCI) country indexes as benchmarks. The drawbacks of MSCI indexes are that they are value-weighted and that their inclusion of FPIs subject to SOX compliance makes them contaminated benchmarks for my purposes. However, these drawbacks allow for addressing concerns

regulation. Investors may also expect some SOX provisions to be implemented with a delay or exempted for the smaller OTC-complying FPIs.

[23] The abnormal returns are smaller in magnitude for country portfolios than those for Table 3. The difference is likely to result from the fact that the country portfolio analysis in Table 4 gives equal weight of 1/36 to each country portfolio and, thus, a weight of 1/(36N) to each stock in a country with *N* stocks. This weighting scheme means that FPIs from countries with a larger number of cross-listing would have a much lower weight than FPIs from countries with a smaller number of cross-listings. In comparison, each FPI is given an equal weight in the FPI-level analysis in Table 3. Because Table 2 shows that more FPIs are from countries with better governance and Table 5 reports that FPIs from countries with better governance have significantly more negative abnormal returns during SOX-related events, the country portfolio analysis effectively gives less weight to FPIs with more negative abnormal returns, thus reducing the magnitude of observed abnormal returns.

related to benchmark-weighting schemes and for estimating the lower bound of the magnitude of abnormal returns. The fourth row reports that the abnormal returns are still highly significant. Unsurprisingly, the magnitude of the abnormal returns is smaller than that in Table 3.[24]

The fifth row shows that when I use market-adjusted returns, $A_{i,t} = R_{i,t} — R_{m,t}$, to measure abnormal performance, the conclusions are not affected. The sixth row shows the results when I also use the cross section of market-adjusted returns during the event period, instead of those of the estimation period, to estimate its variance. Brown and Warner (1985) recommend using this procedure to control for potential variance increases during the event period. Because this procedure ignores the estimation period data, it has weaker power if variance does not increase substantially. Nonetheless, the abnormal returns are still significant at the 1% level.

Many other countries have also conducted legislative or code reforms of corporate governance. These reforms are generally in the spirit of SOX but more limited in scope.[25] Few legislative reforms elsewhere overlap with SOX-related events. In untabulated results, I find qualitatively the same results by excluding cross-listed FPIs on the days of their home reforms. Overall, my results hold for various robustness checks.

4.2. The short-term impact of SOX: Cross-sectional analysis

Given my finding in Subsection 4.1 that SOX has a detrimental effect on cross-listed FPIs, exploring which firms are more affected can be interesting. Given SOX's far-reaching impact on governance, if the abnormal returns around SOX-related events are attributable to SOX, I expect them to have significant relation with the firm-specific and country-level governance characteristics discussed in Subsection 3.2. I, however, have no prediction about the sign of the relation for a specific characteristic.

[24] Although MSCI country indexes are supposed to include about 85% free float-adjusted market capitalization in a country, gauging whether MSCI offers more far-reaching coverage of international stock markets than Datastream is difficult.

[25] See Appendix 2 of Li (2011) for details.

A positive (negative) sign for a characteristic would suggest that SOX has a relatively less detrimental impact on better-governed (worse-governed) FPIs along the dimension of that characteristic.

Anecdotal evidence suggests that better-governed FPIs suffer more from SOX. When Congress first introduced SOX in 2002, foreign companies and governments expressed grave concern about its application to cross-listed FPIs on the grounds that it could contradict or interfere with FPIs' home country regulation and substantially increase the cost of U.S. listings. Western European countries, which generally enjoy better governance, expressed the strongest resistance. Despite these objections, Congress granted the SEC only limited power to accommodate FPIs' home country requirements.

In Table 5, Panel A reports the results of cross-sectional analysis of the abnormal returns of individual FPIs on the 82 event days. I cluster standard errors within countries.[26] Given the different scales of independent variables, I focus on a variable's marginal effect, calculated as its coefficient estimate in Panel A of Table 5 multiplied by its standard deviation in Table 2, in my interpretation of the results. Marginal effects measure the percentage point change in abnormal returns given a one-standard deviation increase in a variable of interest.

[Insert Table 5 near here]

My discussion first focuses on the significant variables for U.S. abnormal returns in column (1), and then compares them to those for the home country abnormal returns in column (2). Three corporate law measures have highly significant impacts on the U.S. abnormal returns. *Shareholder rights* has a coefficient estimate of 5.31. Given a standard deviation of 1.37, its marginal effect is 7.27% (= 5.31 * 1.37%). Similarly, *Judicial efficiency* and *Rule of law* have marginal effects of -3.99% and -9.28%, respectively. Both securities law measures and both institutional monitoring measures have significant impacts on the U.S. abnormal returns. *Public enforcement* and *Disclosure standard* have marginal effects

[26] Additional analysis using bootstrapped *p*-values to gauge the significance level yields similar results.

of -0.07% and -5.67%, respectively.[27] *II block* and *Analyst coverage* have marginal effects of -0.30% and -2.61%, respectively.

The significant relation between the governance measures and the event period reactions of cross-listed FPIs are consistent with the idea that these event period reactions are attributable to SOX. All the significant governance measures are negatively related to abnormal returns except for *Shareholder rights*, which suggests that SOX is more detrimental or less beneficial for better-governed FPIs. When combined with the substantial decline in the market value of cross-listed FPIs, this generally negative relation suggests that SOX is more detrimental for better-governed FPIs. My results suggest that combined with existing regulatory and firm-level governance mechanisms in the U.S. and in home countries, these new measures related to SOX are likely to have pushed the level of investor protection beyond the optimum.

The coefficient estimates on the going-dark probability are positive and significant at the 10% level, which suggests that SOX imposes excessive costs and that FPIs that are more likely to go dark may be able to avoid these costs. *Non-II block* has a negative effect, which is likely due to SOX targeting managerial agency problems in diversely owned U.S. issuers and thus producing less effective and more costly solutions for cross-listed FPIs with relatively more controlling shareholder agency problems.

The results of governance-related variables shown in Column 2 for home market abnormal returns are similar to those for U.S. abnormal returns. Specifically, the differences are that disclosure standard is insignificant, that *Rule of law* and *Analyst coverage* are less significant, and that *Judicial efficiency* is more significant. Further, the statistically significant control variables are largely the same in Columns 1 and 2, and they have the expected signs. Financial development and short-sales restrictions reduce the negative event period reactions, and firms with greater information asymmetry and growth opportunity experience more negative event period reactions.[28]

[27] Because the governance variables are correlated, I also examine them individually. The results are similar, except that the coefficient estimate on *Accounting standard* is negative and significant at the 10% level.

[28] Because only 3% of the sample FPIs is from countries with short-sale constraints, the economic significance of short-sale constraints is much smaller than the magnitude of this coefficient estimate suggests. The insignificant impact of *Time zone* suggests that asynchronous trading between the U.S. and home markets should not affect the results of U.S. abnormal returns in Subsection 4.1.

I obtain the going-dark probability used in Panel A with a probit model whose dependent variable is an indicator that equals one for the 24 FPIs and the 18 FPIs with available data for my U.S. and home sample, respectively, that go dark by the end of 2006 and zero otherwise. In addition to producing the going-dark probability, this analysis yields some inferences about the determinants of FPIs' going-dark decisions. Panel B of Table 5 reports that all the statistically significant independent variables have coefficient estimates with predicted signs. Specifically, *Accounting standard* and non-institutional blockholdings have positive coefficient estimates, and *Cross-listing market cap, Sales growth,* and *Log (TA)* have negative coefficient estimates. Thus, firms with better accounting standard and more controlling shareholdings are more likely to go dark, and firms relying more on U.S. capital markets are less likely to go bark. Overall, the results in this subsection suggest that SOX is more detrimental to better-governed FPIs.

4.3. The long-term impact of SOX: Delisting and deregistration of cross-listed FPIs that go dark

This subsection examines firms' and shareholders' long-term responses in the years following the passage of SOX. It compares across the pre- and post-SOX periods the number of going-dark FPIs, their going-dark returns, and their characteristics such as governance, growth, and performance to determine whether SOX increases the cost of compliance substantially.

The top half of Table 6, Panel A reports the annual number of going-dark FPIs that delist or deregister. During the three and a half years leading up to the passage of SOX, 12 FPIs delist and 11 FPIs deregister voluntarily. By comparison, 38 FPIs delist and 40 deregister voluntarily in the three and a half years after passage. The substantial post-SOX increase in going-dark FPIs is consistent with the findings of Leuz et al. (2008) and Marosi and Massoud (2008). More FPIs decide to leave the U.S. market and regulatory regime after the passage of SOX.

[Insert Table 6 near here]

The growing number of going-dark FPIs is unlikely due to an increase in either total listings or delistings. The lower half of Table 6, Panel A presents annual numbers of new listings and delistings, as well as annual totals of cross-listed FPIs. Both delistings and total listings have declined after 2002. Meanwhile, going-dark FPIs as a percentage of delistings and of total listings increase in the post-SOX period, as shown in the top half of Table 6, Panel A. Further, new listings declined substantially in the post-SOX period. The 3.5-year periods preceding and following the passage of SOX have 292 and 156 new listings, respectively. Although listings and delistings may be affected by other factors, the overall evidence suggests that they are not driving the increase in going-dark FPIs in the post-SOX period.

The increase in going-dark FPIs in the post-SOX period cannot in itself reveal anything about the impact of SOX, due to possible alternative explanations discussed below. Thus, I further examine the going-dark returns and changes in FPI characteristics from the pre- to the post-dark phase. Those characteristics fall into the categories of operating performance, earnings and governance quality, institutional environment, liquidity, growth opportunities, and valuation.

The increase in going-dark FPIs in the post-SOX period could be due to more reduced growth potentials, more severe agency problems, or increased compliance costs due to SOX (Leuz et al., 2008). Compared with the pre-SOX period, if the explanation for FPIs going dark is increased compliance costs, I would predict both (1) relatively higher going-dark returns as FPIs escape costly compliance, and (2) similar or improved changes in all FPI characteristics from the pre- to the post-dark phase during the post-SOX period. In comparison, if the explanation for FPIs going dark is more reduced growth potentials, I would predict relatively lower going-dark returns as investors realize that future growth will be more subdued and worse changes in post-dark growth potentials but similar or improved changes in other FPI characteristics in the post-SOX period. If increased agency problems is the explanation, I would predict relatively lower going-dark returns as (minority) shareholders vote with their feet for fear of exploitation, worse changes in post-dark governance characteristics, and similar or improved post-dark changes in other characteristics in the post-SOX period.

Evidence from any of the above tests could be relatively weak because small samples do not allow controls for other effects with multivariate regressions and these are not mutually exclusive explanations. However, if the results from these largely independent tests are highly consistent with one explanation, I may be able to draw stronger inferences.

Panel B of Table 6 reports the value-weighted home market returns of going-dark FPIs at the delisting and deregistration announcements, adjusted by the returns of the respective MSCI home country indexes using a market model. The estimation period is the (-510, -11) event day window. The panel reports results for the periods before and after July 30, 2002, the date of SOX's final passage. It also provides the number of observations with positive abnormal returns.

I examine both delisting and deregistration abnormal returns because at the time of delisting announcements investors may expect going-dark FPIs to eventually deregister. FPIs also frequently announce their intention to deregister at the time of delisting. For 25 sample FPIs, the delisting and deregistration dates are separated by at least a month. I use home market returns because they are free of issues such as asynchronous trading and because FPIs are rarely traded in the U.S. after deregistration due to the lack of Rule 12g3-2(b) exemption (see Appendix A for details). Also, trading in the U.S. is usually limited prior to going dark. Most FPIs cite limited trading and liquidity in U.S. markets as the main reasons to go dark.

Panel B shows that the delisting and deregistration abnormal returns of going-dark FPIs are both negative in the pre-SOX period. The same returns in the post-SOX period are not only relatively higher than those in the pre-SOX period, but they are also positive. The abnormal returns are large in magnitude but generally statistically insignificant, possibly due to the small sample size. Tests indicate that the differences between abnormal returns in the pre- and post-SOX periods are significant at the 5% level. The number of positive abnormal returns for delistings (deregistrations) is three and 24 (three and 26) for the pre- and post-SOX period, respectively. Given that about half of my sample has different delisting and deregistration dates, my results are consistent with Leuz et al. (2008), who show that delistings and deregistrations are separate events. In untabulated results, I find similar results for different event windows around the announcement dates. Thus, the results for going-dark returns are consistent with the explanation of increased compliance costs due to SOX.

Panel C of Table 6 reports the median characteristics of FPIs before and after they go dark, as well as changes in these characteristics. To formally gauge the impact of SOX, Column 7 reports the significance level of the difference between changes in FPI characteristics from the pre- to the post-dark phase in the pre-SOX period in Column 3 and those in the post-SOX period in Column 6. Relative to going-dark FPIs in the pre-SOX period, those in the post-SOX period exhibit a larger reduction in non-institutional blockholdings, forecast dispersion, and revision volatility, a greater increase in *ROA*, *ROE*, and *Tobin's Q*, a smaller increase in earnings management, and a smaller reduction in liquidity from the pre- to the post-dark phase. Thus, going-dark FPIs in the post-SOX period exhibit more favorable changes on many dimensions.[29] These results are consistent with the explanation of increased compliance costs due to SOX.

To further gauge the impact of SOX, I compare the pre-dark characteristics of going-dark FPIs in the pre- and post-SOX periods (Column 1 versus Column 4). Better pre-dark characteristics in the post-SOX period would be consistent with increased compliance costs, not the two alternative explanations (more reduced growth potentials or more severe agency problems). This is the case for every pre-dark characteristic that is significantly different between the pre- and post-SOX periods as reported in Column 8 of Table 6: relatively better sales growth and operating performance, smaller magnitude of the largest blockholdings, forecast errors, forecast dispersion, and greater magnitude of institutional blockholdings. These characteristics show no sign of either reduced growth potentials or agency problems in the pre-dark phase during the post-SOX period.

[29] Although going-dark FPIs in the post-SOX period exhibit a smaller reduction in forecast errors and a smaller increase in growth opportunities, it is likely that these FPIs already have far superior growth opportunities and smaller forecast errors before going dark, leaving less room for further improvement. For example, the forecast errors of going-dark FPIs in the post-SOX period drop from about 0.27 to 0.18 between the pre- and post-dark periods, and those in the pre-SOX period drop from about 0.69 to 0.24. After a much deeper drop from a much higher level of forecast errors, going-dark FPIs in the pre-SOX period still exhibit much larger forecast errors than going-dark FPIs in the post-SOX period during the post-dark phase. For sales, in the pre-SOX period, after a steep pre-dark decline of about 34%, a 35% post-dark sharp increase would still not help fully recover the pre-dark decline in sales for going-dark FPIs. In contrast, the post-SOX period witnesses a mild pre-dark increase in sales for going-dark FPIs, and the increase experiences a substantial post-dark acceleration.

As a robustness check, I examine a sample that includes FPIs distressed at delisting but deregistered through the voluntary conditions. The untabulated results, including six additional such FPIs with available data, are qualitatively the same.

In summary, the results suggest not only that SOX imposes net costs on shareholders in going-dark FPIs, but also that the net costs more than offset the extant net benefits from cross-listing for these FPIs.[30] Although the evidence from any single test is relatively weak, the consistent results of all the independent tests jointly provide stronger inferences.

5. Conclusion

I examine the short- and long-term impact of the Sarbanes-Oxley Act on cross-listed FPIs. Both short- and long-term results suggest that the costs of SOX compliance significantly exceed its benefits and reduce the net benefits of cross-listings. The results also suggest a need to consider both managerial and controlling shareholder agency problems in the studies of cross-listings.

[30] Due to the small sample size, I conduct *t*-tests on mean abnormal returns, signed tests, and signed rank tests on median abnormal returns and binomial tests with the null hypothesis that the proportion of negative abnormal returns is 0.5. All the results in this subsection are similar. Although it is ideal to use cross-sectional regressions to control for other FPI characteristics, I find insignificant difference for most FPI characteristics examined above, probably due to the small sample size.

Appendix A. How do FPIs acquire SEC reporting obligations and how can they go dark?

U.S. and foreign issuers listed or traded in the U.S. markets are required to comply with SOX provisions if they have Section 13(a) reporting obligations to the SEC. Under the current rules, an issuer attains Section 13(a) reporting obligations mainly by 1) listing on national securities exchanges and registering the securities under Section 12(b); 2) registering a class of equity securities under Section 12(g) either voluntarily or because it has 500 or more record holders and more than $10 million in total assets and, if an FPI, more than 300 U.S. beneficial holders; or 3) raising and registering debt or equity capital in the U.S. under Section 15(d).

Trading on Pink Sheets does not guarantee an exemption from the SEC. Under Rule 12g3-2(a), these FPIs are exempt from SEC reporting and other obligations if the number of worldwide record holders is below 300 (or with fewer than 500 worldwide record holders and less than $10 million assets). These FPIs are also exempt if the number of U.S. beneficial holders is below 300 (or with fewer than 500 U.S. beneficial holders and less than $10 million assets). To identify beneficial holders, issuers have to look through record holders such as financial institutions to determine ownership. Discussions with SEC staff indicate flexibility in the SEC's granting of exemptions. The SEC usually exempts FPIs if they do not substantially exceed the above thresholds, i.e., some FPIs that would have to register according to the above thresholds are exempt from registration. Under Rule 12g3-2(b), these FPIs are exempt if they furnish to the SEC on an ongoing basis information they have made public or distributed or are required to make public or distribute under the laws and regulation that they are subject to outside of the U.S. The exempt firms do not have to deregister because they have never registered.

Regarding the FPIs with SEC reporting obligations, the deregistration regulation changed with the passage of Section12h-6 and amendments to 12(g) in March 2007. Before the new regulation, if FPIs have raised capital in the U.S., as in case 3) above, they can only suspend, not terminate, their obligation to file periodic reports under Section 12h-3. They must always meet the asset and shareholder threshold requirements of 12(g) to avoid reporting. If FPIs have listed shares only in the U.S., as in case 1), they can terminate Section 12(b) reporting obligations by delisting. However, they are automatically subject to the 12(g) reporting obligations if they meet the criterion of 12(g). These delisted FPIs [under Rule 12g-4(a)], as well as reporting OTC FPIs (under 12h-3), can deregister only if they do not exceed the asset and shareholder thresholds.[31]

After deregistration, FPIs are not eligible for Rule 12g3-2(b) exemptions for at least 18 months according to Rule 12g3-2(d)(1). Rule 12g3-2(b) exempts FPIs from registration even if they exceed the asset and shareholder thresholds. The lack of exemptions creates two significant complications for

[31] Under Exchange Act Rule 12g-4(a)1, FPIs and U.S. issuers can deregister if they have fewer than 300 holders of record worldwide (or fewer than 500 worldwide record holders and with assets totaling less than $10 million). Under Exchange Act Rule 12g-4(a)2, FPIs can also deregister under the same conditions, except that the holders are defined as U.S. beneficial holders.

deregistered FPIs. First, these FPIs have to renew registration if they exceed the asset and shareholder thresholds within 18 months. Second, without Rule 12g3-2(b) exemptions, meeting Rule 15c2-11 requirements for trading on Pink Sheets is difficult. Because a market maker rarely quotes the shares of deregistered FPIs on Pink Sheets without the exemption, these FPIs usually have to wait 18 months before their shares can be traded in the U.S. again, even if they want to be traded on Pink Sheets.

The new 12h-6 issued in March 2007 provides a second way to deregister in addition to Rule 12g-4(a). It further allows all reporting FPIs [FPIs under 12(b), 12(g), or 15(d)] to deregister if the U.S. average daily trading volume (ADTV) of the class of securities in the U.S. over a recent 12-month period is no greater than 5% of the worldwide ADTV. Upon deregistration through 12h-6, FPIs are immediately eligible for Rule 12g3-2(b) exemptions. The amended 12(g) in March 2007 also allows 15(d) FPIs to deregister under asset and shareholder thresholds. The new regulation has also relaxed deregistration process in several other important ways.

In February 2008, the SEC issued proposed rules to further amend 12(g) to streamline the Rule 12g3-2(b) exemption process, as well as affording 15(d) FPIs immediate eligibility for Rule 12g3-2(b) exemptions upon deregistration through Rule 12g-4(a).

Examples of pre-SOX accommodations made by the SEC for foreign private issuers

Before the enactment of SOX, the SEC made considerable accommodations for FPIs. In general, governance issues were left to home jurisdictions, while reporting rules were applied with extensive reductions in requirements. Since 1979, the SEC has exempted FPIs from quarterly financial reports, Sections 14a–14c proxy rules, Section 14f tender offer rules, and Section 16 short swing profit rules. In 1999, the SEC adopted exemptive rules for cross-border and exchange offers, business combinations, and rights offerings related to the securities of FPIs. In 2000, the SEC exempted FPIs from Regulation Fair Disclosure (Regulation FD) when it was adopted. The SEC has also adopted procedures to accommodate the scheduling needs of FPIs and policies allowing for confidential treatment of filings that would be public for U.S. issuers. Further, the SEC has created separate forms with less disclosure for FPIs, instead of requiring that they file the same forms as U.S. issuers. For example, since 1979, the SEC has allowed FPIs to file Form 20-F instead of Form 10-K. Since 1982, FPIs can use Forms F-1, F-2, and F-3 for initial public offerings, instead of Forms S-1, S-2, and S-3. In 1985, when the SEC introduced Form S-4 for certain reclassifications, mergers, consolidations, and acquisitions, it allowed FPIs to file Form F-4. Canadian issuers have additional exemptions. Canadian firms file Form 40-F instead of Form 10-K. Since 1991, although still governed by U.S. antifraud rules, the top end of the Canadian market can use Canadian forms for registration.

Appendix B. Variable definitions

B.1. Variables used in cross-sectional regression analysis	
Shareholder rights	Strength of corporate laws to protect shareholder rights from La Porta et al. (1998).
Judicial efficiency	Efficiency and integrity of the legal environment from La Porta et al. (1998).
Rule of law	Law and order tradition assessment from La Porta et al. (1998).
Accounting standard	Index to determine the quality of financial disclosures from La Porta et al. (1998).
Public enforcement	Index of the characteristics and the power of the main government agency in charge of supervising stock exchanges from La Porta et al. (2006).
Disclosure requirements	Index of disclosure requirements from La Porta et al. (2006).
Log (GDP)	Natural logarithm of average per capita GDP for a country from 1999 through 2001 .
Log (TA)	Natural logarithm of total assets in millions of dollars.
PPEPCT	Property, plant, and equipment as a percentage of total assets.
Sales growth	One-year sales growth.
Cross-listing market cap	Market value of FPIs in the U.S. as a proportion of FPIs' total market value.
U.S. volume	U.S. dollar volume as a proportion of FPIs' total trading volume.
Non-II block	Percentage of stockholding by non-institutional blockholders.
II block	Proportion of a firm's common shares held by institutional blockholders.
Analyst coverage	Number of analysts covering each issuer from I/B/E/S.
Short sale	Indicator for countries prohibiting investors from selling shares short
Time zone	Absolute number of time zones separating a given country's main stock exchange from New York.
Illiquidity	Amihud (2002) stock illiquidity.
Synchronicity	Country-level measure of information-based barriers from Morck et al. (2000).
Going-dark probability	Predicted probability of FPIs voluntarily delisting and deregistering
B.2. Additional variables used in going-dark analysis	
Board size	Number of directors.
Non-executive directors	Proportion of non-executive directors.
Independent chairman	Indicator for FPIs with the chairman being different from the CEO.
Largest holding	Holding by the largest blockholder.
Earnings management	Absolute value of accruals divided by the absolute value of operating cash flows.
Forecast dispersion	12-month average of the standard deviation of analysts' earnings forecasts deflated by the stock price at the beginning of the fiscal year.
Forecast error	Absolute value of the 12-month average of actual earnings minus the median analyst forecast deflated by the stock price at the beginning of the fiscal year.
Forecast revision	Standard deviation of 12 monthly forecast revisions, with revisions being the current-month median forecast minus previous month median forecast.
Liquidity	Proportion of days with trading from Lesmond et al. (1999).
ROA	EBITDA divided by total assets.
ROE	EBITDA net of interest expenses and preferred dividends divided by book equity.
Tobin's Q	Sum of total assets and market value of equity minus book equity, divided by total assets.

Table 1.
Events pertaining to passage of the 2002 Sarbanes-Oxley Act and related Securities and Exchange Commission (SEC) rules

Event	Date	Description	Event window
1	1/17/2002	SEC chairman Harvey Pitt recommends establishing an accounting oversight board.	1/17–18
2	2/11–12/2002	Legislation to be introduced in the House.	2/11–15
	2/14/2002	Introduction of H.R. 3763 to the House.	
3	4/22/2002	Committee report issued on H.R. 3763.	4/22–26
	4/24/2002	House of Representatives passed H.R. 3763.	
	4/25/2002	Senate Judiciary Committee approves legislation.	
4	6/11/2002	Progress reported on Senate legislation.	6/11–13
	6/12/2002	Mark-up of Sarbanes bill to occur.	
5	6/18/2002	Senate Banking Committee approves S.2673.	6/18–19
6	6/25/2002	Introduction of S. 2673 to the Senate.	6/25–26
7	7/3/2002	Committee reports on S.2673.	7/3–5
8	7/8–12/2002	Senate deliberation on S. 2673.	7/8–17
	7/15/2002	Senate passed S. 2673. House introduced H.R. 5118.	
	7/16/2002	House passed H.R. 5118.	
9	7/19/2002	Conference committee meeting.	7/19–22
10	7/24/2002	Conference report issued.	7/24–26
	7/25/2002	Congress passed conference report. Bush reportedly will sign the bill.	
11	7/30/2002	Bush signed into law the Sarbanes-Oxley Act of 2002. Final rules to implement Section 304 (forfeiture of compensation and securities related profits) and Section 402 (prohibition on personal loans) became effective immediately.	7/30–31
12	8/2/2002	SEC approves and releases proposed rules to implement Section 302 (management certification of financial statements).	8/2–5
		SEC, in a departure from the original statute, decides to include foreign private issuers for Section 302 compliance as required by SOX.	
13	8/6/2002	SEC approves and releases proposed rules to implement Section 403(a) (accelerated insider transaction reports).	8/6–7
14	8/27/2002	SEC approves final rules to implement Sections 302 and 403(a).	8/27–30
		SEC releases final rules to implement Section 403(a).	
	8/29/2002	SEC releases final rules to implement Section 302.	
15	10/16/2002	SEC approves proposed rules to implement Sections 303 (prohibition of actions designed to improperly influence auditors), 404 (internal controls and procedures), 406 (code of ethics), and 407 (financial experts on audit committee).	10/16– 23
	10/18/2002	SEC releases proposed rules to implement Section 303.	
	10/22/2002	SEC releases proposed rules to implement Sections 404, 406, and 407.	
16	10/30/2002	SEC approves proposed rules to implement Sections 401(a) (disclosure of off-balance sheet arrangements), 401(b) (also called Regulation G, conforming to Generally Accepted Accounting Principles), and 306(a) (prohibition of insider trading during pension plan blackout periods).	10/30–31, 11/4–7
	11/4/2002	SEC releases proposed rules to implement Section 401(a).	
	11/5/2002	SEC releases proposed rules to implement Section 401(b).	

Table 1 – Continued

Event	Date	Description	Event window
	Exemptions:	*Section 401(a):* No exemption. Since FPIs file only annually with SEC, their cost should be lower. *Section 401(b):* Limited exemption for disclosure other than documents such as 20-F. *Section 306(a):* 1) Does not apply to management employee directors. 2) Use a different calculation (15%+50% tests) to determine insider trading prohibition.	
17	12/18/2002	SEC approves proposed rules to implement Section 403 (electronic filing of insider ownership reports).	12/18–21
	12/20/2002	SEC releases proposed rules to implement Section 403.	
18	1/8/2003	SEC approves and releases proposed rules to implement Section 301 (compliance with the audit committee requirements).	1/8–9
	Exemptions:	1) The rules do not apply to non-management employees on board, where board means supervisory or non-management board in two-tier board system. 2) The entire board can be designated audit committee without setting up separate committee. 3) Controlling shareholders can send one observation member to the audit committee. 4) Foreign government can send a representative to be one member of the audit committee. In 3) and 4), the member needs to be a non-management member. 5) Bodies such as board of auditors can substitute for auditor committee if requirements are met, e.g., as in Japan. 6) There is also an exemption for the board of a dual holding company.	
19	1/15/2003	SEC approves and releases final rules to implement Sections 306 (a), 401(b), 406, and 407.	1/15–16
	Exemptions:	*Section 406:* Disclose changes to code of ethics only in annual reports. *Section 407:* Foreign companies can disclose whether financial expert is independent later along with Section 301 requirements.	
20	1/22/2003	SEC approves final rules to implement Section 401 (a).	1/22–23, 1/28–29
	1/28/2003	SEC releases final rules to implement Section 401 (a).	
21	4/1/2003	SEC approves final rules to implement Section 301.	4/1–2, 4/9–10
	4/9/2003	SEC releases final rules to implement Section 301.	
	Exemptions:	1) Compliance by July 31, 2005, rather than 10/31/2004, the deadline for U.S. issuers. 2) Expanded exemption for dual holding company. 3) Amend Section 407 rules and set date of compliance to be July 31, 2005. If exemptions taken, need to disclose.	
22	4/24/2003	SEC approves final rules to implement Sections 303 and 403.	4/24–25, 5/7–8,
	5/7/2003	SEC releases final rules to implement Section 403.	5/20–21
	5/20/2003	SEC releases final rules to implement Section 303.	
23	5/27/2003	SEC approves final rules to implement Section 404.	5/27–28, 6/5–6
	6/5/2003	SEC releases final rules to implement Section 404.	
	Exemptions:	U.S. issuers must comply by 6/15/2004, whereas foreign issuers must comply by 4/15/2005.	

Table 2

Abstract
One of the most important subjects in the financial management is the systematic risk which has always been focused on by the researchers. Due to the vastness of the market, there exist different devices for the investment in every financial market. The main goal of the shareholders, business owners and those who are concerned is to produce the optimum return and they face some risks in order to reach their goals and the fundamental requirement is to keep the relation between the risk and the return balanced. In other words, the decision makers of the stock markets produce their desired return by using the financial information of the companies. Therefore, the investigation into the risk and the factors influencing the risk is of importance. This article studies the reliability of the accounting information upon the systematic risk. To test the hypothesis, the data obtained from 52 companies listed on the Tehran stock exchange from 2006-2010 were chosen by the systematic deletion method and were tested by using the multi-variable regression. The conclusion suggests that there is a significantly positive statistical relation between the reliability of accounting information and the systematic risk.

Key words: Reliability of accounting information, Accruals quality, Earnings quality, Systematic risk, Fama and French three-factor model.

JEL Classification: M41

Introduction

The information offered to the managers, the investors, and the other users should be qualitatively high. The purpose of financial invoices, the final production of accounting system, and financial reporting is to render the brief and classified information about the financial situations, financial operations and financial inflexibility of the commercial units, which can be beneficial for the huge number of the financial invoice users for the purpose of making economic decisions.
According to the theoretical concepts of the financial reporting, a useful piece of the information must have particular qualitative features. The main qualitative features are related to the contents of the information and its reliability (Bolo et al, 2011).
Today, information systems of accounting play a prominent role in the operations of an organization within the economic environment. A large number of economic decisions are made based on the figures and information obtained from these systems. The financial reporting is a reflection of the information and expectations of the users of the financial invoices. Therefore, the passage of time, the development of economic activity, and the growing complexity of economy involve the growth of the purposes and the methods of reporting in order to meet the information needs because the dependable information obtained from the financial reporting is needed for making decisions about the activities of the business units (Khodaie Ardakani, 2008).
The investors make a choice from a wide range of investments based on the characteristics of risk and return. The investment in financial asset always entails some sort of hazard and insecurity which threatens the return and the capital. So, the role of risk in the investment is of importance.
It is quite obvious that the shareholders and the other beneficiaries of the economic centers try to reduce the cost of investment by minimizing the risk of investment. One of the risks the investors are faced with in the documents and negotiable instruments is the systematic risk. That is why it is necessary to draw attention toward the systematic risk and the influential factors on it in the capital market. The purpose of this study is to determine the dependable relation between accounting information which is measured by the accruals quality and it is called the systematic risk.

The Expression of the Question and the Theoretical Principles

The realization and the generation of revenues and the expenses of a company often differ from the time of receiving and paying cash. The accruals quality which distinguishes the profit of accounting from the cash flow is reported from this difference.
According to the point of view of the financial boards of accounting, one of the important roles of the accruals quality is to transfer the determination of the cash flow over the time so that the figures of the cash flow can measure the activity of a company better. The responsible accounting focuses on the economic transactions and events rather than the cash payment and receptions.

In the responsible accounting, the economic transactions and events are registered the moment they occur. In a responsible method, the principles like the realization and agreement are used for the reflection of revenues, the expenses, and the calculation of the benefits of accounting for example, the registration of the received account increases the determination of the cash flow in the benefit, and conforms the time of its determination with the time of gaining the economic benefit from the setting (Dastgir and Pairvand, 2010).

As a matter of fact, the principle of responsible accounting says the revenues are deposited into the accounts when the services are done.

In this method, the contracts made from the cash reception and payments are not only registered, but the business unit registers the contracts made on credit. After the industrial revolution had enhanced the commerce and the complexity of the contracts, the need for the responsible accounting arose. Although the success of a company can be measured by gaining the cash, the cash contract report has difficulty conforming and timing which make the cash flows a dangerous criterion for measuring the activities of companies. Since the companies make contracts on credit, reporting only the cash contract results in the wrong measurement of the activities of the companies. In the responsible accounting, the timing of knowing the cash flow is ignored in the reporting of the benefit. The benefit is made out of surplus and it is registered. According to the principle of the recognition of the revenues, the companies recognize all or considerable part of the cash they receive as the cost of their services. When the cash is reasonably known, and according to the principle of conformity, the companies recognize the cost in a period of time when the revenues are earned (Tousi, 2011).

In order to measure the relation between the risk and the return, a line of thoughts in the framework of the pricing model of capital goods has been generated. In this model, the investment is valued by using proper theory and methodology when gaining benefit is expected from the investment in future. To value and budget the capital of a project, the possibility to gain the capital must be studied. In the decision-making process, the evaluation of this possibility is called the risk rate. In other words, there is a possibility that the real return of an investment will be less than the expected one which is called risk. The systematic risk is inevitable and if it occurs, it can't be controlled. The systematic risk has an effect on all the documents and negotiable instruments, which is called the market risk. The systematic risk arises from the political risk, the economic risk, etc. (Vakili Fard, 2010).

By studying the index of the reliability of accounting information and the systematic risk, the importance of accounting information has been empirically tested and determined whether it has been used by the investors and the other beneficiaries and it has an effect on the systematic risk or not. If any relation between these two is proved, it can be stated that the quality of accounting information can improve the function of documents and negotiable instrument, the reduction of risk, and the capital cost, or other methods should be searched to strengthen the role of accounting information.

The Purposes and the Theoretical Framework

One of the main sources of information for people to make decisions is the accounting information. The high quality information brings about more coordination between the managers and investors to make decisions about their investments. On the contrary, the lower the quality of the information is, the higher is the risk the investors have to sustain. When they tolerate higher risks, they expect the higher return.

One of the functions of the accounting is to provide the useful information for the investors in order to ascertain the value of the documents and negotiable instruments as well as help them to make wise decisions about investments. On this purpose, the systematic risk and its influential factors in the market should be focused on. The aim of this study is to ascertain the reliability of the accounting information which is measured by the accruals quality and it is called the systematic risk.

Niu (2006) studied the corporate governance characteristics on the quality of accounting earnings; his research was conducted from 2001 to 2004 in Canada. He investigated over the ownership concentration and management ownership. The result showed that the corporate governance mechanisms would improve the earnings quality.

Velury and Jenkins (2006) did the research to study the relation between the earnings quality and the corporate governance in the U.S. from 1992 to 1999 and they concluded that the earnings quality wasn’t related to the corporate governance and the concentration of governance wouldn’t influence the reported earnings quality. The conclusion of the research suggests that the concentrated corporate governance may negatively influence the earnings quality.

Pierre and Smith (2008) did a research entitled “The stock prices and accounting information” from 1987 to 1996 in Malaysia and studied how the published accounting information with the stock prices by using the equation of regression. They wanted to know the relations between the variables. The conclusion of the research shows that the two accounting variable, that is, the book value of equity and the benefits reflected in the balance sheet and income statement, in turn, are of high value in the process of valuation, entitling the managers to use the accounting system as a main source of information so as to study the financial activities.

Li and Wang (2010) studied the relation between financial reporting quality and investment efficiency in the China's securities market from 1998 to 2006. The conclusion of the above-said research shows that the quality of the financial reporting is negatively correlated with the upper limit and lower limit investments and the effects of the accruals quality and leveling off the benefit on the upper limit and lower limit investments are of considerable importance.

Iatridis (2010) conducted a research into the admission of international standards of financial accounting on the quality of reported figures accounting. He also focused on the correlation between the information coming from the financial invoices based on IFRS and the value of the company. The results show that the execution of the international standards of accounting improved the quality of accounting figures, so giving the managers a free hand decreases the earnings management and this leads to the timely recognition of the loss, and finally this brings about the accounting information report which is more related with the value. This article suggest that the Less information asymmetry and the less interference with the benefit should result in disclosing high quality and useful financial information, helping the investors to make the wise and impartial judgments.

Rajgopal and Venkatachalam (2011) tested the relationship between financial reporting quality and return volatility in the United States of America during 1962 to 2001 and found that there is a positive relationship between lower earnings quality and return volatility. This positive association holds after employing several mediator variables and the impact of some factors such as new listed firms, hi-tech firms and observations of the company's negative earnings.
El-Sayed Ebaid (2011) conducted a research entitled the accruals quality and the prediction of the cash flow of the future in emerging markets of Egypt. The evidence shows that the retained earnings can predict the cash flow of the future better. He also understood that non-accumulated accruals items (made of main constitutes), changes in the accounts receivable and payable and in inventory, depreciation of fixed assets, amortization of intangible assets and the other accruals items can significantly enhance the prediction of the earnings.
Houmes et al (2012) studied the effect of the leverage of the operation on the systematic risk of the USA transportation industry. They used three indexes of the degree of the operation leverage, the natural net algorithm of the property, plant and equipment, the percentage of the active staff. The research showed that the three variables of the operation leverage would be positively related to the systematic risk (β).
Gill and Biger (2013) tested the impact of corporate governance on the efficiency of the working capital management of the manufacturing listed firms from 2009 to 2011. The sample is composed of 180 listed firms on NYSE. The findings of this study suggest that the corporate governance plays a key role in improving the efficiency of the working capital management.
Cohen et al (2013) studied the role of cash and accrual accounting in the local governments. They investigated 106 municipalities in Greece and found that the information on cash accounting plays a significant role in decision making rather than the role played by the information of accrual accounting. It seems that larger municipalities use extended accounting information for the negotiations about the cash and accrual accounting.

Methodology

Materials and Method

This research is of descriptive-correlative nature because the relation among the variables is examined and valued. Since the study can be used in decision-making process, it is regarded an applied project. The research covers the period from 2002 to 2010 and has been used to measure the reliability of accounting information and estimate the coefficient of the Fama and French accounting information of the period from 2002 to 2005 and investigate the relations among the main variables from 2006 to 2010.
In order to answer the question, the following hypothesis is presented:
There is a significant relation between the systematic risk and the accruals quality.

The statistical Population, the Sample and the Sampling Method

In order to choose a statistical population, we referred to Tehran's documents and negotiable instruments and the statistical sample was chosen by using the deletion sampling and considering the following limitations.

- The fiscal year ends in March every year.

- The shares of the companies were traded at least for 100 days a year.
- The companies shouldn't be insurance companies, investment companies, or broker companies.
- The required data and information should be available for measuring the variables of the research.

Regarding the method conditions and criteria, 52 companies were selected as a sample.

The Means of Data Collection

The data collection is done through the library method. To collect the data needed in the literature, the central bank of the Islamic Republic of Iran and the financial statements of the companies listed to the documents and negotiable instrument center were referred to as the source of information. To access the data, the Rahavard-e-Novin Software, the website of Tehran's stock exchange and the website of Tehran's documents and negotiable instruments can be referred to.

To analyze, results, the multi-variable regression was used and in order to organize the data, Excel and SPSS 20 were utilized. To test the hypothesis, the confidence level was 95%.

The Variables and the Procedure

The variables existent in the research are divided into control, dependent, and independent ones. The reliability of the accounting information is regarded as the independent variable. To calculate the reliability of the accounting information, the accruals quality was used.

In this research, Dechow and Dichev modified model (2002) proposed by Francis et al (2005) was utilized. The following method is used to measure the accruals quality:

$TCA_{it} = \phi_0 + \phi_1 CFO_{it-1} + \phi_2 CFO_{it} + \phi_3 CFO_{it+1} + \phi_4 \Delta REV_{it} + \phi_5 PPE_{it} + \nu_{it}$

TCA is the total current accruals quality which is calculated by the following method:

$TCA_{it} = \Delta CA_{it} - \Delta CL_{it} - \Delta Cash_{it} + \Delta STDebt_{it} - Depn_{it}$

CFO is the operating cash flow which is measured by using the following method:

$CFO_{it} = NIBE_{it} - TCA_{it}$

$NIBE_{it}$ is the net income before the extraordinary items.

ΔCA_{it} is the changes in the current assets.

ΔCL_{it} is the changes in the current liabilities.

$\Delta Cash_{it}$ is the changes in cash.

$\Delta STDebt_{it}$ is the changes in the current share of the long-term debts.

$Depn_{it}$ is the depreciation cost of the tangible and intangible assets.

ΔREV_{it} is changes in the revenues.

PPE_{it} is considered as the gross value of property, plant and equipment (the fixed assets).

ν_{it} is the residual variable which its standard deviation from t to t-4 determines the accruals quality.

The present study exploits the depreciation and amortization costs from the notes accompanied to the basic financial statements and operating cash flows.

The Dependent Variables

In this research, the systematic risk is regarded as the dependent variable, considered as the coefficient of angle (β^M) in the Fama and French (1993) three-factor asset pricing model.

$r_t - r_{f,t} = \alpha + \beta^M MKT_t + \beta^S SMB_t + \beta^H HML_t + \varepsilon_t$

Where in:

r is the stock return.

r_f is the risk-free rate.

α is the Intercept.

B^M, β^S, β^H are the angle coefficients of the market factor, size factor and value factor.

MKT is the market factor.

SMB is the size factor.

HML is the book value to market value (value factor).

t is the time.

ε is the residual value.

MKT is the market risk which is originally the beta factor of the model presented by CAPM. Market risk is defined as the difference between the market return and the risk-free return. The market return can be obtained from the total index of end subtracted from the total index of beginning divided by the total index of beginning. The index of the risk-free return is defined as the profit of government bonds.

The second factor, SMB, is the difference between the mean return of the portfolio of the shares of small companies and the portfolios of the shares of big companies, which is also called the size factor.

The third factor, HML, is the difference between the return of the portfolios of company shares with higher book value than the high market value and the return of the portfolios of company shares with the lower book value than the low market value which is called the value factor.

The Control Variables

The control variables are as follows:

The Size: The size of the company can be obtained from the natural logarithm of the value of capital market.

The proportion of the book value to the market value: This can be obtained when the book value of the shareholders is divided by the market value of the shareholders.

The proportion of the fixed assets to the total assets (capital intensity): the proportion of the net property, plant and equipment to the total assets.

The cash ratio is the proportion of the cash and equivalent amount of cash to the total current debts. In addition, the control variables include the angle coefficient of the size factor (β^S) and the value factor (β^H).

The Total Model of the Research

$\beta_{it}^{M} = \psi_0 + \psi_1$ Accruals Quality$_{it}$ + $\psi_2 \beta_{it}^{S} + \psi_3 \beta_{it}^{H} + \psi_4$ Size$_{it}$ + $\psi_5 \beta$
Book-to-Market$_{it}$ + ψ_6 Capital Intensity$_{it}$ + ψ_7 Cash Ratio$_{it}$ + ε_{it}

In the model β^M, the systematic risk of the *i* company in a year equals *t*. The index of the reliability accounting information, that is, the accruals quality and the control variable have already been discussed in the above paragraphs.

Results

The Statistical Description of the Data

Table 1. The Descriptive Statistics of the Variable

	Mean	Median	Standard Deviation	Skewness	Kurtosis	Minimum	Maximum
Capital intensity	0.215	0.164	0.182	1.166	0.852	0.0016	0.8321
Cash ratio	0.084	0.047	0.157	8.919	108.490	0.0023	2.1108
Accruals quality	0.604	0.626	0.205	-0.303	-0.801	0.1267	0.9918
Size	27.284	26.902	1.454	0.827	-0.125	23.8749	30.7716
Book-to-market	0.467	0.301	0.604	7.216	77.748	0.0077	7.2770
β^M	1.866	30.429	722.382	-9.946	122.601	-9049.480	2309.350
β^S	0.7184	-0.133	12.9562	8.828	99.571	-35.99	153.310
β^H	-0.3103	-0.2081	9.875	8.914	119.648	-43.65	122.840

Testing the Hypothesis

There is a significant relation between the accruals quality and the systematic risk.

Table 2. Analysis of Variance

Source	Degree of Freedom	Residual squares	Mean squares	F	Sig. level	Durbin Watson	R2	Adj. R2
Regression	8	92220038.47	11527504.8	569.858	0.000	1.635	0.819	0.817
Residual	147	2973621.916	20228.721					
Total	155	95193660.38						

Table 3. Regression coefficients

Variable	Coefficient	Standard Deviation	t	Sig.
constant	62.425	221.570	0.282	0.779
Capital intensity	4.381	670156	0.065	0.948
Cash ratio	-22.578	123.267	-0.183	0.855
Size	-3.276	7.819	-0.419	0.676
Book-to-market	4.768	31.461	0.152	0.880
Accruals quality	130.849	63.148	2.072	0.040
β^S	17.080	5.483	3.115	0.002
β^H	99.807	16.928	5.896	0.000

Regarding Table 2, the level of significance of the statistic F shows that there is a significant regression and a linear relation between the dependent and independent variables with 95% confidence level. To study the independence of error of each other, Durbin-Watson test was used. The lack of correlation among errors is accepted when the statistic is between 1.5 to 2.5.
The finding of Durbin-Watson statistic shows the relative independence of data. According to Table 2, the modified coefficient of determination of the model is 0.81, that is, 81% of the changes of the systematic risk can on average be shown by the model. In Table 3, it is obvious that there is a significantly positive relation between the accruals quality and the systematic risk regarding the confidence level of the statistic *t* obtained from the accruals quality and the systematic risk. In addition, regarding the findings of Table 3 and the level of significance, it can be said that the measures of β^H and β^S have a significant relation with the systematic risk, but other control variables have a significant relation with the systematic risk.

Discussion and Conclusion

The hypothesis in relation to the reliability of the accounting information is calculated by the accruals quality, and the systematic risk is tested. By using the modified model of Dechow and Dichev (2002) presented by Francis et al (2005) is tested and the systematic risk is measured by Fama and French three-Factor model.
Moreover, the study shows that there is a significantly positive relation between the accruals quality and the systematic risk. The large size of the accruals quality shows the small size of the measure of the accruals quality.
The findings show that the accounting information is becoming increasingly popular with the other users, shareholders, and the managers. The findings refer to the importance of the accounting information in Tehran Stock Exchange.
Considering the findings of the research and importance of the accruals quality in the estimation of systematic risk of investors in the capital market, it is suggested that the reliability of the accounting information should be relied on more than ever. To improve and strengthen the accounting information, the clarity of the revealed accounting information, and assuring the investors, the Stock Exchange should execute a number of strategies.
The other findings suggest that there is a significantly positive relation between the risk of the size factor (β^S), and the value factor (β^H), and the systematic risk. It is also suggested that the beneficiaries and the decision makers should take these two factors into account while making decisions about the estimation of the risk.

Earnings quality

ABSTRACT

The properties of earnings have changed dramatically over the past 40 years. Prior studies interpret this trend as a decline in earnings quality but disagree on whether it results from changes in the real economy or changes in accounting standards. I find that each new cohort of listed firms exhibits lower earnings quality than its predecessors, mainly because of higher intangible intensity. I conclude that the trend of decline in earnings quality is due more to changes in the sample of firms than to changes in generally accepted accounting principles (GAAP) or in the earnings quality of previously listed firms.

1. Introduction

The literature finds that over the past 40 years or so, there has been an increase in the volatility of earnings and a decrease in both the relevance of earnings and the degree of matching between concurrent revenues and expenses.[1] The literature interprets these changes as a decline in earnings quality (EQ). But there is disagreement about whether the decline is "due to changes in GAAP or due to real economic changes" (Collins et al., 1997, p. 65). I reexamine this question by using

[1] See Collins et al. (1997), Lev and Zarowin (1999), Givoly and Hayn (2000) and Dichev and Tang (2008). The relevance of earnings is measured by the adjusted-R^2 of the regression of annual stock returns on the levels of, and changes in, annual earnings (Easton and Harris, 1991; Lev and Zarowin, 1999). The volatility of earnings is measured by the standard deviation of earnings over a rolling four-year window. Matching is measured by the coefficient on the current expenses in a regression of revenues on past, current, and future expenses (Dichev and Tang, 2008). Matching represents the contemporaneous revenue–expense correlation.

more recent data than do most prior studies, allowing me to shed light on the issue in three ways. First, I show a strong negative correlation between intangible intensity and average EQ measures, i.e., volatility, relevance, and matching. (For ease of discussion, an increase in earnings volatility is viewed as a declining EQ measure.) Second, I show that successive cohorts of newly listed firms exhibit increasing intangible intensity and decreasing EQ measures. Third, I show that the progressive declines in EQ measures are largely the result of the assimilation of successive cohorts of newly listed firms into the firm population. Hence, I identify the "new-list" phenomenon as the biggest reason for the decline in average EQ measures over the study period of 1970 to 2009.

By the outset of the twenty-first century, the United States had moved from being primarily an industrial economy to becoming mainly a knowledge-based economy (Baumol and Schramm, 2010; Shapiro and Varian, 1998). As a result, U.S. firms have increased their investments in intangible capital such as innovation, advertising, information technology, human capital, and customer relations (Corrado and Hulten, 2010). Consistent with this trend, there has been a dramatic increase over time in U.S. firms' average intangible intensity as measured by research and development (R&D) expenses, market-to-book ratios, and selling, general, and administrative (SG&A) expenses (Francis and Schipper, 1999; Banker et al., 2011; Eisfeldt and Papanikolaou, 2013).

I hypothesize that increases in intangible intensity reduce earnings quality for several reasons. An intangible-intensive firm is likely to display high volatility in its revenues and cash flows because intangible investments carry higher uncertainty about future benefits than do tangible investments (Kothari et al., 2002). Furthermore, relative to material-intensive firms, intangible-intensive firms are more likely to have growth options, whose values and changes in values are typically not recognized in the balance sheet and income statement (Smith and Watts, 1992; Watts, 2003; Roychowdhury and Watts, 2007; Skinner, 2008). Similarly, firms generally expense their investments in internally generated intangibles as incurred, except for industry-specific practices (e.g., SOP 98-1 [AICPA 1998] for software firms). An immediate expensing of intangible investments, irrespective of when their associated benefits materialize, should increase the volatility in expenses and reduce the matching between concurrent revenues and expenses. The increased revenue and expense volatilities, compounded by the decline in matching, should increase the volatility in earnings. But volatile earnings are less informative for predicting a firm's future fundamentals (Dichev and Tang, 2009; Barton et al., 2010). Thus, intangible-intensive firms should display less earnings relevance. As expected, I find a strong and negative association between intangible intensity and average EQ measures (volatility, relevance, and matching).

I next examine whether the temporal trends in intangible intensity and EQ measures encompass all firms. I find that an increasing percentage of "new" firms, i.e., those listed after 1970 (Fama and French, 2004), enter knowledge-intensive industries such as business services, communications, pharmaceuticals, healthcare, and computers. These industries mainly transform "information from one pattern into another," unlike material-intensive industries that transform "matter and energy from one form into another" (Apte et al., 2008, p. 15). Thus, knowledge-intensive industries need a higher proportion of intangible inputs in their production functions than do material-intensive industries. Consistent with this idea, successive cohorts of new firms show increasing intangible intensity. In contrast, "seasoned" firms (those listed before 1970) continue to operate in material-intensive industries, such as textiles, utilities, aircraft, steel, and railroads. Following Fama and French (2004), these findings show that seasoned firms continue to pursue businesses that have reached the mature phases of their lifecycles (Anthony and Ramesh, 1992; Jovanovic and MacDonald, 1994).[2] In such phases, firms tend not to radically change their production functions unless breakthroughs in production technology occur (Hambrick, 1983; Chen et al., 2010). Consistent with this concept, increases in average intangible intensity over time mainly reflect the increasing intangible intensity of the successive cohorts of new firms rather than increasing intangible usage by seasoned firms.

In addition, I find that the average EQ measures of the firm population exhibit a declining trend. More important, successive cohorts of new firms display declining EQ measures despite controls for overall time trends. I investigate these trends by dividing the firm population into seasoned-firm and new-firm segments. The number of firms in the new-firm segment increases and its average EQ measures decline with the arrival of each new listing cohort. As a result, the average EQ measures of the new-firm segment decline more rapidly than those of the seasoned-firm segment. The average earnings relevance (the adjusted-R^2 of the regression of annual stock returns on levels of, and changes in, annual earnings) of the new-firm segment declines from 20.4% to just 2.6% from the period 1970–1974 to the period 2005–2009. This decline shows that the earnings of new firms no longer explain the variation in their stock returns in any economically significant way. In comparison, the average earnings relevance for seasoned firms declines less dramatically, from 20.1% to 14.4%. Further, for the new-firm segment, the average matching, measured by the concurrent revenue–expense association (Dichev and Tang, 2008), declines from 1.05 to just 0.59. This decline shows that a significant portion of the new firms' outlays are now expensed before recognition of the associated revenues. In comparison, the average revenue–expense matching of the seasoned-firm segment declines by much less, from 1.05 to 0.94. Similarly, the average earnings volatility of the new-firm segment increases more sharply. As a result, at the end of the study period, relative to the seasoned-firm segment, the new-firm segment's average earnings relevance is 82% lower, matching is 37% lower, and earnings volatility is 476% higher.

Because new firms have lower EQ measures than seasoned firms, the addition of new firms to the firm population should lower overall average EQ measures. I quantify this effect by disaggregating the changes in average EQ measures over the sample period of 1970 to 2009 into new-list and seasoned-firm effects. The seasoned-firm effect reflects the decline in

[2] Fama and French (2004) find seasoned firms to be relatively large firms with high survival rates and stable profits, but low growth prospects.

average EQ measures with no new firms joining the firm sample. The new-list effect is the change in average EQ measures that results from of the addition of new firms. I measure the new-list effect by the difference between the average EQ measures of the new- and seasoned-firm segments multiplied by the increases in the percentage of new firms in the firm population. I find that the new-list effect contributes as much as 73.9%, 80.0%, and 92.9% to the changes in average relevance, matching, and volatility, respectively, from the period 1970–1974 to the period 2005–2009. Hence, I show that the bulk of the changes in EQ measures over the last 40 years is due to the assimilation of newly listed firms into the firm population and not to changes in the EQ measures of existing firms. This is my main contribution to the literature.

In addition, I find that the biggest factor behind the new-list effect is the widening gap between the intangible intensities of the new- and seasoned-firm segments. Thus, changes in GAAP cannot be the main reason for the observed decline in earnings quality because the standards that require immediate expensing of in-house intangible investments have existed since the early 1970s.[3] Nevertheless, to control for changes in GAAP, I estimate trends in the properties of earnings by using the cash components of revenues, expenses, and earnings, which should be less affected by changes in GAAP (Dichev and Tang, 2008).[4] I find trends similar to those based on the accounting numbers. For example, successive firm cohorts display increasing volatility in operating cash flows, reflective of their increasing business risks (Fama and French, 2004). Hence, I conclude that the observed changes in average EQ measures have more to do with changes in average firm characteristics than with changes in GAAP. With this finding, I also contribute to the debate on whether the decline in earnings relevance over time is associated with increases in intangibles [Collins et al. (1997, p. 42) versus Francis and Schipper (1999, p. 321)]. I find a strong association between these two trends. However, I offer a more nuanced interpretation. I show that this phenomenon represents a shift in the firm population toward intangible-intensive firms due to new listings, rather than a general increase in the intangible intensity of all firms.

My findings differ from the literature in several respects. For example, I find that most of the observed declines in earnings relevance and matching reflect changes in the sample of firms. In contrast, Lev and Zarowin (1999, p. 358) and Dichev and Tang (2008, p. 1426), who also examine changing samples, conclude that the decline in average EQ measures is unrelated to the changes in their sample firms. Furthermore, my finding that the average matching and the volatility of core costs (McVay, 2006) have significantly changed over time differs from that of Donelson et al. (2011, p. 950). Additionally, I extend Givoly and Hayn (2000, p. 313) and Dichev and Tang (2008, p. 1452) by showing that the increase in the volatility of operating cash flows over time is a significant factor in the increase in earnings volatility. The differences between my study and the literature arise because I include firms listed in the 1990s and the first decade of the 2000s, whereas previous studies largely exclude those firms. These new firms make up three-quarters of the listed firm population today, use large amounts of intangible inputs, and display significantly lower EQ measures than do seasoned firms.

The rest of the paper proceeds as follows. Section 2 summarizes the literature and presents the hypotheses. Section 3 describes the sample selection, the measurement of the variables, and the correlational tests. Section 4 describes the tests of the hypotheses and examines the factors that cause the new-list effect. Section 5 presents concluding remarks.

2. Prior research, theory, and motivation of hypotheses

2.1. Prior research

Dechow et al. (2010) summarize the research on the changes in the properties of earnings over time. A brief summary of that research follows. Lev and Zarowin (1999) and Collins et al. (1997) document a decline in the relevance of earnings; Givoly and Hayn (2000) and Dichev and Tang (2008) find increases in the volatility of earnings; and Dichev and Tang (2008) find a decline in the matching of concurrent revenues and expenses. These studies interpret such trends as a decline in the quality of earnings.

However, the literature disagrees on whether it is changes in the real economy or changes in GAAP that have caused the declines in earnings quality. For example, Lev and Zarowin (1999, p. 358) conclude that "the declining returns-earnings association is not the result of new firms joining the sample." Similarly, Dichev and Tang (2008, p. 1426) find that the decline in matching is not driven by changes in the industry composition of the firm population, the characteristics of the sample firms, or the real economy. Also, Francis and Schipper (1999, p. 321) find no difference between the levels of, or changes in, the earnings relevance of high- and low-technology firms. In contrast, Collins et al. (1997, p. 59) find that the decline in earnings relevance is related to increases in the percentage of intangible-intensive industries. Additionally, Donelson et al. (2011) conclude that the decline in matching is related to the increases in special items that arise from both economic developments and changes in GAAP.

However, none of these studies includes firms listed in the late 1990s and the first decade of the 2000s, which now constitute a significant portion of the listed firm population (details described in Section 3). Thus, I reexamine changes in the

[3] SFAS No. 2 (FASB, 1974) requires an immediate expensing of R&D outlays. Some subsequent changes include a modification in the rule for reporting advertising expenses (Heitzman et al., 2010). In addition, SOP 98-1 (AICPA 1998) permits the selective capitalization of software-development costs, which should reduce reported R&D expenses. I find similar results by excluding advertising expenses and software firms.

[4] For example, the cash received from revenue transactions is less affected by changes in revenue recognition standards than are reported revenues (Altamuro et al., 2005).

properties of earnings by using more recent time-series data than do most prior studies. I respond to Dechow et al. (2010, p. 345), who call for more research on "how fundamental performance affects earnings quality." I also respond to Collins et al. (1997, p. 65), who call for an investigation into the effects of changes in industry composition and the resultant variation in the properties of earnings.

2.2. Changes in economic conditions over time

From the latter part of the twentieth century to the outset of the twenty-first century, the United States has moved from being an industrial economy to becoming a knowledge and services economy (Baumol and Schramm, 2010). Consequently, the demand for informational products has replaced the demand for many physical products (Shapiro and Varian, 1998). The literature offers probable reasons for the increases in the service and knowledge sectors of the U.S. economy. On a conceptual level, Keynes (1930) forecasted that technological improvements and rising productivities would lead to everyone experiencing more fun, leisure, and pleasure. Since Keynes's prediction, technological and agricultural productivities have improved significantly (Clark, 2010). As a result, the relative prices of basic goods have declined by two-thirds during the twentieth century (Zanias, 2005). In addition, Aguiar and Hurst (2007) find significant increases in leisure hours since 1965. Because of these developments, the demand for knowledge products and services has increased at a faster rate than the demand for physical products (Apte et al., 2008).

Further, while the United States built comparative advantages in the industrial sector through much of the twentieth century, these advantages had largely eroded by the dawn of the twenty-first century (Sachs and Schatz, 1994). In contrast, over the last few decades, the United States has built comparative advantages through innovation, ideas, knowledge, and competencies (Crescenzi et al., 2007; Bartram et al., 2012). The use of knowledge has also expanded because of increases in economies of scale and scope that have resulted from greater globalization (Romer, 1986; Jones and Romer, 2010). Technological developments have aided the growth of knowledge businesses by reducing consumers' search costs (Bakos, 1997), by facilitating instantaneous and low-cost delivery of knowledge products to remote customers (Spohrer and Engelbart, 2004), and by enabling a quicker assimilation of existing knowledge products into the creation of new knowledge products (Shapiro and Varian, 1998).

Apte et al. (2008) quantify the temporal increases in U.S. firms' intangible inputs by dividing the U.S. economy into two distinct domains. The first is the material domain, which transforms "matter and energy from one form into another." The second is the knowledge domain, which transforms "information from one pattern into another." Apte et al. (2008) show that the share of U.S. gross domestic product (GDP) deriving from the material domain declined from 71% in 1958 to 37% in 1997. Over this period, the economic share of the knowledge domain increased to 63% of U.S. GDP.

Furthermore, using macro-level indicators, Corrado and Hulten (2010) estimate aggregate expenditures in innovation, marketing, customer support, human capital, computerized data and algorithms, and organizational development by U.S. firms. They refer to these expenditures as "investments." They argue that savings occur when resources are used to provide future, not current, benefits. They estimate that U.S. firms' annual intangible investments more than doubled from 5.9% of U.S. GDP in the early 1970s to 11.3% by the end of the first decade of the 2000s.

2.3. Motivation for H1: successive cohorts' increasing knowledge intensity

Because knowledge-intensive firms mainly transform information from one pattern to another (Apte et al., 2008), the creation of knowledge products should require a higher proportion of intangible inputs, such as R&D, expert human capital, databases, and information technology, relative to the manufacture of physical goods. Analogously, knowledge production should consume fewer material inputs. Further, an increasing percentage of new firms coevolving with economic trends are likely to pursue knowledge-based businesses. Thus, successive cohorts of listed firms should use an increasing percentage of intangible inputs in their production functions.

To the extent that seasoned firms continue to pursue mature industrial businesses, they are unlikely to radically change their production functions (Hambrick, 1983; Fama and French, 2004; Chen et al., 2010).[5] Specifically, these firms are unlikely to significantly reduce their materials and energy usage unless breakthroughs in production technologies occur.[6] However, seasoned firms might exploit IT developments to increase their intangible intensity (Porter, 1985). Whether seasoned firms increase their intangible intensity and whether these increases are sufficient to keep pace with the increasing intangible intensity of the successive cohorts of new firms remain empirical questions.

[5] In the mature phases of an industry's lifecycle, the marketplace becomes relatively stable and firms avoid sudden, large moves to keep the beneficial status quo (Chen et al., 2010).

[6] Outsourcing of production activities merely replaces one form of product costs [in-house cost of goods sold (COGS)] with another (purchased COGS). For example, Ford has progressively increased outsourcing and has increased its focus on product design, brands, and customer relationships (Lev, 2001). Yet its COGS to total expense ratio has changed little—from 84.6% in 1970 to 82.9% in 2009. Contrast these COGS ratios against those of knowledge firms: Pfizer and Microsoft have average COGS ratios of just 31.9% and 19.1%, respectively.

I use SG&A intensity as a proxy for intangible intensity because firms typically expense in-house intangible expenditures through SG&A accounts (Banker et al., 2011; Eisfeldt and Papanikolaou, 2013).[7] I also use R&D expenditures and market-to-book ratios as additional proxies for intangible intensity (Francis and Schipper, 1999). Thus, I hypothesize the following:

H1A. Successive cohorts of new firms exhibit increasing SG&A intensities.

Intangible expenditures can generate benefits in the future (Lev and Sougiannis, 1996; Ittner and Larcker, 1998; Brynjolfsson and Hitt, 2000). Yet these outlays are typically expensed as incurred and are reported as SG&A expenses (Banker et al., 2011). This immediate expensing of intangible outlays should lower the correlation between SG&A expenses and current revenues. Further, increases in immediately expensed intangible outlays, to the extent that they are sporadically incurred, should increase year-to-year volatility in SG&A expenses. This effect is similar to increases in expense volatilities if property, plant, and equipment (PP&E) outlays were immediately expensed. This discussion leads to two hypotheses:

H1B. Successive cohorts of new firms exhibit decreasing matching between concurrent SG&A expenses and revenues.

H1C. Successive cohorts of new firms exhibit increasing volatility in SG&A expenses.

2.4. Motivation for H2: successive cohorts' decreasing EQ measures

At least two economic developments in the U.S. business environment should reduce average EQ measures. The first is the increase in business competitiveness and uncertainty (Irvine and Pontiff, 2005). This development increases firms' idiosyncratic stock-return volatilities and lowers firms' survival rates (Campbell et al., 2001; Fama and French, 2004). This development should also increase special items because of more frequent asset impairments, restructuring, and gains or losses from asset sales (Donelson et al., 2011). Increases in special items should reduce EQ measures for the following reasons. Special items are less correlated with current revenues than are other expenses, thus reduce matching (Donelson et al., 2011). Moreover, special items are less persistent than other earnings components, thus they increase the volatility of earnings (Fairfield et al., 1996; Givoly and Hayn, 2000; Jones and Smith, 2011). The resulting increase in volatility should lower the relevance of earnings (Elliott and Hanna, 1996).

The other significant development in the U.S. economy is the increase in firms' intangible usage. This development is likely to change EQ measures by affecting firms' business performance and their financial reports. As discussed in Section 2.3, the immediate expensing of intangible outlays intended to produce future revenues should reduce matching. In addition, any year-to-year fluctuations in intangible investments should increase the volatility of earnings because current revenues might not increase or decrease with investments. Further, intangible-intensive firms should exhibit high earnings volatility because their investments carry high uncertainty about future benefits (Kothari et al., 2002). The resultant increases in earnings volatility should reduce investors' ability to project a firm's future performance (Barton et al., 2010), thereby reducing the relevance of earnings. Furthermore, relative to material-intensive firms that typically have assets-in-place, which are recognized in financial reports, intangible-intensive firms are likely to have a higher proportion of growth options, which are not recognized in financial statements unless they are purchased (Smith and Watts, 1992; Watts, 2003; Skinner, 2008). Specifically, the values and the changes in values of growth options are typically not recognized in the balance sheet and the income statement (Roychowdhury and Watts, 2007). Therefore, intangible-intensive firms are likely to exhibit lower earnings relevance than material-intensive firms.

Because I expect successive cohorts of new firms to show increasing intangible intensity, I hypothesize the following:

H2A. Successive cohorts of new firms exhibit decreasing matching between concurrent revenues and expenses.

H2B. Successive cohorts of new firms exhibit increasing volatility in earnings.

H2C. Successive cohorts of new firms exhibit decreasing relevance of earnings.

3. Sample selection, measurement of key variables, and correlational tests

I use 189,608 firm-year observations with valid data from the years 1970 through 2009. I exclude all finance firms because the traditional cost classifications, i.e., cost of goods sold (COGS) versus SG&A, do not apply to these firms. In addition, I exclude the industry categorized as “almost nothing” in the Fama–French classification (Fama and French, 1997), as it is difficult to interpret its results in an industry context. Thus, I exclude the Fama–French industries identified by numbers 44–47 (representing finance firms) and 48 (representing “almost nothing”), which leaves 43 industries. The first year in which a firm's data are available in Compustat is referred to as the “listing year.”[8] All of the firms with a listing year before 1970 are classified as “seasoned firms” (Fama and French, 2004). The remaining firms are classified as “new firms.” All of the cohorts listed in a common decade are referred to as a “wave” of new firms (Brown and Kapadia, 2007).

[7] The measurement of SG&A intensity is described in Section 3.2.1.

[8] Alternatively, I could use the first year of data availability in the Center for Research in Security Prices (CRSP) as the listing year. I find qualitatively similar results using CRSP-based listing years. I opt to use the listing year based on Compustat data availability to align my sample with the empirical tests.

Table 1
The number of firm-year observations from the successive listing cohorts in each year.

This table presents the number of firm-year observations from the successive listing cohorts in each year from 1970 to 2009. All of the firms are divided into five listing cohorts in the following steps. The first year in which a firm's data are available in Compustat is referred to as the "listing year." All of the firms with a listing year before 1970 are classified as "seasoned firms." The remaining firms are classified as "new firms." All of the cohorts listed in a common decade are referred to as a "wave" of new firms. Consequently, all of the firms are divided into seasoned firms or a wave from the 1970s, 1980s, 1990s, or 2000s.

Fiscal year	Total number of firms	Seasoned firms	New firms			
			1970s wave	1980s wave	1990s wave	2000s wave
1970	2,470	**2,304**	166			
1971	2,786	2,263	523			
1972	2,975	2,219	756			
1973	3,121	2,169	952			
1974	3,206	2,108	1,098			
1975	3,213	2,051	1,162			
1976	3,214	1,977	1,237			
1977	3,105	1,886	1,219			
1978	3,051	1,806	1,245			
1979	3,247	1,731	**1,516**			
1980	3,510	1,657	1,413	440		
1981	3,656	1,587	1,336	733		
1982	4,109	1,533	1,264	1,312		
1983	4,273	1,428	1,160	1,685		
1984	4,396	1,348	1,046	2,002		
1985	4,526	1,257	978	2,291		
1986	4,544	1,186	900	2,458		
1987	4,661	1,098	822	2,741		
1988	4,629	1,024	760	2,845		
1989	4,636	970	705	**2,961**		
1990	4,684	944	667	2,712	361	
1991	4,868	935	650	2,538	745	
1992	5,098	921	636	2,371	1,170	
1993	5,319	905	602	2,159	1,653	
1994	5,713	873	578	1,986	2,276	
1995	6,166	847	555	1,877	2,887	
1996	6,593	813	539	1,913	3,328	
1997	6,578	757	502	1,783	3,536	
1998	6,635	705	461	1,629	3,840	
1999	6,500	651	417	1,506	**3,926**	
2000	6,347	605	393	1,384	3,495	470
2001	6,399	586	366	1,286	3,185	976
2002	6,183	561	351	1,190	2,839	1,242
2003	6,076	546	328	1,121	2,622	1,459
2004	5,852	524	311	1,037	2,407	1,573
2005	5,755	510	296	956	2,201	1,792
2006	5,597	472	276	882	1,989	1,978
2007	5,482	455	267	822	1,813	2,125
2008	5,344	443	257	791	1,677	2,176
2009	5,091	431	242	735	1,555	**2,128**
Percentage of firms that survived in 2009 from the last year of formation of that listing cohort (highlighted in bold letters)						
		18.71	15.96	27.10	44.49	100.00
Breakdown by listing cohorts in 2009						
Numerical proportion (%)		8.47	4.75	14.44	30.54	41.80
Market capitalization (%)		25.92	7.91	17.72	24.40	24.06

Consequently, all of the firms are divided into seasoned firms or a wave from the 1970s, 1980s, 1990s, or 2000s. Table 1 shows the annual distribution of firm-year observations by waves.

3.1. Changes in the composition of the Compustat firm population

The firm population refers to firms with valid data in Compustat.[9] Table 1 describes how the firm population changed during the 40-year study period. In 1970, there were 2,470 firms. From 1970 to 1997, the firm population increased to 6,578, at a compounded annual growth rate of 3.6%. The firm population declined thereafter to 5,091 in 2009.

[9] For reasons discussed in Section 3.2, each firm-year observation requires data on assets; earnings; revenues from the previous two years, the current year, and the next year; and stock-price data from the end of the previous and current years.

Before 1970, the firm population consisted entirely of seasoned firms, by definition. At the end of 2009, the percentage of seasoned firms stood at just 8.5%, respectively. Thus, from 1970 to 2009, the dominant firm-population segment changed from the seasoned-firm segment to the new-firm segment. Therefore, the changes in the average EQ measures over time should be related to changes in the sample of firms if EQ measures differ for seasoned and new firms.

3.2. Measurement of variables

3.2.1. SG&A intensity

Following Dichev and Tang (2008), I first calculate "total expenses" by subtracting income before extraordinary items (Compustat IB) from revenues (Compustat SALES). I measure COGS and SG&A expenses by the Compustat data items COGS and XSGA, respectively. Consistent with McVay (2006), I refer to the sum of COGS and SG&A as "core expenses." I call the other expenses "noncore." I calculate the relative proportions of the three types of expenses (COGS, SG&A, and noncore expenses) for each firm-year by dividing them by that firm-year's total expenses and refer to them as "SG&A intensity," "COGS intensity," and "noncore intensity," respectively.

3.2.2. Volatility of SG&A expenses, total expenses, revenues, and earnings

Following Givoly and Hayn (2000, p. 313) and Dichev and Tang (2008, p. 1441), I scale SG&A expenses, revenues, total expenses, and earnings by the average of the beginning and ending total assets. I then estimate the standard deviations of these variables for each firm-year using four rolling annual observations ($t-2$ through $t+1$).[10]

3.2.3. Matching

Following Dichev and Tang (2008, Table 3, p. 1436), I estimate the following regression on an annual cross-sectional basis for each wave-year:

$$Revenues_{i,t} = \beta_{1,t} + \beta_{2,t} \times TotalExpenses_{i,t-1} + \beta_{3,t} \times TotalExpenses_{i,t} + \beta_{4,t} \times TotalExpenses_{i,t+1} + \varepsilon_{i,t} \quad (1)$$

I scale all of the variables by average total assets. I measure "matching" by the regression coefficient on the contemporaneous expenses (β_3), which represents the contemporaneous revenue–expense correlation. I measure the "forward association" by the coefficient on past expenses (β_2) that represents the correlation between expenses and future revenues.

Similarly, I measure the matching of SG&A expenses by β_4 in the following equation:

$$Revenue_{i,t} = \beta_1 + \beta_2 \times TotalExpense_{i,t-1} + \beta_3 \times COGS_{i,t} + \beta_4 \times SG\&A_{i,t} + \beta_5 \times NoncoreExpenses_{i,t} + \beta_6 \times TotalExpenses_{i,t+1} + \varepsilon_{i,t} \quad (2)$$

3.2.4. Relevance

Consistent with Easton and Harris (1991, Table 3, p. 31), I estimate the following regression on an annual cross-sectional basis for each wave-year:

$$Ret_{i,t} = \beta_{1,t} + \beta_{2,t} \times \Delta Earnings_{i,t} + \beta_{3,t} \times Earnings_{i,t} + \varepsilon_{i,t} \quad (3)$$

These variables are defined in Appendix A. I measure the "relevance" of earnings by the adjusted R-square of the above regression.

3.3. Industry analysis

Before testing the hypotheses, I examine the principal ideas that underlie H1 and H2. Specifically, I examine whether successive firm cohorts pursue more knowledge-intensive businesses and whether EQ measures decline with intangible intensity. These tests also respond to Collins et al. (1997, p. 65), who call for an investigation into the effects over time of changes in the industry composition of the listed firm population.

3.3.1. Changes in industry composition

I assign "wave-order" values of 1 to seasoned firms and 2, 3, 4, and 5 to firms from the 1970s, 1980s, 1990, and 2000s waves, respectively. For example, firms listed in 1955 and 2006 are assigned wave-order values of 1 and 5, respectively. I categorize all of the firms by the Fama–French 48-industry classification. I calculate an industry's "recency" by averaging the wave-order values of all of its pooled firm-year observations from 1970 to 2009. Therefore, an industry with observations only from the seasoned-firm category has a recency of 1. Similarly, an industry with observations only from firms from 2000s wave has a recency of 5. Thus, an industry's recency ranges from 1 to 5—the higher the recency, the higher is the proportion of firm-year observations coming from the most recent waves.

[10] Using this method ($t-2$ through $t+1$) instead of using observations ($t-3$ through t) makes the data requirements consistent with those of Eq. (1). Nevertheless, I lose the first observation of each wave because I do not have asset data for year $t-3$ to estimate the average total assets for the year $t-2$.

I sort the industries by the highest to lowest values of recency and present them in Panel A of Table 2. This table shows that the ten industries with the highest recency are pharmaceuticals (recency of 3.48), business services (3.34), gold and precious metals (3.30), healthcare (3.24), medical equipment (3.14), communication (3.10), computers (3.09), entertainment (3.01), electronic equipment (2.85), and personal services (2.85). All of these industries are innovation and knowledge intensive except for the gold and precious metals industry. The ten industries with the lowest recency are utilities (1.49), aircraft (1.73), tobacco products (1.85), shipbuilding and railroad equipment (1.87), textiles (1.92), shipping containers (1.93), business supplies (1.94), construction materials (1.97), food products (2.05), and steel (2.10).

Panel A of Table 2 also shows the average attributes of each industry based on all of its pooled firm-year observations from 1970 to 2009. For expositional purposes, I highlight the five industries with the highest (lowest) values in each attribute by using bold (bold italic) letters. This panel shows that in general, industries with the highest recency have the highest market-to-book ratios and SG&A intensity. Furthermore, in unreported tests, I find that each new wave of firms exhibits higher growth and higher stock-return volatility than its predecessors (Brown and Kapadia, 2007). In contrast, I find seasoned firms to be relatively large firms with low growth (Fama and French, 2004). Taken together, the results show that new firms increasingly pursue evolving, knowledge-intensive businesses but seasoned firms largely continue to operate in mature, material-intensive industries.

3.3.2. Correlational tests

Panel B of Table 2 presents the Pearson and Spearman's rank correlations among the average attributes of the industries. These correlations support the principal ideas underlying this study. First, SG&A intensity is negatively correlated with matching (correlation coefficient of -0.640 and significant at a p-value <0.01) but positively correlated with forward association (results not reported). These correlations are consistent with the idea that intangible investments are often immediately expensed and reported in the SG&A category of expenses. Second, SG&A intensity is strongly correlated with the market-to-book ratio (correlation coefficient of 0.787 and significant at a p-value <0.01). This correlation indicates that a measure based on SG&A expenses is consistent with a widely used measure of intangible intensity. Third, SG&A intensity is negatively correlated with relevance (correlation coefficient of -0.360 and significant at a p-value of 0.02) and positively correlated with earnings volatility (correlation coefficient of 0.732 and significant at a p-value <0.01). These correlations indicate that the immediate expensing of investment outlays reduces the three EQ measures. Also, the correlations among the EQ measures indicate that relevance improves with matching (correlation coefficient of 0.463 and significant at a p-value <0.01) but declines with earnings volatility (correlation coefficient of -0.512 and significant at a p-value <0.01).

Other correlations provide preliminary support for my hypotheses. Recency is positively correlated with both SG&A intensity and the market-to-book ratio (correlation coefficients of 0.652 and 0.756, respectively, and both significant at a p-value <0.01). Consistent with H1A, which posits that successive firm cohorts exhibit increasing SG&A intensities, these correlations indicate that industries with more recently listed firms exhibit higher intangible intensity. Also, recency is negatively and positively correlated with SG&A matching and volatility, respectively (correlation coefficients of -0.408 and 0.774 and both significant at a p-value <0.01). These correlations show that industries with more recently listed firms have lower SG&A matching but higher SG&A volatility, consistent with hypotheses H1B and H1C, respectively. In addition, recency is negatively correlated with matching and relevance (correlation coefficients of -0.710 and -0.459, respectively, and both significant at a p-value <0.01) and positively correlated with earnings volatility (correlation coefficient of 0.834 and significant at a p-value <0.01). These correlations indicate that industries with recently listed firms exhibit low EQ measures, which is consistent with H2A, H2B, and H2C.

4. Tests of hypotheses

4.1. H1A: successive waves' increasing SG&A intensity

I first calculate the cross-sectional average of SG&A intensity by wave-year. This calculation results in 140 wave-year averages made up of 40 annual observations for the seasoned-firm category (1970–2009) and 40 (1970–2009), 30 (1980–2009), 20 (1990–2009), and ten (2000–2009) annual observations for the 1970s, 1980s, 1990s, 2000s waves, respectively. I then calculate the overall average of the annual wave-year averages for each wave. The first column of Panel A in Table 3 shows that average SG&A intensities for seasoned firms and for the 1970s, 1980s, 1990s, and 2000s waves are 16.2%, 21.8%, 29.5%, 29.5%, and 38.3%, respectively. This pattern indicates increasing intangible intensity across successive cohorts of listed firms. Because COGS and SG&A constitute approximately 89% of the firms' total costs, I find opposite patterns for COGS intensity. Specifically, the second column of Panel A in Table 3 shows decreasing COGS intensities of 72.9%, 67.3%, 58.9%, 58.6%, and 47.9%, respectively, indicating decreasing material intensity.[11]

Nevertheless, the above averages might not be comparable across waves because they are calculated over different periods. Thus, the above patterns could simply represent overall time trends. For example, the average for the 2000s wave is calculated using only ten wave-year observations. In contrast, the average for the seasoned firms is calculated using 40

[11] COGS represent the costs of procurements of goods or the costs of direct and indirect labor, material, and energy required for the production of goods.

Table 2
Cross-sectional analysis: intangible intensity; recency; selling, general, and administrative expenses (SG&A) attributes; and earnings quality by Fama–French 48-industry classification.

All of the firms are classified by the Fama–French 48-industry method. Four industries representing the finance firms and one "almost nothing" category are excluded. Panel A presents the average attributes of each industry calculated by using all of the pooled observations from that industry from 1970 to 2009. These attributes are calculated by using the methods described in Appendix A. The top (bottom) five industries for each attribute are highlighted in bold (bold italic) letters. All of the industries are sorted by the highest to lowest values of recency, which is calculated in the following steps. First, the firms listed before 1970 and the firms listed in the 1970s, 1980s, 1990s, and the first decade of 2000s are assigned the "wave-order" values of 1, 2, 3, 4, and 5, respectively. Then, an industry's "recency" is calculated by averaging the wave-order values of all of its pooled firm-year observations. The higher the recency, the higher is the percentage of firm-year observations from the most recently listed firms.

Panel A: The average attributes of industries

** Indicates significance at the 5% level.

Table 3

The cost composition and intangible intensity of the successive listing cohorts.

Panel A presents the average attributes of the successive listing cohorts. All of the firms are divided into five listing cohorts in the following steps. The first year in which a firm's data are available in Compustat is referred to as the "listing year." All of the firms with a listing year before 1970 are classified as "seasoned firms." The remaining firms are classified as "new firms." All of the cohorts listed in a common decade are referred to as a "wave" of new firms. Consequently, all of the firms are divided into seasoned firms or a wave from the 1970s, 1980s, 1990s, or 2000s. All attributes are first calculated on a wave-year basis by using the methods described in Appendix A. These methods result in 40 annual observations for the seasoned-firm category (1970–2009), 40 annual observations for the 1970s wave (1970–2009), 30 annual observations for the 1980s wave (1980–2009), 20 annual observations for the 1990s wave (1990–2009), and 10 annual observations for the 2000s wave (2000–2009) for each attribute. Volatility has one fewer observation per wave. The overall average attribute of a listing cohort is calculated by averaging all of its annual attributes.

Panel A: The average characteristics of the successive listing cohorts

	Composition of total costs			Other measures of intangible intensity		Attributes of SG&A expenses	
Listing cohort	SG&A intensity (%)	COGS intensity (%)	Noncore intensity (%)	R&D intensity (%)	Market-to-book ratio	SG&A matching	SG&A volatility
Seasoned firms	16.2	72.9	10.9	1.13	1.39	1.05	0.024
1970s wave	21.8	67.3	11.0	1.94	1.61	0.9	0.051
1980s wave	29.5	58.9	11.6	5.47	2.56	0.54	0.100
1990s wave	29.5	58.6	11.9	8.15	2.52	0.55	0.097
2000s wave	38.3	47.9	13.8	9.39	3.53	0.1	0.25

Differences in the SG&A attributes of the successive listing cohorts after controlling for overall time trends

Panel B examines whether the attributes of SG&A expenses (intensity, matching, and volatility) differ across successive listing cohorts after controlling for overall time trends. All of the firms are divided into five listing cohorts in the following steps. The first year in which a firm's data are available in Compustat is referred to as the "listing year." All of the firms with a listing year before 1970 are classified as "seasoned firms." The remaining firms are classified as "new firms." All of the cohorts listed in a common decade are referred to as a "wave" of new firms. Consequently, all of the firms are divided into seasoned firms or a wave from the 1970s, 1980s, 1990s, or 2000s. All of the SG&A attributes are calculated on a wave-year basis by using the methods described in Appendix A. Then the following regression is estimated by using 140 wave-year observations, comprising 40 annual observations for the seasoned-firm category (1970–2009), 40 annual observations for the 1970s wave (1970–2009), 30 annual observations for the 1980s wave (1980–2009), 20 annual observations for the 1990s wave (1990–2009), and ten annual observations for the 2000s wave (2000–2009). Volatility has one less observation per wave.

$$SG\&AAttribute_{Wave,year} = \beta_1 + \beta_2 \times FiscalYear + \gamma_1 \times DummyListYear1970\_79 + \gamma_2 \times DummyListYear1980\_89 + \gamma_3 \times DummyListYear1990\_99 + \gamma_4 \times DummyListYear2000\_09 + \varepsilon_{Wave,year},$$

where the dummy variables *DummyListYear1970_79*, *DummyListYear1980_89*, *DummyListYear1990_99*, and *DummyListYear2000_09* take the value of one for the wave-year observations of the 1970s, 1980s, 1990s, and 2000s waves, respectively, and zero otherwise. Because a dummy variable for the seasoned-firm observations is not included in the above regression, they form the base case.

Panel B: Differences in the SG&A attributes of the successive listing cohorts

	SG&A intensity		SG&A matching		SG&A volatility	
	Estimate	*t*-Statistic	Estimate	*t*-Statistic	Estimate	*t*-Statistic
Intercept	−1.322	−5.02***	23.318	8.15***	−1.619	−4.26***

Average Seasoned firms = *1970s wave* (γ_1)		< 0.001		0.001		< 0.001
Average 1970s wave = *1980s wave* ($\gamma_1 = \gamma_2$)		< 0.001		< 0.001		< 0.001
Average 1980s wave = *1990s wave* ($\gamma_2 = \gamma_3$)		0.417		0.189		0.315
Average 1990s wave = *2000s wave* ($\gamma_3 = \gamma_4$)		< 0.001		< 0.001		< 0.001

*** Indicates statistical significance (two-sided) at the 1% level.

wave-year observations. Thus, the seasoned-firms' average includes the earliest observations from the sample period, which are characterized by the lowest intangible usage. To control for overall time trends, I estimate the following regression, which is similar to Brown and Kapadia (2007, p. 374):

$$SG\&A - Intensity_{Wave,Year} = \beta_1 + \beta_2 \times Year + \gamma_2 \times DummyListYear1970\_79$$

$$+\gamma_3 \times DummyListYear1980\_89 + \gamma_4 \times DummyListYear1990\_99$$
$$+\gamma_5 \times DummyListYear2000\_09 + \varepsilon_{Wave,Year} \quad (4)$$

I use 140 wave-year observations to estimate this regression. The *Year* variable controls for the overall time trend. The dummy variables *DummyListYear1970_79*, *DummyListYear1980_89*, *DummyListYear1990_99*, and *DummyListYear2000_09* take the value of one for the wave-year observations of the 1970s, 1980s, 1990s, and 2000s waves, respectively, and zero otherwise. Because I do not include a dummy variable for the observations of seasoned firms, they form the base case. Hence, the coefficients on the dummy variables represent the differences between the waves' and the seasoned firms' averages after controlling for overall time trends.

The first column of Panel B in Table 3 shows that the coefficients on all of the wave dummies are positive and significant. Thus, each new cohort shows higher SG&A intensity relative to the seasoned firms. In addition, the *F*-tests on the differences in the regression coefficients of the other successive waves (that is, γ_1 versus γ_2, γ_2 versus γ_3, and γ_3 versus γ_4) suggest that each successive wave exhibits higher SG&A intensity than its predecessor. The only exception is that I do not find a significant difference between the 1980s and 1990s waves.[12]

I use Eq. (4) to test the subsequent hypotheses by using alternative dependent variables. Therefore, for brevity, I do not repeat this equation or the manner of its interpretation.

4.1.1. Additional tests using R&D and market-to-book ratios

I calculate the average R&D intensity and market-to-book ratio for each wave (formulae described in Appendix A). The fourth column of Panel A in Table 3 shows that the successive waves exhibit increasing R&D intensity of 1.13%, 1.94%, 5.47%, 8.15%, and 9.39%. Similarly, the fifth column shows that the successive waves exhibit increasing market-to-book ratios of 1.39, 1.61, 2.56, 2.52, and 3.53. These findings, along with the SG&A intensity results, provide consistent evidence that the successive waves display increasing intangible intensity.

4.2. H1B and H1C: successive waves' decreasing SG&A matching and increasing SG&A volatilities

The sixth column of Panel A in Table 3 shows that the successive waves exhibit declining SG&A matching of 1.05, 0.90, 0.54, 0.55, and 0.10. I estimate Eq. (4) to control for overall time trends and find similar results, as shown in the second column of Panel B in Table 3. Further, in unreported tests, I find a declining trend in average SG&A matching for the firm population.[13] In this respect, my results differ from those of Donelson et al. (2011), who find no temporal decline in average SG&A matching. This difference arises because Donelson et al. (2011) largely exclude new firms from their study sample.[14]

The seventh column of Panel A in Table 3 shows that successive waves have increasing SG&A volatility of 0.02, 0.05, 0.10, 0.10, and 0.25. The third column of Panel B in Table 3 shows similar trends despite controlling for overall time trends. Arguably, this increase in SG&A volatility reflects increases in one-off core costs that are expensed as incurred, such as senior executive hiring, brand launches, IT system installations, advertising campaigns, and market-research projects. As a result, the total-expense volatility shows an increasing pattern of 0.13, 0.20, 0.27, 0.27, and 0.47 (the third column of Panel A in Table 4). In this respect, my findings differ from those of Dichev and Tang (2008), who find no temporal increase in average expense volatility. However, as noted in footnote 14, Dichev and Tang (2008) also largely exclude new firms from their study.

4.3. H2A: successive waves' decreasing matching

If COGS matching is held constant, then a reduction in SG&A matching and an increase in SG&A intensity should lower the matching of total expenses. Indeed, the matching of total expenses across successive waves shows a decreasing pattern of 1.00, 0.96, 0.80, 0.77, and 0.38 (the first column of Panel A in Table 4). The first column of Panel B in Table 4 shows similar results despite controlling for overall time trends. Further, I find similar results after controlling for special items (results not reported). The forward association shows an increasing pattern (results not reported). These results, along with the H1 results, are consistent with the idea that the SG&A expense category of new firms increasingly includes immediately expensed investment outlays.

4.3.1. Additional tests using the cash components of revenues and expenses

I estimate matching in Eq. (1) by using the cash components of revenues and expenses. The second column of Panel A in Table 4 shows declining matching of 0.85, 0.83, 0.71, 0.72, and 0.44 across the successive waves. This result shows that the decline in matching of total expenses is strongly associated with developments in the underlying revenue–expense relation. In this respect, my conclusion differs from Dichev and Tang (2008), who rule out real developments as a reason for the decline in matching over time.

[12] Similarly, I find no significant differences between the 1980s and 1990s waves in most of the tests described later. For brevity, I do not repeat this point.

[13] I estimate a "trend rate" (γ_2) using 40 annual averages of the firm population and the following equation: $AverageAnnualAttribute_t = \gamma_1 + \gamma_2 \times t + \varepsilon_t$. I find a negative trend rate for SG&A matching.

[14] To examine "economically substantial firms," Dichev and Tang (2008) and Donelson et al. (2011) select a sample of one thousand firms with the largest assets. Their tests require each firm to have at least 12 years of prior data. Their selection criteria result in a sample with an average listed age of 26 years. Thus, their sample largely excludes new firms.

Table 4

The average revenue–expense matching, earnings volatility, and earnings relevance of the successive listing cohorts.

Panel A presents the average measures of earnings quality (EQ) of the successive listing cohorts. All of the firms are divided into five listing cohorts in the following steps. The first year in which a firm's data are available in Compustat is referred to as the "listing year." All of the firms with a listing year before 1970 are classified as "seasoned firms." The remaining firms are classified as "new firms." All of the cohorts listed in a common decade are referred to as a "wave" of new firms. Consequently, all of the firms are divided into seasoned firms or a wave from the 1970s, 1980s, 1990s, or 2000s. The EQ measures are first calculated on a wave-year basis by using the methods described in Appendix A. These methods result in 40 annual observations for the seasoned-firm category (1970–2009), 40 annual observations for the 1970s wave (1970–2009), 30 annual observations for the 1980s wave (1980–2009), 20 annual observations for the 1990s wave (1990–2009), and ten annual observations for the 2000s wave (2000–2009) for each attribute. Volatility has one fewer observation per wave. The overall average EQ measure of a listing cohort is calculated by averaging all of its annual estimates.

Panel A: The average earnings quality of the successive listing cohorts

Listing cohort	Matching	Matching of cash components of revenues and expenses	Expense volatility	Revenue volatility	Earnings volatility	Volatility of cash flow from operations	Earnings relevance (%)
Seasoned firms	1.00	0.85	0.13	0.14	0.03	0.06	15.26
1970s wave	0.96	0.83	0.20	0.20	0.07	0.10	10.73
1980s wave	0.80	0.71	0.27	0.22	0.15	0.18	5.00
1990s wave	0.77	0.72	0.27	0.22	0.16	0.17	4.79
2000s wave	0.38	0.44	0.47	0.25	0.37	0.38	2.41

Differences in the earnings qualities of the successive listing cohorts after controlling for overall time trends.

Panel B examines whether the measures of earnings quality (EQ) differ across successive listing cohorts after controlling for overall time trends. All of the firms are divided into five listing cohorts in the following steps. The first year in which a firm's data are available in Compustat is referred to as the "listing year." All of the firms with a listing year before 1970 are classified as "seasoned firms." The remaining firms are classified as "new firms." All of the cohorts listed in a common decade are referred to as a "wave" of new firms. Consequently, all of the firms are divided into seasoned firms or a wave from the 1970s, 1980s, 1990s, or 2000s. Matching and earnings relevance are calculated on a wave-year basis by using the methods described in Appendix A. Then, the following regression is estimated by using 140 wave-year observations, comprising 40 annual observations for the seasoned-firm category (1970–2009), 40 annual observations for the 1970s wave (1970–2009), 30 annual observations for the 1980s wave (1980–2009), 20 annual observations for the 1990s wave (1990–2009), and ten annual observations for the 2000s wave (2000–2009).

$$EQMeasure_{Wave,year} = \beta_1 + \beta_2 \times FiscalYear + \gamma_1 \times DummyListYear1970\_79 + \gamma_2 \times DummyListYear1980\_89 + \gamma_3 \times DummyListYear1990\_99 + \gamma_4 \times DummyListYear2000\_09 + \varepsilon_{Wave,year},$$

where the dummy variables *DummyListYear1970_79*, *DummyListYear1980_89*, *DummyListYear1990_99*, and *DummyListYear2000_09* take the value of one for the wave-year observations of the 1970s, 1980s, 1990s, and 2000s waves, respectively, and zero otherwise. Because a dummy variable for the seasoned-firm observations is not included in the above regression, they form the base case.

Panel B: Differences in the earnings qualities of the successive listing cohorts.

	Matching		Earnings relevance	
	Estimate	*t*-Statistic	Estimate	*t*-Statistic
Intercept	14.152	6.87***	5.971	8.17***
Fiscal Year × 1,000	−6.612	−6.38***	−2.921	−7.95***
DummyListYear1970_79	−0.039	−1.47	−0.046	−4.83***
DummyListYear1980_89	−0.163	−5.50***	−0.088	−8.58***
DummyListYear1990_99	−0.157	−4.54***	−0.073	−6.32***

Adjusted *R*-square (%)		67.28		61.83
F-tests		*p*-Value		*p*-Value
Average seasoned firms = 1970s wave (γ_1)		0.001		< 0.001
Average 1970s wave = 1980s wave ($\gamma_1 = \gamma_2$)		< 0.001		< 0.001
Average 1980s wave = 1990s wave ($\gamma_2 = \gamma_3$)		0.872		0.199
Average 1990s wave = 2000s wave ($\gamma_3 = \gamma_4$)		< 0.001		0.478

*** and ** indicate statistical significance (two-sided) at the 1% and 5% levels, respectively.

Differences in the earnings volatilities of the successive listing cohorts after controlling for overall time trends.

Panel C examines whether the volatilities of revenues, expenses, and earnings differ across successive listing cohorts after controlling for overall time trends. All of the firms are divided into five listing cohorts in the following steps. The first year in which a firm's data are available in Compustat is referred to as the "listing year." All of the firms with a listing year before 1970 are classified as "seasoned firms." The remaining firms are classified as "new firms." All of the cohorts listed in a common decade are referred to as a "wave" of new firms. Consequently, all of the firms are divided into seasoned firms or a wave from the 1970s, 1980s, 1990s, or 2000s. Volatility is calculated on a wave-year basis by using the methods described in Appendix A. Then, the following regression is estimated by using 135 wave-year observations, comprising 40 annual observations for the seasoned-firm category (1970–2009), 39 annual observations for 1970s wave

Table 4 (*Continued*)

Table 4 (*continued*)

(1971–2009), 29 annual observations for 1980s wave (1981–2009), 19 annual observations for 1990s wave (1991–2009), and nine annual observations for 2000s wave (2001–2009):

$$Volatility_{Wave,year} = \beta_1 + \beta_2 \times FiscalYear + \gamma_1 \times DummyListYear1970\_79 + \gamma_2 \times DummyListYear1980\_89 + \gamma_3 \times DummyListYear1990\_99 + \gamma_4 \times DummyListYear2000\_09 + \varepsilon_{Wave,year},$$

where the dummy variables *DummyListYear1970_79*, *DummyListYear1980_89*, *DummyListYear1990_99*, and *DummyListYear2000_09* take the value of one for the wave-year observations of the 1970s, 1980s, 1990s, and 2000s waves, respectively, and zero otherwise. Because a dummy variable for the seasoned-firm observations is not included in the above regression, they form the base case.

Panel C: Differences in the earnings volatilities of the successive listing cohorts

* and *** indicate statistical significance (two-sided) at the 10% and 1% levels, respectively.

4.4. H2B: successive waves' increasing earnings volatility

The successive waves exhibit increasing revenue volatilities of 0.14, 0.20, 0.22, 0.22, and 0.25 (the fourth column of Panel A in Table 4). This pattern arguably reflects increases in underlying business risks (Brown and Kapadia, 2007) or the higher uncertainty of the benefits associated with intangible investments (Kothari et al., 2002). In addition, the successive waves exhibit increasing expense volatility, as discussed in Section 4.2. These developments, along with a decline in matching, should increase earnings volatility. Specifically, earnings volatility should increase because it equals the sum of the expense and revenue volatilities minus twice their covariance. The fifth column of Panel A in Table 4 shows that the successive waves display increasing earnings volatility of 0.03, 0.07, 0.15, 0.16, and 0.37. And the last column of Panel C in Table 4 shows similar patterns despite controlling for overall time trends.

4.4.1. Additional tests on the volatility of operating cash flow

The sixth column of Panel A in Table 4 shows an increase in the volatility of operating cash flows across successive waves of 0.06, 0.10, 0.18, 0.17, and 0.38. In unreported tests, I find that more than 95% of the increase over time in average earnings volatility is explained by the increase in average cash flow volatility. This inference differs from Givoly and Hayn (2000, p. 313). Their Fig. 3, based on a constant sample of firms, shows a large increase in earnings volatility over time but shows no corresponding increase in the volatility of operating cash flows.[15] Similarly, Dichev and Tang (2008, p. 1452) find large changes in the time-series properties of earnings but no significant change in the time-series properties of operating cash flows. Thus, by examining a changing sample of firms that represent the changing firm population, my study extends both of these studies. I show that the change over time in the properties of underlying cash flows is a significant factor for the observed change in the time-series properties of earnings.

4.5. H2C: successive waves' decreasing earning relevance

Relevance is a widely employed measure of earnings quality. The correlational tests in Section 3.3.2 show that relevance improves with matching but declines with earnings volatility. Moreover, in H2A and H2B tests, I find significant declines in

[15] However, they do not test the significance of temporal changes in cash flow volatility. They find that the principal reason for the increase in earnings volatility is the increase in the volatility of non-operating accruals that results from the increase in special items.

Table 5
Disaggregation of the changes over time in the average measures of earnings quality.

This table examines the contribution of the increases in the numerical percentage of "new" firms in the firm population and their distinctive attributes to the changes over time in the average measures of earnings quality (EQ). All of the EQ measures are calculated on an annual basis for the "new-firm" and "seasoned-firm" segments by using the methods described in Appendix A. All of the firms are divided into these two segments in the following steps. The first year in which a firm's data are available in Compustat is referred to as the "listing year." All of the firms with a listing year before 1970 are classified as "seasoned firms." The remaining firms are classified as "new firms." The average EQ measure in a year should equal the weighted average of EQ measures of the new and seasoned firm segments. As described in Appendix B, the changes in average EQ measure from the early 1970s to the late 2000s should be:

$$\begin{aligned} EQ_{Population,Late2000s} - EQ_{Population,Early1970s} &= Percent_{SeasonedFirms,Early1970s} \times (EQ_{SeasonedFirms,Late2000s} - EQ_{SeasonedFirms,Early1970s}) \quad \text{[first term]} \\ &+ Percent_{NewFirms,Early1970s} \times (EQ_{NewFirms,Late2000s} - EQ_{NewFirms,Early1970s}) \quad \text{[second} - \text{A term]} \\ &+ (Percent_{NewFirms,Late2000s} - Percent_{NewFirms,Early1970s}) \times (EQ_{NewFirms,Late2000s} - EQ_{SeasonedFirms,Late2000s}), \quad \text{[second} - \text{B term]} \end{aligned}$$

where the early 1970s and the late 2000s refer to the years 1970–1974 and 2005–2009, respectively, and the percentages of the new-firm segment in the early 1970s and the late 2000s equal 24.01% and 91.53%, respectively. The "seasoned-firm effect" measures the contribution of changes in the EQ measures of the seasoned-firm segment, holding its percentage in the firm population constant at the early 1970s level. This effect is measured by the first term in the equation. The "new-list" effect represents the combined effect of the new-firm segment's distinctive EQ measures as well as its percentage increase in the firm population. The sum of the second-A term and the second-B term represents the new-list effect. The trend rate is measured by $\gamma_2 \times 1{,}000$ where γ_2 is obtained from the following regression estimated by using 40 annual observations from 1970 to 2009: $EQMeasure_t = \gamma_1 + \gamma_2 \times t + \varepsilon_t$.

	EQ measures		
	Earnings relevance	Matching	Earnings volatility
Seasoned-firm segment			
Attribute (early 1970s)	20.12%	1.049	0.022
Attribute (late 2000s)	14.40%	0.935	0.040
Percent change in attribute	−28.43	−10.84	79.21
New-firm segment			
Attribute (early 1970s)	20.42%	1.052	0.038
Attribute (late 2000s)	2.56%	0.591	0.230
Percent change in attribute	−87.44	−43.83	513.34
Percent difference in attributes of new- and seasoned-firm segments			
Early 1970s	1.47	0.32	68.34
Late 2000s	−82.19	−36.80	476.12
Trend rates			
Seasoned-firm segment	−1.83	−2.83	0.62
New-firm segment	−4.07	−13.40	5.73
Difference	−2.24	−10.57	5.11
(p-value)	(< 0.01)	(< 0.01)	(< 0.01)
Percent contribution to changes in the average attributes of the firm population			
First term (seasoned-firm effect)	26.15	20.11	7.13
Second-A term	25.78	25.78	24.59
Second-B term	48.07	54.11	68.28
New-list effect	73.85	79.89	92.87

matching and significant increases in earnings volatility for the successive waves. Therefore, not surprisingly, the seventh column of Panel A in Table 4 shows that successive waves exhibit decreasing earnings relevance of 15.26%, 10.73%, 5.00%, 4.79%, and 2.41%. The relevance of the latest wave is 84% lower than that of the seasoned firms. This result shows that the extent to which the "earnings of the reporting period reflect the information used by the market in forming prices during that period" (Easton et al., 1991, p. 120) declines with new waves.

To control for overall time trends, I estimate Eq. (4) with relevance as the dependent variable. The results presented in the second column of Panel B in Table 4 show that the 1970s wave has significantly lower relevance than the seasoned firms and that the 1980s wave has significantly lower relevance than the 1970s wave. Yet the earnings relevance measures of the last three waves (1980s, 1990s, and 2000s) do not significantly differ from each other. Nevertheless, all four waves show dramatically lower relevance than that of seasoned firms.

I also estimate a regression of stock returns on the levels of, and changes in, operating cash flows [instead of earnings in Eq. (3)]. In unreported tests, I find a declining pattern in the adjusted R-squares of the modified Eq. (3) across the successive waves. This finding suggests that the decline in relevance of the successive waves is at least partly due to the decline in the relation between stock returns and concurrent cash flows.

4.6. *Differences in trends of EQs of the new-firm and the seasoned-firm segments*

The H2 tests show that successive waves display declining EQ measures even after controlling for overall time trends. As a result, each new wave's arrival should reduce the EQ measures of the new-firm segment. Also, the EQ measures of the new-firm segment should decline faster than that of the seasoned-firm segment. Table 5 shows that for each of the three EQ measures, the magnitude of the trend rate (calculation described in footnote 13) is significantly higher for the new-firm segment than for the seasoned-firm segment. As a result, over the sample period, the new-firm segment's relevance declined from 20.4% to just 2.6%, or by 87%. The seasoned-firm segment's relevance also declined, but less dramatically, from 20.1% to 14.4%. Furthermore, the new-firm segment's matching declined from 1.05 to 0.59. In contrast, the seasoned-firm segment's matching declined much less, from 1.05 to 0.94.[16] In addition, the earnings volatility increased more significantly for the new-firm segment. Consequently, at the end of the study period, relative to the seasoned-firm segment, the new-firm segment's earnings relevance was lower by 82%, matching was lower by 37%, and earnings volatility was higher by 476%.

4.6.1. The relative contributions of the new-list and seasoned-firm effects to changes in average EQ measures

The firm populations' average EQ measure equals the weighted average of the new and seasoned firms' EQ measures:

$$EQ_{Population} = Percent_{SFirms} \times EQ_{SFirms} + (1 - Percent_{SFirms}) \times EQ_{NFirms}, \tag{5}$$

where *EQ* equals the earnings quality measure, *SFirms* equals the seasoned firms, and *NFirms* equals the new firms.

Thus, as described in Appendix B, the changes in the average EQ measures from the early 1970s (i.e., 1970–1974) to the late 2000s (i.e., 2005–2009) can be expressed as follows[17]:

$$\begin{aligned} EQ_{Population,Late2000s} - EQ_{Population,Early1970s} &= [Percent_{SFirms,Early1970s} \times (EQ_{SFirms,Late2000s} - EQ_{SFirms,Early1970s})] \\ &+ [Percent_{NFirms,Early1970s} \times (EQ_{NFirms,Late2000s} - EQ_{NFirms,Early1970s}) + (Percent_{NFirms,Late2000s} - Percent_{NFirms,Early1970s}) \\ &\times (EQ_{NFirms,Late2000s} - EQ_{SFirms,Late2000s})] \end{aligned} \tag{6}$$

I refer to the first term in the square brackets as the seasoned-firm effect. This term measures the contribution of the changes in EQ measures of the seasoned-firm segment, holding its percentage in the firm population constant. I refer to the second term in square brackets as the new-list effect. This term represents the combined effect of the new-firm segment's distinctive EQ measures and the increase in their numerical percentage in the firm population. I then calculate the percentage contributions of the seasoned-firm and new-list effects to changes in the average EQ measures from the early 1970s to the late 2000s.

Table 5 shows that the new-list effect accounts for 73.9%, 80.0%, and 92.9% of the temporal changes in average earnings relevance, matching, and volatility, respectively. The seasoned-firm effect accounts for the remaining 26.1%, 20.0%, and 7.1%, respectively. Hence, I conclude that the bulk of the changes over time in the EQ measures reflects the new-list effect. This is my main contribution to the literature. My conclusion differs from that of Lev and Zarowin (1999, p. 358), who conclude that the declining returns-earnings association is not the result of new firms joining the sample. This difference occurs because I include firms listed in the late 1990s and the first decade of the 2000s that Lev and Zarowin (1999) do not examine. These firms display significantly lower EQ measures than do seasoned firms.[18] In addition, my conclusion differs from that of Dichev and Tang (2008, p. 1426), who conclude that the decline in matching is not because of changes in the firm sample.

4.7. Factors related to the new-list effect

I next examine the principal reasons for the widening gap between the EQ measures of the new- and the seasoned-firm segments. I estimate the following univariate regression with factors that potentially affect the EQ measures as explanatory variables:

$$DifferenceEarningsQuality_{Year} = \alpha + \gamma_1 \times DifferenceAttribute_{Year} + \varepsilon_{Year} \tag{7}$$

I use the differences between annual cross-sectional averages of the attributes of the new- and seasoned-firm segments as dependent and independent variables. Specifically, I use one of the annual differences in relevance, matching, or volatility as the dependent variable and one of the annual difference in special items (Elliott and Hanna, 1996), revenue volatility (Hribar and Nichols, 2007), market-to-book ratio, or SG&A intensity as the independent variable. Of these factors, market-to-book ratio and SG&A intensity represent intangible intensity. Accordingly, I use 40 annual observations (1970–2009) to estimate each of the 12 [3 (earnings qualities) × 4 (explanatory variables)] univariate regressions.

The results of these 12 regressions, presented in Panels A–D of Table 6, show that the *R*-squares of the regressions based on intangible intensity, ranging from 25% to 71%, are the highest. These results indicate that the widening gap between the intangible intensities of the new- and seasoned-firm segments is the most important factor in explaining the widening gap

[16] The core expenses of the seasoned firms remain highly correlated with their current revenues. And the matching for the seasoned firms declines largely due to increases in special items (Donelson et al., 2011).

[17] The early 1970s refers to the five-year period from 1970 to 1974. Similarly, the late 2000s refer to the five-year period from 2005 to 2009. I examine changes from the early 1970s to the late 2000s instead of from 1970 to 2009 to control for temporary year-to-year variations. I reach similar conclusions by examining changes from 1970 to 2009.

[18] The Lev and Zarowin (1999) conclusion is based on findings of significant declines in the relevance of both constant and total firm samples and no significantly higher trend rate in the total sample relative to the constant sample. Nevertheless, the data presented in their Table 1 show that the new firms have lower relevance than the old firms. More important, by extending the Lev and Zarowin (1999) study period to 2009, I find that the difference between the trend rates of the two samples becomes significant.

Table 6
Factors associated with the new-list effect.

This table examines the principal reasons for the widening gap between the average earnings quality (EQ) measures of the "new-firm" and the "seasoned-firm" segments. All of the firms are divided into these two segments in the following steps. The first year in which a firm's data are available in Compustat is referred to as the "listing year." All of the firms with a listing year before 1970 are classified as seasoned firms. The remaining firms are classified as new firms. The following univariate regression is estimated by using one of the factors that potentially affect the EQ measures as an explanatory variable:

$$DifferenceEQ_{Year} = \alpha + \gamma_1 \times DifferenceAttribute_{Year} + \varepsilon_{Year}$$

In this equation, the dependent variable is the annual difference between one of the EQ measures (earnings relevance, matching, or earnings volatility) of the new- and seasoned-firm segments. And the independent variable is one of the annual differences between the new- and seasoned-firm segments' special items, revenue volatility, market-to-book ratio, or SG&A intensity. All of the variables are defined in Appendix A. Each regression is estimated using 40 annual observations (1970–2009).

***Indicates statistical significance (two-sided) at 1% level.

This panel uses the partial *R*-square method (Wold, 1966) to examine the relative contributions of the principal reasons for the widening gap between the average EQ measures of the new-firm and the seasoned-firm segments. The market-to-book ratio is excluded from the following multivariate regression because it is highly correlated with SG&A intensity.

Panel E: $DifferenceEQ_{Year} = \alpha + \gamma_1 \times DifferenceSpecialItems_{Year} + \gamma_2 \times DifferenceRevenueVolatility_{Year} + \gamma_3 \times DifferenceSG\&A\text{-}Intensity_{Year} + \varepsilon_{Year}$

between their EQ measures. I find similar results by using R&D as an alternative measure of intangibles (results not reported).

I also use the partial *R*-square method (Wold, 1966) to examine the relative contributions of the principal reasons for the widening gap between the EQ measures of the new- and the seasoned-firm segments. I estimate the following multivariate regression[19]:

$$DifferenceEarningsQuality_{Year} = \alpha + \gamma_1 \times DifferenceSpecialItems_{Year} + \gamma_2 \times DifferenceRevenueVolatility_{Year} + \gamma_3 \times DifferenceSG\&A - Intensity_{Year} + \varepsilon_{Year} \quad (8)$$

Results presented in Panel E of Table 6 show that the partial *R*-squares of SG&A intensity are the highest. Results in this section, along with the results in Section 4.6.1, are consistent with the idea that the increases in intangible intensity of the new-firm segment along with its percentage increase in the listed firm population are the principal factors for the observed decline in the average EQ measures.

5. Concluding remarks

This study shows that successive cohorts of newly listed firms since 1970 exhibit progressively lower EQ measures. One of the principal reasons for this development is the successive cohorts' increasing intangible intensity, which affects the firms' business performance and their financial reports. Specifically, successive cohorts display increasing volatility of both revenues and cash flows, arguably because of high uncertainty about the benefits of intangible investments. Further, successive cohorts display decreasing matching and increasing expense volatility, mainly because of the immediate expensing of intangible investments. The increases in revenue and expense volatilities, in conjunction with the decline in

[19] The partial *R*-square (or coefficient of partial determination) measures the marginal contribution of one explanatory variable when all other variables are included in the model. I do not include market-to-book ratio in this regression because it is highly correlated with SG&A intensity.

matching, heighten earnings volatility. The increased earnings volatility makes earnings less useful for predicting a firm's future performance. Hence, successive cohorts show a declining relevance of earnings.

Consequently, each new cohort's arrival lowers the average EQ measures of the firm population. And the cumulative addition of new cohorts explains approximately three-quarters of the changes in EQ measures since 1970. Accordingly, I conclude that the main reason for the observed trend in average EQ measures is not the changes in the earnings quality of the seasoned firms but rather the inclusion of new firms in the firm population. Further, I find similar trends by using the cash components of revenues, expenses, and earnings, which are less likely to be affected by changes in GAAP and more likely to reflect changes in the nature of the underlying transactions. Accordingly, I conclude that the observed trend in EQ measures is strongly related to changes in the business activities of the listed firms.

Appendix A. Definitions of variables

The firm population consists of all nonfinancial firms that in a sample formation year have assets, earnings, and revenue data from the previous two years, the current year, and the next year; and stock-price data from the end of the previous and current years.

The corresponding data items in the Compustat annual database are listed in capital letters.

Total Assets	=	AT
Revenues	=	SALE, scaled by average Total Assets for the year
Earnings	=	IB, scaled by average Total Assets for the year
Total Expenses	=	(SALE – IB), scaled by average Total Assets for the year
COGS	=	Cost of Goods Sold (COGS), scaled by average Total Assets for the year
SG&A	=	Selling, General, and Administrative expenses (XSGA), scaled by average Total Assets for the year
Noncore Expenses	=	Total Expenses – (*COGS*+*SG&A*)
Market-to-Book Ratio	=	[Market Value of Equity (Price {PRCC_F} × Number of Shares Outstanding {CSHO})+Total Liabilities [Total Assets−Shareholder Equity {CEQ}])/Total Assets.
Accruals	=	[Change in Current Assets (ACT)−Change in Cash (CHE)−Change in Current Liabilities (LCT)−Change in Tax Payable (TXP)−Depreciation and Amortization (DP)], scaled by average Total Assets for the year
Revenue Accruals	=	[Change in Accounts Receivable (AR)−Change in Deferred Revenue (DRC+DRLT)], scaled by average Total Assets for the year
Expense Accruals	=	Accruals−Revenue Accruals
Cash Flow from Operations (*CFO*)	=	Earnings−Accruals
Cash Component of Revenues	=	Revenues−Revenue Accruals
Cash Component of Expenses	=	Total Expenses−Expense Accruals
Attributes		
SG&A Intensity	=	Selling, General, and Administrative expenses (XSGA)/Total Expenses
COGS Intensity	=	Cost of Goods Sold (COGS)/Total Expenses
Noncore Intensity	=	1−(*SG&A* Intensity+*COGS* Intensity)
R&D Intensity	=	Research and Development Expenditures (XRD)/Total Expenses
Matching and Forward Association	=	The following regression is estimated on an annual cross-sectional basis for each wave-year: $Revenue_t = \beta_1 + \beta_2 \times TotalExpense_{t-1} + \beta_3 \times TotalExpense_t + \beta_4 \times TotalExpense_{t+1} + \varepsilon_t$. Forward Association and Matching are measured by β_2 and $\beta_{3,}$ respectively.
Matching of SG&A	=	The following regression is estimated on an annual cross-sectional basis for each wave-year: $Revenue_{i,t} = \beta_1 + \beta_2 \times TotalExpense_{t-1} + \beta_3 \times COGS_{i,t} + \beta_4 \times SG\&A_{i,t} + \beta_5 \times NoncoreExpenses_{i,t} + \beta_6 \times TotalExpenses_{i,t+1} + \varepsilon_{i,t}$ Matching of *SG&A* is measured by β_4.
Volatility of *SG&A*, Revenues, Expenses, Earnings, and *CFO*	=	Standard deviation of *SG&A*, Revenues, Expenses, Earnings, and *CFO*, respectively, for the four-year rolling windows (years $t-2$ through $t+1$)
Relevance	=	Adjusted *R*-square of the following regression, estimated on an annual cross-sectional basis for each wave-year: $RET_{i,t} = \beta_{1,t} + \beta_{2,t} \times \Delta Earnings_{i,t} + \beta_{3,t} \times Earnings_{i,t} + \varepsilon_{i,t}$ *RET* is [(End-of-Year Share Price {PRCC_F}/Adjustment Factor {AJEX}+Dividend per Share {DVPSP_F}/Adjustment Factor−Beginning-of-Year Share Price/Beginning-of-Year Adjustment Factor)/(Beginning-of-Year Share Price/Beginning-of-Year Adjustment Factor)]. Earnings and change in Earnings are scaled by average Total Assets.
EQ measures	=	Earnings Volatility, Revenue–Expense Matching, and Earnings Volatility.
Firm category		
Listing year	=	First year in which the firm has valid data in Compustat.
Seasoned firms	=	Firms whose listing year is before 1970.
New firms	=	Firms that are not Seasoned firms.
Listing cohorts	=	All of the cohorts listed in a common decade are referred to as a "wave" of New firms. Consequently, all of the firms are divided into Seasoned firms or a wave from the 1970s, 1980s, 1990s, or 2000s.

Dummy variables for waves	=	Dummy variables *DummyListYear1970_79*, *DummyListYear1980_89*, *DummyListYear1990_99*, and *DummyListYear2000_09*, take the value of one for the wave-year observations of the 1970s, 1980s, 1990s, and 2000s waves, respectively, and zero otherwise.
Industry	=	All of the firms are classified by the Fama–French 48-industry method. Four industries representing the finance firms and one "almost nothing" category are excluded, leaving 43 industries.
Recency	=	Wave-order values of 1, 2, 3, 4, and 5 are assigned to the Seasoned firms, and the firms listed in the 1970s, 1980s, 1990s, and the first decade of 2000s, respectively. An industry's average recency is calculated by averaging the wave-order values of its pooled firm-year observations.

Notes:

- All variables are winsorized at the 1st and 99th percentiles.
- Industry tests (Table 2)
  - The average attribute for an industry, measured by a proportion or a volatility, is first calculated on a firm-year basis and then averaged across all of that industry's pooled observations. Other attributes (relevance and matching) are estimated by pooled panel-data regressions by industry. These methods results in 43 industry observations for each attribute.
- Time-series tests (Tables 3–6)
  - An attribute for a wave-year, measured by a proportion or a volatility, is first calculated on a firm-year basis and then averaged across all of the cross-sectional observations in that wave-year. Other attributes (relevance and matching) are estimated by cross-sectional regressions by wave-year. These methods result in 140 wave-year observations for each attribute, comprising 40 observations for seasoned firms (1970–2009), 40 observations for the 1970s wave (1970–2009), 30 observations for the 1980s wave (1980–2009), 20 observations for the 1990s wave (1990–2009), and observations for the 2000s wave (2000–2009). Volatility has one less observation per wave. The overall average attribute of a listing cohort is calculated by averaging all of its annual wave-year attributes.
  - The annual attribute of the new-firm segment is calculated by averaging the wave-year attributes of the 1970s, 1980s, 1990s, and 2000s waves.
  - Years 1970–1974 and 2005–2009 are referred to as the early 1970s and the late 2000s, respectively.

Appendix B. Contributions of the new-list and seasoned-firm effects to changes in EQ measures

The observed earnings quality of the firm population equals the weighted average of the EQ measures of the new- and the seasoned-firm segments as described below:

$$EQ_{Population,T1} = WT_{SF,T1} \times EQ_{SF,T1} + WT_{NF,T1} \times EQ_{NF,T1} \tag{B.1}$$

where EQ=EQ measures, WT=percentage in firm population, SF=seasoned firms, NF=new firms, T1=early 1970s (1970–1974), and T2=late 2000s (2005–2009).

$$EQ_{Population,T2} = WT_{SF,T2} \times EQ_{SF,T2} + WT_{NF,T2} \times EQ_{NF,T2} \tag{B.2}$$

because

$$WT_{SF,T2} = WT_{SF,T1} + [WT_{SF,T2} - WT_{SF,T1}] \tag{B.3}$$

and

$$WT_{NF,T2} = WT_{NF,T1} + [WT_{NF,T2} - WT_{NF,T1}]. \tag{B.4}$$

Eq. (B.2) can be written as

$$EQ_{Population,T2} = (WT_{SF,T1} + [WT_{SF,T2} - WT_{SF,T1}]) \times EQ_{SF,T2} + (WT_{NF,T1} + [WT_{NF,T2} - WT_{NF,T1}]) \times EQ_{NF,T2} \tag{B.5}$$

$$= WT_{SF,T1} \times EQ_{SF,T2} + WT_{NF,T1} \times EQ_{NF,T2} + (WT_{SF,T2} - WT_{SF,T1}) \times EQ_{SF,T2} + (WT_{NF,T2} - WT_{NF,T1}) \times EQ_{NF,T2} \tag{B.6}$$

but

$$(WT_{SF,T2} - WT_{SF,T1}) = -1 \times (WT_{NF,T2} - WT_{NF,T1}). \tag{B.7}$$

Thus, (B6) can be expressed as

$$EQ_{Population,T2} = WT_{SF,T1} \times EQ_{SF,T2} + WT_{NF,T1} \times EQ_{NF,T2} + (WT_{NF,T2} - WT_{NF,T1}) \times (EQ_{NF,T2} - EQ_{SF,T2}). \tag{B.8}$$

Subtracting (B.1) from (B.8) gives

$$\begin{aligned} EQ_{Population,T2} - EQ_{Population,T1} = {} & WT_{SF,T1} \times (EQ_{SF,T2} - EQ_{SF,T1}) \quad \text{(first term)} \\ & + WT_{NF,T1} \times (EQ_{NF,T2} - EQ_{NF,T1}) \quad (second - A\ term) \\ & + (EQ_{NF,T2} - EQ_{SF,T2}) \times (WT_{NF,T2} - WT_{NF,T1}) \quad (\text{second} - \text{B term}) \end{aligned}$$

1. First term: Changes in the EQ measures of the seasoned-firm segment over time holding their percentage in the firm population constant. This term is referred to as the "seasoned-firm effect."
2. Second-A term: Changes in the EQ measures of the new-firm segment over time holding their percentage in the firm population constant.
3. Second-B term: Differences between the EQ measures of the new- and the seasoned-firm segments at the end of the study period × the percentage increase of the new-firm segment.

The sum of the second-A term and the second-B term is the "new-list" effect.

Abstract

In contrast to theoretical and empirical evidence linking disclosure to information environment benefits, recent research concludes that guidance increases volatility, but leaves open the question of whether volatility plays a role in prompting the issuance of guidance. Consistent with the notion that managers react to rising volatility by providing guidance, we document a link between abnormal run-ups in volatility and the decision to issue a forecast after controlling for the market's ability to anticipate the guidance. Upon disentangling pre-guidance volatility changes from post-guidance volatility changes, we find no evidence that guidance increases volatility. Indeed, our evidence consistently supports the view that managers seek to and do mitigate share price volatility with guidance.

1. Introduction

Theory and empirical evidence establish a close link between voluntary, value-relevant disclosure and share price volatility. Theoretical models indicate that managers engage in voluntary disclosure in order to decrease information asymmetry (Diamond 1985; Diamond and Verrecchia 1991) and reduce investor uncertainty (Dye 1985; Lewellen and Shanken 2002; Pastor and Veronesi 2003). In these models, investors are uncertain about the parameters of the distribution of firms' future cash flows and earnings, and learn about the parameters of the distribution over time as information is revealed about the firm. Investors' uncertainty positively correlates with future stock return volatility and, as disclosure lowers uncertainty, it also lowers subsequent return volatility (Barry 1978; Brown 1979). In other words, disclosure increases the precision of investors' beliefs regarding the parameters of the distribution of future cash flows/earnings, and this belief precision links to forward-looking volatility of stock returns.[1] Consistent with this literature's focus on the volatility of firms' future stock returns, this paper examines the link between a specific type of disclosure—earnings guidance—and a forward-looking measure of the market's estimate of stock price volatility—option implied volatility. In so doing, we provide evidence that speaks to the hotly debated question of whether managers seek to and do mitigate share price volatility with earnings guidance (McKinsey 2006; Rogers, Skinner and Van Buskirk 2009).

A wealth of empirical evidence indicates that managers care about their firms' information environment, and specifically about stock return volatility: large stock price movements have been linked to decreased liquidity (Chordia, Sarkar and Subrahmanyam 2005), and the increased likelihood of both lawsuit filings (Kim and Skinner 2012) and CEO turnover (Engel, Hayes and Wang 2003), all naturally of great concern to corporate managers. Indeed,

[1] Thus, in a Capital Asset Pricing Model setting, managerial supplied information about a firm's future prospects influences the stock's beta. Barry and Brown (1985) demonstrate that differential amounts of disclosure among firms affect the firm's equity cost of capital.

consistent with the notion that volatility concerns influence managers' disclosure decisions, research documents that managers respond to shocks to their firm's information environment with increased disclosure (Leuz and Schrand 2009) and, in particular, with increased guidance (Anantharaman and Zhang 2011; Balakrishnan, Billings, Kelly and Ljungqvist 2014). Accordingly, a substantial literature connects managers' curative guidance efforts with various information environment benefits, including decreased information asymmetry (Coller and Yohn 1997), reduced litigation risk (Billings and Cedergren 2014), increased analyst coverage (Anantharaman and Zhang 2011), economically meaningful improvements in liquidity (Balakrishnan et al. 2014), and compliance with disclose-or-abstain insider trading regulations (Li, Wasley and Zimmerman 2014).[2]

Survey evidence corroborates the above findings: when asked about their ongoing communication with investors, managers express concern about excessive share price volatility, which they widely believed to escalate investors' risk perceptions about the firm and increase the likelihood of costly shareholder litigation. Consequently, executives often mention guidance's effectiveness in promoting a reputation for transparency, attracting analyst following, and constraining volatility, when explaining why they are committed to guidance (Graham, Harvey and Rajgopal 2005; Johnson 2009; National Investor Relations Institute 2009). Thus, from managers' points of view, reducing volatility is an important objective, and guidance is an effective means for achieving this objective.

Yet, in contrast to the theoretical and empirical evidence linking disclosure to information environment benefits, recent research links guidance to both *increased* volatility (Rogers et al. 2009) and increased crash risk (Hamm, Li and Ng 2014). In so doing, it provides support for consultants and influential institutions (including McKinsey, Deloitte, the Business

[2] Prior work also links improvements in analysts' ratings of firms' disclosure policies to capital market benefits (Lang and Lundholm 1993, 1996; Healy et al. 1999; Healy and Palepu 2001).

Roundtable and the CFA Institute) who advise against providing guidance — citing litigation and market penalties associated with missed earnings targets, as well as a lack of evidence that disclosure actually curbs volatility (McKinsey 2006). Thus, while empirical evidence suggests that managers can use guidance to positively shape their firm's information environment, recent research examining volatility and crash risk contends that guidance achieves just the opposite.

Weighing in on this important debate, we consider the interplay between guidance and volatility. Consistent with recent theoretical work by Clinch and Verrecchia (2013) that underscores the importance of considering the endogeneity of disclosure choice when examining hypothesized benefits to disclosure, we begin our analysis by investigating whether volatility concerns play a role in prompting the issuance of guidance—a question left open by the prior literature. Then, controlling for determinants of disclosure, we examine the link between guidance and subsequent share price volatility. In particular, as shown in Panel A of Figure 1, we focus on: (1) whether abnormal increases in volatility are associated with managers' decisions to bundle a forecast (guidance) with current-quarter earnings news, and (2) how volatility changes after the issuance of a bundled forecast compare to volatility changes in quarters in which earnings are released without guidance.

Our analyses examine a sample of 107,307 quarterly earnings announcements made during the decade since Regulation Fair Disclosure ("Reg FD") took effect in October of 2000. In our primary empirical tests, we compare the volatility dynamics surrounding quarterly earnings announcements bundled with guidance to quarterly earnings announcements without guidance. Recognizing that not all managers may seek to quiet volatility and because the theoretical disclosure literature emphasizes that it is a sustained commitment to disclosure that improves a firm's information environment (Diamond and Verrecchia 1991; Leuz and Verrecchia 2000; Clinch and Verrecchia 2013), our tests concentrate on firms with a demonstrated willingness to guide.[3] Thus, because we aim to predict *when* a firm with a guiding history chooses to supply guidance (as opposed to *if* a firm chooses to be a guiding firm), we use firms' guiding histories to narrow our focus to the firm-quarters in which guiding firms choose whether to guide or not.

Prior work linking guidance to increases in volatility examines volatility *surrounding unbundled forecasts* (Rogers et al. 2009) and in the context of crash risk studies a yearly count of only *annual forecasts* (Hamm et al. 2014). Our research design and main tests, in contrast, focus on whether a *bundled quarterly or annual forecast* is given and the volatility dynamics *both before and after* that forecast (although we do examine unbundled forecasts in some of our empirical tests to corroborate our results). The overwhelming majority of guidance now arrives bundled with a quarterly earnings release. Over our sample period, approximately 80% of all forecasts are bundled and, in later years, the proportion climbs above 90%. Further, excluding either quarterly or annual forecasts leaves out approximately half of all post-Reg-FD guidance. Thus, bundled forecasts of *both* quarterly and annual earnings offer the most representative sample of guidance practices. Consistent with this notion, Rogers and Van Buskirk (2013) document the shift in guidance practices toward the issuance of bundled forecasts and caution against drawing inferences from non-representative samples of unbundled guidance.[4]

In contrast to prior work's focus on the volatility changes *surrounding* unbundled forecasts (as depicted in Panel B of Figure 1), in this study we separate pre-forecast changes

[3] In particular, it is possible that some management teams face conflicting incentives that cause them to remain silent in the face of rising volatility. For example, So (2013) finds that firms with high sensitivities of firm value to changes in underlying volatility (i.e., "high-vega" firms) are more likely to be firms that abstain from giving guidance (i.e., "non-guiding" firms), consistent with the notion that these managers enjoy benefits associated with increased volatility. In our analyses, we test whether volatility concerns help to explain when a guiding firm chooses to give guidance.

[4] Although researchers often limit analysis to a small sample of unbundled forecasts in an effort to isolate guidance effects, the decision to provide a forecast (bundled or unbundled) is endogenous and, as we document later, unbundled forecasts are frequently accompanied by value-relevant information events that contaminate the analysis. This prior work that examines unbundled forecasts controls for the endogeneity of managers' disclosure decisions only by matching on the gap in earnings expectations (Rogers et al. 2009). Because earnings announcements are well-defined information events that occur routinely for all firms (Bushee et al. 2010), in our analyses we control for various determinants of managers' disclosure decisions documented by prior work and augment these models to control for other factors, most notably, firms' guiding histories, as well as the presence of "disclose-or-abstain" insider trading incentives (as discussed in Li et al. 2014). See Section 5 for further discussion.

from post-forecast changes in volatility (as depicted in Panel A of Figure 1). Disentangling the change in volatility surrounding the forecast into two distinct windows (pre- and post-guidance) allows us to examine the role that volatility plays in prompting firms to guide. Further, and just as important, this measurement precision allows us to control for pre-forecast movements in volatility when examining post-forecast volatility changes. Absent separation of pre-guidance changes from post-guidance changes in volatility, tests examining the link between guidance and volatility are biased in favor of finding a positive relation if managers issue forecasts in response to some other volatility-provoking event and the measurement window commingles pre-guidance movement with post-guidance movement.

Supporting the notion that volatility concerns factor into managers' quarterly decisions to guide, we find that guidance is more likely to be bundled with earnings announcements when the release follows an abnormal run-up in forward-looking stock price volatility. Thus, in an attempt to calm a particularly turbulent pre-earnings release information environment, some managers choose to accompany current-quarter earnings news with forward-looking guidance. Shifting attention to the effectiveness of managers' guidance efforts, we find no evidence that guidance increases volatility. To the contrary, we document that earnings releases bundled with guidance are associated with abnormally large post-announcement reductions in volatility—after controlling for both the run-up in pre-announcement volatility and the average (typical) post-announcement rundown in volatility.

Our evidence of a link between pre-announcement run-ups in volatility and the decision to guide is consistent with: (1) managers reacting to the rising volatility with guidance, and/or (2) investors anticipating the arrival of a forecast (and its impact on prices). Because we are interested in examining the presence of the former effect, we make a number of adjustments to our research design in an effort to control for (or hold constant) investors' expectation of guidance (the latter effect). Most notably, all of our regressions explaining current-quarter guidance include the average run-up in volatility for the prior four quarters. This average run-up serves as a proxy for the expected (and well-documented) run-up around earnings releases and allows the current-quarter run-up to capture the abnormal increase in uncertainty. Further, all of our regressions explaining post-announcement reductions in volatility control for the current-quarter run-up as well as the average rundown in volatility from the prior four quarters. This allows our tests to link the decision to guide to abnormally large reversions in volatility.

In a further effort to hold constant the market's expectation of guidance, we re-estimate our regressions focusing on subsamples where investors are either very unlikely or are very likely to anticipate guidance. Focusing on subsets of *unlikely* guiders and *unexpected* guiders for which guidance is *un*anticipated, we continue to find that an abnormally *high* run-up in current quarter volatility predicts the quarters in which these firms that rarely bundle (and for which bundling should be *un*expected by the market) choose to bundle. In contrast, focusing on the subset of *likely* guiders for which guidance is to be expected, we find that an abnormally *low* run-up in current quarter volatility predicts the quarters in which these firms that bundle almost 9 out of every 10 quarters (and for which bundling should be expected by the market) choose *not* to bundle. Taken collectively, these subsample tests provide further support for the notion that abnormal changes in volatility explain the quarters in which guiders do and do not give guidance.

We execute a number of additional robustness tests that continue to lend support to our hypotheses and all of our findings hold: (1) when we examine uncontaminated (and seemingly unexpected) instances of unbundled guidance, (2) when we employ backward-looking measures of *realized* volatility and abnormal news items, and (3) when managers do not appear to be using guidance to adjust gaps in earnings expectations (i.e., when we control for the expectations gap faced by managers). Thus, our tests provide robust evidence of an important interplay between guidance and volatility.

Our evidence consistently supports the view that managers seek to and do mitigate share price volatility with guidance. Consequently, by considering the interplay between guidance and volatility, this paper helps to reconcile the recent findings linking guidance to increased uncertainty with the wealth of prior literature that suggests disclosure improves firms' information environments. In so doing, we enhance research that seeks to explain the decision to bundle guidance with the firm's quarterly earnings announcement—improving the explanatory power of existing models by greater than 50%. Given the recent shift in guidance practices and the importance of controlling for endogeneity associated with disclosure choice, our findings offer researchers an approach to studying bundled guidance, which represents the predominant form of guidance in recent years.

The remainder of this paper progresses as follows. Section 2 reviews the relevant literature and presents our predictions. Section 3 discusses our data and Section 4 provides descriptive statistics. Section 5 presents our findings concerning the motives of guidance. Section 6 discusses alternative explanations. Section 7 presents findings on the consequences of guidance. Section 8 concludes the study.

2. Related Literature and Hypotheses

Patell and Wolfson (1976, 1981) document that implied volatility increases before an earnings announcement and subsequently falls, while Rogers et al. (2009) document a similar pattern surrounding bundled forecasts. Shifting attention to unbundled forecasts, Rogers et al. (2009) observe a rise in pre-issuance volatility, but note that volatility remains elevated thereafter (see their Figure 2 on page 96). Thus, their work establishes that volatility escalates before the market receives a management forecast, but leaves open the important question of whether this pre-forecast rise in volatility reflects investors' expectation of a the forthcoming forecast, or if the pre-forecast rise in volatility motivates managers to issue a forecast aimed at calming the market. As Rogers et al. (2009) observe:

> "This increase in volatility likely occurs for two reasons. First, the sample includes some regular forecasts for which timing is predictable. Second, forecasts may be issued in response to some other event that caused an increase in volatility." (footnote 13 of Rogers et al. 2009).

The second possibility (i.e., guidance is given in response to volatility increases) suggests that managers believe that they can use guidance to positively shape their firm's information environment.

Thus, we begin by examining the question of whether volatility plays a role in the decision to supply a forecast. Given that managers committed to the practice of guidance do so because they believe that it aids in reducing investor uncertainty (e.g., Verrecchia (1983), Diamond (1985), and Diamond and Verrecchia (1991)) and in curbing volatility (Graham, Harvey, and Rajgopal 2005; McKinsey survey 2006), our first prediction focuses on the role that an unsettled information environment, as measured by volatility, plays in prompting managers to provide guidance in a given quarter. We posit that recent upturns in volatility induce managers to provide a forecast along with the current quarter's regularly scheduled earnings release. In particular, for managers who guided in the past, even sporadically, we expect that a recent increase in volatility (or the presence of volatility-generating events, such as an increase in material news items) will give guiding managers increased incentive to provide a forecast that quarter. Accordingly, our first hypothesis predicts:

H1: Abnormally large increases in pre-earnings announcement share price volatility are associated with an increased likelihood of bundling guidance for managers with a history of providing guidance.

The prior literature examining the benefits and costs to disclosure emphasizes that it is a sustained commitment to disclosure that affects a firm's information environment (Diamond and Verrecchia 1991; Leuz and Verrecchia 2000; Clinch and Verrecchia 2011). Consistent with this literature, H1 focuses on making predictions about when a firm with a demonstrated willingness to guide in the past chooses to guide in the current quarter. In other words, H1 suggests that an abnormal run-up in volatility explains when guiding firms guide versus remain silent in a particular quarter.

Shifting attention to the consequences of guidance, we note that prior evidence suggests that guidance might not result in reductions in volatility. While some work connects earnings guidance (and/or improvements in disclosure ratings) to decreased stock price volatility and other information environment benefits (Welker, 1995; Bushee and Noe 2000; Balakrishnan et al. 2014), other work links the issuance of negative earnings guidance to increased volatility (Rogers et al. 2009) and the frequency of annual guidance to heightened crash risk (Hamm et al. 2014). Collectively, these studies suggest that guidance not only fails to decrease volatility, but might actually increase it. Consequently, these latter findings lead us to examine whether bundled guidance (pertaining to both annual and quarterly earnings), which now constitutes the vast majority of guidance cases, alters the typical post-earnings-announcement decline in volatility documented by Patell and Wolfson (1976, 1981). Accordingly, we make the following prediction with respect to post-announcement declines in volatility during quarters in which managers bundle guidance with earnings news:

H2: The general post-earnings-announcement decrease in volatility is further enhanced by the presence of guidance with the earnings release.

3. Data

We begin our data collection by obtaining the report date of quarterly earnings announcements (*RDQ*) for all firm quarters in Compustat from the beginning of 2001 through the end of 2010. To these firm-quarter observations, we add guidance data from First Call's

Company Issued Guidelines files maintained by Thomson Reuters.[5] We code a variable (*BUNDLE*) to indicate when a management forecast occurs during the 5 trading days centered on the earnings announcement.[6] We also code several indicator variables that reflect the firm's guidance history. *GUIDE_CQTR* indicates whether the firm previously provided guidance for the current quarter's earnings. *BUNDLE_PRIOR* reflects whether the firm bundled earnings guidance with the prior quarter's earnings announcement. *BUNDLE_SQLY* equals one for firm-quarters in which the firm bundled earnings guidance with the earnings announcement for the same fiscal quarter of the previous year. *RECENT_GUIDER* denotes firms with at least three instances of guidance in the prior 12 quarters. Finally, *UNBUNDLED* indicates instances when the firm provides guidance this quarter outside of the five-day window around the *RDQ*.

Within guiding firms (i.e., *RECENT_GUIDER*=1), we code two additional variables that allow us to examine subsamples of firms where the market is likely/unlikely to expect guidance: *LIKELY_GUIDER* denotes guiding firms that bundled in the prior quarter (i.e., *BUNDLE_PRIOR*=1) and also bundled in the same quarter of last year (i.e., *BUNDLE_SQLY*=1). In contrast, *UNLIKELY_GUIDER* denotes guiding firms that did not bundle in the prior quarter (i.e., *BUNDLE_PRIOR*=0) and also did not bundle in the same quarter of last year (i.e., *BUNDLE_SQLY*=0).

Next, we collect analyst forecast data from I/B/E/S, using the unadjusted, detail file three days prior to each earnings announcement. From this file, we derive the number of analyst forecasts (*NUMEST*), conditional on the forecast being no more than 90 days old (i.e., non-stale), the median non-stale analyst forecast, and the standard deviation of non-stale analyst forecasts

[5] Limiting attention to the guidance behavior of firms with a history of guidance in the post-Reg-FD time period helps to address concerns as to bias in First Call's coverage, as all firms included in this analysis appear in the guidance dataset at least once (and often many times) in the prior 12 quarters. In addition, other sample selection and data availability constraints lead us to examine a sample of firms with high analyst following and large institutional ownership, which prior research also suggests mitigates concerns as to coverage issues. Refer to the appendix of Anilowski et al. (2007) for a discussion of the evolution of First Call as a provider of earnings forecast data and to Chuk et al. (2013) for a discussion of possible incompleteness of the CIG dataset.

[6] The 5-day window follows from prior work (Anilowski et al. 2007; Rogers et al. 2009). All results remain if we exclude the 3% of our firm-quarter observations where the forecast does not arrive exactly on the *RDQ*.

(*DISPERSION*). We measure each quarter's earnings surprise (*SURPRISE*) as the reported actual earnings (obtained from Compustat quarterly files) minus the most recent median analyst estimates, deflated by stock price three trading days prior to the earnings release date. That is, we examine the typical standardized unexpected earnings (*SUE*). Following Rogers and Van Buskirk (2013), we create indicator variables for positive earnings surprises (*P_SURPRISE* equals one if *SURPRISE* > +0.0001) and for negative earnings surprises (*N_SURPRISE* equals one if *SURPRISE* < -0.0001). In addition, we code an indicator variable (*LOSS*) for firm quarters where the firm reports negative earnings. To capture the recent history of earnings surprises, we compute the proportion of the four prior quarters that *SURPRISE* was non-negative, i.e., the proportion of quarters the firm met or beat analysts' median forecasts (*PROPMB*). For earnings announcements with a bundled management forecast of future earnings, we also compare the guidance to the prevailing median analyst forecast for the same horizon. Three binary variables are used to denote instances where the management forecast exceeds the analysts' forecast (*POSITIVE_BUNDLE*), is equal to (i.e., confirms) the analysts' forecast (*NEUTRAL_BUNDLE*), or is less than the analysts' forecast (*NEGATIVE_BUNDLE*).[7]

In addition to actual and forecasted earnings information, we collect share price, return, number of shares and volume data from CRSP. We use these data to compute the market value of a firm's equity each quarter (*MVE*), the 90-day return ending three days prior to the earnings release date (*PRIOR_RET*), and the standard deviation of returns over that 90-day period (*SVOL_LEVEL*).

Earnings announcements often generate substantial anticipatory news and uncertainty about a firm's prospects. Our intuition is that managers can use earnings forecasts (guidance) to help investors digest the many, possibly disparate, pieces of information about the firm that

[7] Rogers and Van Buskirk (2013) identify econometric problems associated with classifying news of bundled forecasts and describe an alternative approach to classifying bundled forecast news based on conditional expectations. All of our results remain when we reclassify the nature of the guidance news using their conditional approach to measurement.

occur around the earnings release date. In the theoretical models linking disclosure behavior to cost of capital, disclosure is useful to investors in forming beliefs about the distribution of future earnings/cash flows. Early work studying the effect of parameter uncertainty (e.g., Barry 1978 and Brown 1979) suggests that the volatility of future stock returns is positively correlated with the uncertainty regarding these distributional parameters. Therefore, in selecting an empirical proxy for investor uncertainty, we wish to employ a statistic that is forward-looking. Option implied volatility is a common proxy used to capture uncertainty about a firm's prospects: it is a reasonably available, market-determined estimate of the stock price's fluctuation between the date of observation and the option's expiration. Thus, changes in investor belief precision are reflected in the value of options and, thereby, implied volatility. Consequently, following Rogers et al. (2009), we gather close-of-day implied volatility data from the standardized option files of OptionMetrics. These are the implied volatilities on 30-day, standardized at-the-money options during the days before and after each earnings release date. This allows us to determine an average level of implied volatility in the days before a quarterly earnings release (*IVOL_LEVEL*) and the changes in implied volatility over various time periods before (*ΔIVOL_PRE*) and after quarterly earnings releases (*ΔIVOL_POST*).[8] We also collect closing levels of the Chicago Board Option's Exchange volatility index (*VIX_LEVEL*) from their website during the three-day window centered on an earnings announcement date to control for market-wide volatility effects.

As noted by Rogers et al. (2009, Table 1), although options exchanges exhibit a coverage bias toward larger firms, exchanges now list options covering a wide spectrum of over 3,000 publicly-traded firms, which increases the generalizability of the results. Further, in robustness tests, we use alternative proxies for changes in uncertainty to replicate our findings using the full

---

[8] As depicted in Figure 1, Rogers et al. (2009) study movements in volatility in the 7-day period surrounding the forecast. Because we are interested in disentangling the role that volatility plays in prompting the forecast from post-forecast movements in volatility, we measure volatility changes before, during and after the forecast.

sample of firms. This addresses concerns about sample selection bias introduced by restricting the sample to firms with traded options. But, because of the strong theoretical ties and measurement advantages associated with the use of implied volatility measures, we tabulate all of our main analyses using implied volatility metrics.[9]

We suggest that at informationally intense times, managers aim to influence the firm's information environment by releasing guidance. We use two measures of informational intensity in our tests. In addition to the implied volatility measures discussed above, we count the number of material news events using the Key Developments database from Capital IQ. For this measure, we count the number of news items during the 15, 30 and 90 days leading up to each quarter's earnings release. For a given quarter, we also compute "abnormal" news items as the percentage difference between the number of news items in the quarter of interest and the number in the same quarter in the prior year (*ABNEWS15D*, *ABNEWS30D*, and *ABNEWS90D*).

Finally, we gather insider trading data (sales + purchases) from Thomson Reuters Stock Transactions file. In constructing our trading measures, we concentrate on the behavior of directors and officers, consistent with prior work (e.g., Johnson et al. 2007; Li et al. 2014). This focuses our attention on the trading decisions of insiders who are most likely to be aware of impending earnings news and also most likely to be in a position to influence the firm's disclosure decisions. To further concentrate on the trading behavior of individuals most central to disclosure choices, we restrict our measure of insider trading to actions of the CEO and CFO. Insider trading is measured both within the quarter of interest ($INSIDERTRADE_{qtr}$ and CEO/CFO_TRADE_{qtr}) and in the 15-day period of time after the earnings release ($INSIDERTRADE_{post15d}$ and $CEO/CFO\_TRADE_{post15d}$). This 15-day window corresponds to the

[9] Please refer to page 91 of Rogers et al. (2009) for a discussion of the advantages of using implied volatility as an empirical proxy for investor uncertainty and page 95 for a discussion of potential bias in OptionMetrics coverage. Because we require First Call and I/B/E/S data, our sample is already predisposed toward larger capitalization firms.

period of time when Bettis et al. (2000) find that managers are typically not restricted in trading shares of the firm's stock. We fully define all the variables used in our analyses in Appendix A.

4. Descriptive Statistics

Table 1 characterizes the variables of interest for the 107,307 sample observations. We condition the data on whether the earnings announcement is or is not accompanied by guidance (i.e., *BUNDLED*). In the overall sample, about 31% (32,910 of 107,307) of the quarterly earnings announcements are bundled with guidance, which aligns with prior work (Anilowski et al. 2005; Rogers and Van Buskirk 2013). Consistent with idea that the guidance decision is sticky, this fraction increases substantially when we examine the subsample of recent guiders. Specifically, in untabulated analyses, we find that over 55% of current-quarter earnings announcements contain guidance if we condition on a recently demonstrated willingness to guide (i.e., *RECENT_GUIDER*=1).

[Insert Table 1]

As shown in last two columns of Table 1, we find statistically significant differences between the means and medians of the bundled and non-bundled earnings announcements for all the variables tabulated. Notably, the current quarter bundling decision is highly correlated with past guiding decisions (*GUIDE_CQTR*, *BUNDLE_PRIOR, UNBUNDLED*). Managers who report positive current and past earnings news (*P_SURPRISE* and *PROPMB*) are more likely to bundle guidance with the earnings release than managers reporting less favorable earnings news. Firms providing bundled guidance tend to have greater market capitalizations (*MVE*) and be more widely followed by analysts (*NUMEST*) than non-guiders. There also tends to be less disagreement among analysts following firms that guide than those that do not guide (*DISPERSION*). The decision to provide guidance with earnings is positively correlated with insiders' (either in general or just the CEO and CFO) total trading behavior both in the quarter leading up to the earnings release or in the typically open trading window after the earnings release. That is, total insider trades are larger for the firm quarters where firms choose to guide than for quarters where firms do not guide. This association between insider trading and disclosure decisions is consistent with recent research highlighting the disclosure incentives created by "disclose-or-abstain" insider trading rules (Li et al. 2014).

The final three variables in Table 1 provide insight into the public news activity of the sample firms in the 15, 30, and 90 days leading up to the earnings announcement date (*ABNEWS15D*, *ABNEWS30D*, and *ABNEWS90D*). In all cases, we find that the percentage change in news activity leading up to a quarter with a bundled earnings release is larger than that leading up to an earnings release without a bundled forecast. For example, firm-quarters without bundled guidance are associated with a mean increase in abnormal news of −2.7%, while firm-quarters with bundled guidance are associated with a significantly larger mean increase in news events (10.1%) in the 15 days prior to the earnings announcement.

5. The Decision to Bundle Guidance with an Earnings Release

This section reports the results of our investigation into the association between pre-announcement changes in uncertainty (as measured by option implied volatility and abnormal news activity) and the decision to bundle guidance with a particular earnings release. Because theory emphasizes a commitment to disclosure as being key to obtaining disclosure benefits, our empirical tests identify firms with a history of guidance (i.e., *RECENT_GUIDER*=1).

Univariate findings

Table 2 provides descriptive statistics for the stock price volatility measures we use in our analyses. We include only firm-quarters of recent guiders with OptionMetrics data (47,947 observations), but note that results are nearly identical when tabulated for the full sample (and all statistical differences remain). To get a sample-wide idea of volatility levels and changes in volatility around earnings, we compute the (unreported) overall sample means by combining the bundlers and the non-bundlers in Table 2. On average, the realized stock price volatility (*SVOL_LEVEL*) in the 90 days prior to the earnings announcement is 2.8% per day, or about 44.1% annualized (assuming identically and independently distributed returns) to a 252 trading-day year. Implied volatility from OptionMetrics, *IVOL_LEVEL*, is, on average, 47.6%. As noted in prior literature, implied volatility rises in the days prior to an earnings announcement (by 1.98% over three days, as evidenced by *ΔIVOL_PRE3D*, and by 3.48% over 15 days, as evidenced by *ΔIVOL_PRE15D*, on average), and falls substantially on the earnings announcement day (2.44%, on average, as evidenced by *ΔIVOL_RDQ*) and the immediately following days (by 6.92% to 7.7%, *ΔIVOL_POST3D* or *ΔIVOL_POST15D*).

[Insert Table 2]

Using the conditional statistics from Table 2, consistent with prior work (e.g., Waymire 1985), we document that guiding firms have lower volatility *levels* (either historical or implied) than non-guiding firms. We also find that bundled quarters are associated with larger *increases* in volatility prior to the earnings release than non-bundled quarters. The average volatility increase in the 15 days prior to earnings announcements of bundled quarters (4.2% or 1.9 volatility points based on the 0.447 mean *IVOL_LEVEL* for bundlers) exceeds that of all non-bundled quarters (2.6% or 1.3 volatility points relative to the 0.512 mean *IVOL_LEVEL* for non-bundlers that recently guided). This suggests that the decision to bundle might be related to the pre-earnings volatility increase—a finding not reported in the existing literature, but consistent with Rogers et al. (2009)'s findings for unbundled forecasts. This result is also consistent with our finding (see Table 1) that firm-quarters having guidance bundled with earnings are associated with a larger number of news stories than firm-quarters without such guidance. Further, it corroborates the univariate evidence presented in Coller and Yohn (1997), as they find bid-ask spreads rise in the year prior to a sample of 278 unbundled forecasts.

We also document significantly larger declines in post-earnings volatility for bundled quarters (around 11%, consisting of 2.8% on the earnings announcement day and at least 8% in the days thereafter) than for non-bundled quarters (less than 9%)—as evidenced by contrasting *ΔIVOL_RDQ*, *ΔIVOL_POST3D* and *ΔIVOL_POST15D* across the bundled guidance partition. To gain understanding of the overall movement in volatility surrounding the earnings announcement, we define the net overall change in volatility as the pre-announcement change in implied volatility (*ΔIVOL_PRE*), which is typically positive, combined with report date change (*ΔIVOL_RDQ*) as well as the post-earnings change (*ΔIVOL_POST*), which are both typically negative. On average, bundled firm-quarters are associated with a more negative net change (i.e., a larger overall decrease) in implied volatility as compared to non-bundled quarters. For example, the mean seven-day net volatility change from three days before the announcement through three days afterward is −8.6% for bundled quarters as compared to −5.9% for non-bundled quarters.

Multivariate findings

H1 predicts that increased uncertainty is associated with a higher likelihood of bundled guidance. To test this hypothesis, we estimate the following logistic regression model that builds on the model supplied in Rogers and Van Buskirk (2013):

$$\begin{aligned}
\text{BUNDLE}_{i,t} &= \alpha_0 + \alpha_1\left(\Delta\text{UNCERTAINTY}_{i,t}\right) \\
&+ \alpha_2\left(\text{AVG}\Delta\text{UNCERTAINTY_4Q}_{i,t}\right) + \alpha_3\left(\text{VOL_LEVEL}_{i,t}\right) \\
&+ \alpha_4\left(\text{GUIDE_CQTR}_{i,t}\right) + \alpha_5\left(\text{UNBUNDLED}_{i,t}\right) + \alpha_6\left(\text{BUNDLE_PRIOR}_{i,t}\right) \\
&+ \alpha_7\left(\text{INSIDER_TRADE_QTR}_{i,t}\right) + \alpha_8\left(\text{INSIDER_TRADE_POST15D}_{i,t}\right) + \alpha_9\left(\text{VIX_LEVEL}_{i,t}\right) \\
&+ \alpha_{10}\left(\Delta\text{VIX}_{i,t}\right) + \alpha_{11}\left(\text{P_SURPRISE}_{i,t}\right) + \alpha_{12}\left(\text{N_SURPRISE}_{i,t}\right) + \alpha_{13}\left(\left|\text{SURPRISE}_{i,t}\right|\right) + \alpha_{14}\left(\text{LOSS}_{i,t}\right) \\
&+ \alpha_{15}\left(\text{DISPERSION}_{i,t}\right) + \alpha_{16}\left(\text{PRIOR_RET}_{i,t}\right) + \alpha_{17}\left(\text{LOG_MVE}_{i,t}\right) + \alpha_{18}\left(\text{LOG_NUMEST}_{i,t}\right) \\
&+ \alpha_{19}\left(\text{PROPMB}_{i,t}\right) + \varepsilon_{i,t}.
\end{aligned} \tag{1}$$

The presence of a bundled forecast with the current quarter's earnings announcement (i.e., *BUNDLE*) serves as the dependent variable. H1 predicts a positive coefficient for *ΔUNCERTAINTY*: increased uncertainty in the current quarter (as measured by *ΔABNORMAL_NEWS* or *ΔIVOL_PRE15D*) is associated with an increased likelihood of a bundled forecast. Given the positive correlation between the decision to bundle and pre-release changes in volatility (Table 2) and the stickiness of the decision to guide (Table 1), the inclusion of *AVGΔUNCERTAINTY_4Q* captures the "typical" information environment leading into earnings releases and, thereby, provides a control for the market's anticipation of guidance in the current quarter. This allows the current-quarter variable, *ΔUNCERTAINTY*, to capture the *abnormal* or *unanticipated* increase in uncertainty.

In addition to controlling for the expected/typical rise in uncertainty prior to the firm's earnings announcement, we also include controls for firm-level volatility. Prior work indicates that managers tend to disclose more frequently when earnings are less volatile (Waymire 1985) and easier to predict (Chen, Matsumoto, and Rajgopal 2011). Consistent with this, Cotter, Tuna, and Wysocki (2006) find that "management guidance is more likely when ... analysts' forecast dispersion is low." Similarly, Houston, Lev, and Tucker (2010) argue that forecast dispersion reflects greater difficulty in predicting earnings and document a positive relation between guidance cessation and increased dispersion. Collectively, these studies indicate that managers are less likely to commit to guidance (and, accordingly, be a guiding firm) when the *level* of stock price volatility is high. When *ΔABNORMAL_NEWS* (*ΔIVOL_PRE15D*) is our proxy for the change in uncertainty we use *SVOL_LEVEL* (*IVOL_LEVEL*) to control for firm-level volatility in our regressions. Using historical volatility instead of implied volatility allows us to follow extant work with the largest possible sample by not requiring option data. Following Kim et al. (2014), we also control for market-wide volatility by using the Chicago Board Option Exchange's volatility index (*VIX_LEVEL* and ΔVIX).

Further, recent work by Li et al. (2014) underscores the importance of controlling for the presence of "disclose-or-abstain" insider trading incentives. Consequently, we also include measures of total insider trading during the quarter ($INSIDER\_TRADE_{QTR}$) and in the typically open trading window following the report date of quarterly earnings ($INSIDER\_TRADE_{POST15D}$) in the regression. Because we expect the disclosure and trading decisions to be most salient for the CEO and CFO, we tabulate results using measures of trading based exclusively on the trades of the CEO and CFO (i.e., CEO/CFO_TRADE_{QTR} and $CEO/CFO\_TRADE_{POST15D}$). Our results are robust to either approach to measurement.[10]

As mentioned, our model adjusts and augments the model introduced by Rogers and Van Buskirk (2013). Accordingly, the remaining control variables follow directly from their analysis. In particular, consistent with Rogers and Van Buskirk (2013), we predict that the likelihood of current-quarter guidance increases with past guidance (i.e., *GUIDE_CQTR* and *BUNDLE_PRIOR*).[11] In addition, because the existence of an earlier unbundled management forecast in the current quarter might alter the relation we anticipate between pre-announcement changes in volatility and the decision to bundle guidance, we also include a binary variable (*UNBUNDLED*) to indicate if the firm issued an unbundled piece of guidance earlier in the quarter of interest. Again following Rogers and Van Buskirk (2013) we also control for the current quarter's earnings news (*P_SURPRISE*, *N_SURPRISE*, |*SURPRISE*|, and *LOSS*), the

[10] Although sample size is reduced by approximately 20%, all of our results are robust when we exclude all observations where any trading occurs in the 15-day window following the report date of quarterly earnings (and, hence, the management forecast). Thus, our results remain robust to the exclusion of management forecasts that are potentially issued in response to disclose-or-abstain rules (Li et al. (2014).

[11] *BUNDLE_PRIOR* and *GUIDE_CQTR* are highly correlated (61% Spearman correlation in the full sample of firm-quarter observations and 38% Spearman correlation in the subsample of firm-quarter observations for recent guiders). Following Rogers and Van Buskirk (2013) we include both in our tabulated regressions. All of our results remain when we re-estimate our regressions excluding either *BUNDLE_PRIOR* and *GUIDE_CQTR.* More important, in the subsample analyses below that predict bundling within the groups of firms that are more/less likely to guide, both of these variables are no longer needed in the model, as they are held constant within these subsamples.

information environment of the firm (*DISPERSION*, *LOG_NUMEST*, *LOG_MVE*), and recent performance (*PRIOR_RET* and *PROPMB*).[12]

We report results from two samples and two measures of uncertainty in Table 3. The two samples are all firm-quarter observations and the firm-quarter observations associated with recent guiders. Uncertainty measures include abnormal news items and changes in option implied volatilities using options with 30 days until expiration during the 15 days prior to the earnings announcement.[13]

[Insert Table 3]

In columns [1] and [2], we use all observations in the sample with complete relevant data. This includes all 107,307 firm quarters in column [1], while column [2] uses all 72,016 firm quarters with available OptionMetrics data. In column [3], we use only the observations characterized as coming from recently guiding firms (*RECENT_GUIDER*=1) with options data. The advantage of focusing the sample on recent guiders is that we consider only firms with a demonstrated willingness to provide guidance. These firms are more consistent with the theory motivating disclosure as a means to impact firms' information environments and less consistent with the firms highlighted in So (2013). Thus, while the regressions in columns [1] and [2] at least partially distinguish guiding firms from non-guiding firms, the regression in column [3] focuses more sharply on explaining why a firm with a history of guiding chooses to guide or remain silent in a particular quarter.

[12] Rogers and Van Buskirk (2013) also include an indicator variable to identify earnings announcements that are accompanied by conference calls. When we re-estimate all of our regressions using a subset of data for which we have available conference call data, all of our results remain when we include a conference call indicator. Because we conduct all of our main tests using the subsample of firms with guiding histories and for which publicly traded options exist, the vast majority of our firms host conference calls surrounding their earnings announcements.

[13] In addition to examining shorter-term measures of uncertainty, we also examine longer-term measures of uncertainty (based on 60- and 91-day volatility). Our results are robust to the use of these alternative measures. Further, Patell and Wolfson (1976, 1981) document that implied volatility increases before an earnings announcement and subsequently falls. Consequently, this causes concern that our tests are picking up the normal rise in volatility associated with investors' anticipation of the forthcoming earnings and perhaps forecast news. Although we believe that including $\boldsymbol{AVG\Delta UNCERTAINTY_{4Q}}$ addresses this concern because it allows our tests to focus on the abnormal, current-quarter run-up in volatility, we further address this concern by moving the window over which we measure the run-up back to ten days prior to the report date of quarterly earnings (i.e., we measure from day -20 to day -10), as Figure 2 of Rogers et al. (2009) indicates that most of this rise in volatility occurs in the 10 days before the announcement. Our results are robust to this alternative measurement.

In all specifications in Table 3 the relation between the change in "unexpected" pre-earnings uncertainty (volatility) and management's decision to bundle guidance with the earnings is positive. We also report the coefficient estimates of variables designed to control for the typical/normal increase in volatility prior to an earnings release (*AVGΔUNCERTAINTY*), the level of earnings volatility (*VOL_LEVEL*), the firm's guidance history (*GUIDE_CQTR* and *BUNDLE_PRIOR*), the existence of a management forecast during the quarter of interest that is not bundled with earnings (*UNBUNDLED*), and insider trading (CEO/CFO_TRADE_{qtr} and $CEO/CFO\_TRADE_{post15d}$).

Although we do not report the coefficient estimates for the remaining control variables, our conclusions are consistent with prior findings. Further, the addition of our volatility and trading variables significantly improves the fit of the model, as the Pseudo R^2 for our model estimated on the full sample is 65.5%. This improves considerably upon the 42.49% shown in Rogers and Van Buskirk (2013, Table 3) for a similar time period—suggesting a 54% increase in explanatory power for the model.

Focusing on the full-sample specifications, we find that both *ABNORMAL_NEWS* and *ΔIVOL_PRE15D* (our proxies for *ΔUNCERTAINTY*) are associated with an increased likelihood of bundled guidance. Because we control for the "typical" increase in uncertainty prior to earnings with $AVG\Delta UNCERTAINTY_{4Q}$, this mitigates the likelihood that the increases in uncertainty reflect the market's anticipation of the bundling decision. Thus, the coefficient estimate for *ΔUNCERTAINTY* represents the effect that the current-quarter elevation in *unanticipated* uncertainty has on the bundling decision. For the most part, reported control variables have the expected sign. Firms with higher volatility levels are less likely to bundle. Firms that guided in the past (either via bundled or unbundled forecasts) are more likely to continue to provide guidance in the quarter of interest. Finally, consistent with the idea that managers must disclose or abstain from trading (Li et al. 2014), we find that guidance positively relates to both backward-looking and forward-looking measures of insider trading.

Because we aim to predict *when* a firm with a demonstrated willingness to guide chooses to issue guidance (as opposed to *if* a firm chooses to be a guiding firm), the specification presented in column [3] narrows our focus to *recent* guiders. Said differently, we remove non-guiding firms from the analysis in order to allow our tests to focus on explaining the quarters in which guiders do and do not guide. In so doing, we increase the difficulty of predicting when firms will choose to bundle. Here too, we find strong evidence that an abnormal run-up in volatility helps to explain when recent guiders choose to bundle a forecast with the current-quarter earnings news. Thus, the evidence in Table 3 indicates that regardless of whether we measure the current-quarter pre-announcement rise in uncertainty using news stories or option implied volatility, we detect a consistently robust, positive relation between abnormal run-ups in investor uncertainty and the decision to issue earnings guidance.

6. Is the run-up in volatility related to the market's expectation of guidance?

Evidence of a link between run-ups in volatility prior to providing guidance is consistent with two explanations: (1) the market anticipating the act of bundling (and its associated impact on stock price), and (2) managers reacting to the rising volatility by providing guidance. The fact that managers of firms with a history of guidance are also more likely to guide following quarters containing an *abnormal* increase in uncertainty provides initial evidence consistent with the latter effect: the presence of a managerial reaction. In our next analyses, we provide additional evidence in support of the presence of a managerial reaction effect by limiting variation in the extent to which investors might reasonably anticipate guidance (Table 4), by substituting backward-looking realized volatility for forward-looking implied volatility in our tests (Table 5), and by examining the run-up in volatility prior to unbundled guidance (Table 6).

Holding constant investors' expectation of guidance: subsample analyses

As shown in Panel A of Table 4, focusing on the subset of *likely* guiders for which guidance is expected (as measured by the *presence* of a bundled forecast in the same quarter of last year as well as the *presence* a bundled forecast last quarter—i.e., *BUNDLE_PRIOR*=1 and *BUNDLE_SQLY*=1), we find that this set of firms bundles 87.2% of the time in the current quarter. Given that these firms bundle the vast majority of the time (i.e., nearly 9 out of every 10 quarters), investors should rationally anticipate a bundled forecast in the current quarter. In contrast, focusing on the subset of *unlikely* guiders, for which guidance is *not* expected (as measured by the *absence* of a bundled forecast in the same quarter of last year, as well as the *absence* a bundled forecast last quarter—i.e., *BUNDLE_PRIOR*=0 and *BUNDLE_SQLY*=0), we find that these firms only bundle 24.2% of the time in the current quarter. Thus, partitioning based on firms' guidance histories allows us to isolate subsamples where investors are more and less likely to expect the guidance.

[Insert Table 4]

In Panel A of Table 4, we compare the pre-earnings run-up in volatility across four groups within these subsubsamples:

(1) ***Likely guiders who DO guide:*** firms that are more likely to bundle this quarter and, as expected, *do* bundle in the current quarter (i.e., *BUNDLE_PRIOR*=1, *BUNDLE_SQLY*=1 and *BUNDLE*=1),

(2) ***Likely guiders DO NOT guide:*** firms that are more likely to bundle this quarter and, unexpectedly, *do not* bundle in the current quarter (i.e., *BUNDLE_PRIOR*=1, *BUNDLE_SQLY*=1 and *BUNDLE*=0),

(3) ***Unlikely guiders who DO guide:*** firms that are less likely to bundle this quarter and, unexpectedly, *do* bundle in the current quarter (i.e., *BUNDLE_PRIOR*=0, *BUNDLE_SQLY*=0 and *BUNDLE*=1), and

(4) ***Unlikely guiders DO NOT guide:*** firms that are less likely to bundle this quarter and, as expected, *do not* bundle in the current quarter (i.e., *BUNDLE_PRIOR*=0, *BUNDLE_SQLY*=0 and *BUNDLE*=0).

First, we hold constant the likelihood of bundling and compare *ΔIVOL_PRE15D* for GROUP 1 to that of GROUP 2 and *ΔIVOL_PRE15D* for GROUP 3 to that of GROUP 4—i.e., we compare *ΔIVOL_PRE15D* across the bundled columns *within* the likely (row [a]) and unlikely (row [b]) subsamples. These comparisons are less plausibly influenced by differences in the market's anticipation of bundling and more likely to represent management's reaction to changes in uncertainty. For firms likely to bundle (row [a]), the mean volatility increase is 4.3% for the firms that actually bundle (GROUP 1) in the current quarter compared to 2.3% for firms that do not bundle (GROUP 2). For firms unlikely to bundle (row [b]), the mean volatility increase is 4.4% for the current-quarter bundlers (GROUP 3) and 3.1% for the current-quarter non-bundlers (GROUP 4). Both of these differences are statistically significant. Thus, holding constant the market's anticipation of bundling, *ΔIVOL_PRE15D* is higher in quarters when the firm actually bundles as compared to non-bundled quarters. These differences are consistent with a managerial reaction to rising volatility in the current quarter, as the likelihood of bundling is similar across compared groups.

Next, we hold constant the presence/absence of a bundled forecast in the current quarter and compare *ΔIVOL_PRE15D* for GROUP 1 to that of GROUP 3 and *ΔIVOL_PRE15D* for GROUP 2 to that of GROUP 4—i.e., we compare *ΔIVOL_PRE15D* across groups that differ with respect to the market's ability to anticipate guidance based on historical guiding history but identical with respect to the current quarter's guidance choice. For firms that bundle in the current quarter, the mean volatility run-up is 4.3% for firms for which the market should anticipate guidance (i.e., GROUP 1) and 4.4% for firms that the market should not anticipate guidance (i.e., GROUP 3). Likewise, the mean volatility increase in non-bundled quarters is 2.3% for likely bundlers (i.e., GROUP 2) as compared to 3.1% for unlikely bundlers (i.e., GROUP 4). None of these differences in means (or medians) is statistically significant at traditional levels. Hence, holding constant the guidance decision in the quarter of interest, we detect no differences in volatility run-up between likely and unlikely bundlers. The absence of significant differences in these comparisons is inconsistent with notion that the volatility increase is due solely to the market's anticipation of bundled guidance.

Building upon the univariate evidence of a managerial reaction effect presented in Panel A of Table 4, in Panel B of Table 4 we re-consider the multivariate analysis presented in Table 3 but this time we differentiate between instances where investors are more or less likely to anticipate current-quarter guidance from guiding firms. In column [1], we consider firm-quarter observations where the market is *more* likely to expect guidance (i.e., the group described in row [a] of Panel A). In column [2], we consider firm-quarter observations where the market is *less* likely to expect guidance (i.e., the group described in row [b] of Panel A).

Column [1] reports the results of estimating Equation (1) using firm quarters of likely guiders. The incidence of guiding increases with changes in implied volatility. Recall from Panel A, 87.2% of these sample firms guided with the current quarter's earnings. Thus, for this subset of firms, the variation in the dependent variable that remains to be explained by our logistic regression is limited (as the overwhelming majority of these observations come with bundled forecasts). Yet, we continue to find strong evidence of a positive association between the abnormal run-up in volatility (Δ*UNCERTAINTY*) and the decision to bundle. Said differently, we find that the abnormal run-up in current quarter volatility predicts the quarters in which firms that bundle the vast majority of the time (and for which bundling should be largely expected by the market) choose *not* to bundle. In column [2], we shift attention to the unlikely guiders for which guidance is *less* likely to be anticipated, as Panel A indicates that these firms bundle 24.2% of the time. Thus, for this subset of firms, the market should not be routinely anticipating guidance. Yet, we continue to find strong evidence of a positive association between the abnormal run-up in volatility (Δ*UNCERTAINTY*) and the decision to bundle.

Because investors are unlikely to be assessing a high likelihood of bundling for these firms, we argue that the decision to bundle is a reaction to the larger increase in volatility rather than the volatility increasing because the market anticipates guidance.

Finally, in column [3], we re-estimate our logistic regression using a sample of "unexpected" guiders. To construct this subsample, we begin with the full sample of 72,016 firm-quarter observations having complete data. Using this sample, we estimate the likelihood of bundling in the current quarter using Equation (1) and select the quartile of firm-quarters with the lowest estimated likelihood of bundling. As shown in the bottom row of Table 5, this subsample only bundles 2.5% of the time. Thus, guidance is very unlikely to be anticipated by investors for this subset of firms. Nonetheless, the run-up in uncertainty prior to the earnings release continues to be significantly positively associated with the decision to guide in the current quarter for firm-quarters where there should be virtually no anticipation of guidance.

Taken collectively, these subsample tests support the notion that guidance is prompted by an abnormal volatility run-up, even after we hold constant the expectation of bundling (by narrowing in on the firm-quarters where bundling is expected the vast majority of the time or by narrowing in on the firm-quarters where bundling is unexpected).

Importantly, we notice that when we limit the analysis to the subsamples that hold constant the expectation of guidance (i.e., Panel B), we do not detect a significant relation between the average run-up ($AVG\Delta UNCERTAINTY_{4Q}$) and the decision to bundle in the current quarter. In contrast, when estimating the regression on the full sample of guiding firms (i.e., Table 3) we detect a significantly positive relation. The lack of significance in the subsample regressions is consistent with the notion that focusing on subsamples successfully controls for the expectation of guidance in the current quarter and, thus, the inclusion of the normal run-up is no longer important in explaining *BUNDLE*.[14]

Substituting backward-looking realized volatility for forward-looking implied volatility

If investors anticipate that a firm will guide in the upcoming quarter's earnings release, then pre-earnings implied volatility could increase because of the added information potential of guidance. Although we believe that the subsample results examined in Table 4 mitigate this concern, we take an alternative approach to addressing this issue in Table 5. In particular, we replace the forward-looking option implied volatility with backward-looking realized (actual) stock price volatility into our estimate of Equation (1). Backward-looking measures of volatility lack the theoretical tie to asset pricing, but are less likely to be influenced by future events. We report results using the standard deviation of stock returns in the 15 days prior to the earning release (as this matches the windows used to evaluate implied volatility) but results are not sensitive to using longer windows to compute this metric. To compute an abnormal change in uncertainty we subtract the 15-day pre-earnings standard deviation of returns from the same quarter last year (i.e., *abnormal_rvol_pre15d*). If the previously documented positive association between the decision to bundle and the pre-earnings increase in uncertainty is purely an anticipation effect, then we do not expect to find any relation between the decision to bundle this quarter and changes in backward-looking, *realized* volatility. If the manager reacts to increasing uncertainty by bundling, however, then we expect that realized volatility is indicative of an unsettled information environment and also positively correlates with the guiding choice.

[Insert Table 5]

In Table 5, we report the results of substituting realized (backward-looking) volatility for implied (forward-looking) volatility. The results documented in Table 4 are confirmed; firm-

[14] The magnitude of the coefficient estimate on *ΔUNCERTAINTY* is reduced if observations with extremely large and extremely small uncertainty changes are removed (or if the sample is winsorized at the 5% tails), but the coefficient remains significant in all specifications.

quarters with higher abnormal *realized* volatility are those where management tends to bundle. This is inconsistent with the notion that our results solely reflect market anticipation of bundling and, instead, supports the hypothesis that managers react to increased uncertainty by guiding.[15]

Examining volatility movement before unbundled guidance

Finally, in Table 6 we aim to limit the expectation of guidance by examining whether there is an abnormal run-up in volatility prior to *unbundled* guidance. As unbundled guidance can be issued at any date, not just with earnings, it is arguably more difficult for the market to anticipate. We focus on the 8,039 firm-quarters in which guiding firms supplied an unbundled piece of guidance during the quarter (i.e., *UNBUNDLED*=1). In this analysis, we test whether the run-up in volatility prior to an unbundled forecast (as measured by Δ*IVOL_PRE15D_UNBUNDLED*) is greater than the run-up in volatility during the same time in the prior quarter (as measured by Δ*IVOL_PRE15D_UNBUNDLED_PRIOR*) or than the run-up in volatility during the same time last year (as measured by Δ*IVOL_PRE15D_UNBUNDLED_SQLY*). We find evidence of a significant difference between the run-up prior to an unbundled forecast as compared to the run-up during the same time last quarter (i.e., [a]>[b]) and as compared to the run-up same time in the same quarter of last year (i.e., [a]>[c]). This again supports the hypothesis that managers react to rising volatility with guidance.

[**Insert Table 6**]

Yet, as Rogers et al. (2009) note, a sample of unbundled forecasts may include some forecasts for which the timing is predictable or forecasts that are issued in response to a volatility-provoking news event. Using the Key Developments database from Capital IQ, we find support for this notion: 3,655 (59%) of the 6,197 unbundled forecasts (with available OptionMetrics data) occurring after 2004 (the point at which Capital IQ data becomes stable)

[15] Abnormal number of news items (see Table 4) is a similar backward-looking measure of an informationally unsettled environment and produces similar results.

contain a contaminating news item in the 3-day window prior to and including the date of the forecast, some of which can be anticipated by investors.[16] To address this issue of potential anticipation by investors, we limit our analysis to the 2,542 uncontaminated, unbundled forecasts that are not contemporaneous with another announcement or event. Although the mean/median changes in volatility run-ups are now smaller in magnitude, we continue to find evidence consistent with a managerial reaction to rising volatility, as the increase in volatility before unbundled forecasts is greater than the volatility change in the same 15 days of the prior quarter or the same 15 days of the prior year.

Given that recent research cautions against drawing inferences from small samples of unbundled guidance, our main analyses focus on the decision to supply bundled guidance. Nonetheless, this small sample evidence is consistent with volatility concerns influencing the decision to supply unbundled guidance. This provides further evidence of a managerial reaction to rising volatility, as uncontaminated, unbundled forecasts are relatively infrequent and are less likely to be anticipated by investors.

Collectively, the evidence presented in Tables 4, 5, and 6 indicates that managers aim to calm short-term investor uncertainty with guidance in the current quarter. In our next set of tests, we examine the extent to which this anticipated benefit manifests.

7. The Change in Implied Volatility following the Guidance

In this section, we investigate whether bundled earnings releases are associated with larger declines in volatility than the volatility declines following earnings releases that are not

[16] Additional (untabulated) analysis of the Key Developments database indicates that from 2005 through 2010, the mean (median) number of key events per firm per year is 24 (17), with a lower quartile of 7 and an upper quartile of 32. This suggests that the typical firm experiences a key event approximately every two weeks, although many key events cluster in time. Of the 8,913 unbundled forecasts occurring during this period, 3,431 (38.5%) of those forecasts are given on the same date that the firm holds a conference call (which are announced in advance) and in total 5,838 (65.5%) of those forecasts have a contaminating event in the 7-day window surrounding the forecast. The most frequent contaminating events are conference presentation calls, client announcements, CEO/CFO/executive board change announcements, product related announcements, and monthly sales announcements/calls. Because some of these events have predictable timing, investor anticipation can be an issue even with unbundled guidance.

accompanied by guidance. We do this by estimating the following regression equation for the sample of recent guiders:

$$
\begin{aligned}
&\Delta\text{IVOL\_POST15D}_{i,t} = \beta_0 + \beta_1\left(\text{BUNDLE}_{i,t}\right) \\
&\quad + \beta_2\left(\text{AVG}\Delta\text{IVOL\_POST15D\_4Q}_{i,t}\right) + \beta_3\left(\Delta\text{IVOL\_PRE15D}_{i,t}\right) + \beta_4\left(\Delta\text{IVOL\_RDQ}_{i,t}\right) \\
&\quad + \beta_5\left(|\text{SURPRISE}|_{i,t}\right) + \beta_6\left(\text{INSIDER\_TRADE\_QTR}_{i,t}\right) + \beta_7\left(\text{INSIDER\_TRADE\_POST15D}_{i,t}\right) \quad (2) \\
&\quad + \beta_8\left(\text{VIX\_LEVEL}_{i,t}\right) + \beta_9\left(\Delta\text{VIX}_{i,t}\right) + \beta_{10}\left(\text{VOL\_LEVEL}_{i,t}\right) + \beta_{11}\left(\text{LOG\_MVE}_{i,t}\right) \\
&\quad + \beta_{12}\left(\text{LOG\_NUMEST}_{i,t}\right) + \beta_{13}\left(\text{PROBMB}_{i,t}\right) + \varepsilon_{i,t}.
\end{aligned}
$$

The change in implied volatility measured in the 15 days subsequent to the earnings announcement, Δ*IVOL_POST15D*, serves as the dependent variable in this regression. H2 predicts a negative coefficient for *BUNDLED*: bundled guidance is associated with abnormally large reversions in post-announcement volatility.

The above regression equation follows from Rogers et al. (2009), with a few notable exceptions. First, we disentangle the change in volatility surrounding the forecast into two distinct windows (pre- and post-guidance). Absent efforts to separate pre-guidance changes from post-guidance changes in volatility, tests examining the link between guidance and volatility are biased in favor of finding a positive relation if managers issue forecasts in response to some other volatility-provoking event (such as an abnormal amount of news) and the measurement window commingles pre-guidance movement with post-guidance movement. Consequently, we adjust Rogers et al. (2009)'s research design to disentangle the pre- and post-guidance movements in volatility, which allows us to sharpen our tests.

In addition, this measurement allows us to control for pre-forecast movements in volatility when examining post-forecast volatility changes. In particular, if the run-up is greater, then we expect that the reversion will likely be greater. Our analyses address this issue with the inclusion of the current-quarter run-up (Δ*IVOL_PRE15D*), the day 0 movement (Δ*IVOL_RDQ*), and the average rundown from the prior four quarters *AVG*Δ*IVOL_POST15D*$_{4Q}$). As such, our analysis speaks to the relation between *BUNDLE* and the abnormal rundown in volatility (Δ*IVOL_POST15D*) after the current-quarter earnings announcement. In our opinion, this is a strong test, as the average rundown will be higher for frequently guiding firms, as there may have been bundled guidance in the prior four quarters. Hence, our tests link abnormally large reversions to guidance after controlling for the run-up in volatility and after controlling for the typical rundown that follows the firm's earnings announcement.

Our main findings, as shown in Table 7, is that the firm-quarters including guidance (regardless of the contemporaneous earnings news) consistently have *larger* post-earnings announcement *decreases* in volatility than firm-quarters without guidance, as evidenced by the significantly negative coefficient for *BUNDLE*. This result holds after controlling for the earnings news (i.e., moving across the negative (columns [1] and [2]), neutral (columns [3] and [4]), and positive (columns [5] and [6]) current-quarter earnings news samples), as well as the typical run-down in volatility post earnings, the change in volatility levels leading up to the earnings release, and the change in volatility on the earnings release date. The clear message is that bundling guidance with earnings announcement is associated with larger decreases in post-earnings announcement volatility than unbundled earnings releases. The coefficients in the 15-day regression average almost -0.015 across the various subsamples, suggesting that bundling firms' implied volatility falls an additional 1.5%, on average ceteris paribus, than non-bundlers. That compares to an overall mean post earnings 15-day volatility change of -7.7% for the recent-guider sample (Table 2). Thus, bundling is associated with a 19% greater run-down (1.5% marginal effect compared to an unconditional average of 7.7%). As we have selected our sample from guiding firms, this result is not simply due to a distinction between firms that never guide and firms that guide, but reflects differences in firms that are willing to guide between quarters when they guide and quarters when they do not guide.

[Insert Table 7]

In additional (untabulated) analyses, we repeat these analyses: (1) replacing forward-looking option implied volatility with backward-looking realized (actual) volatility examined earlier (see Table 5) and (2) focusing on the subsamples of Unlikely/Unexpected guiders examined earlier (see Panel B of Table 4). Despite the added measurement error (associated with imprecise measurement of changes in realized volatility) and reduced sample size, we continue to find strong support for our predictions, as the presence of a bundled forecast is associated with abnormal reductions in post-announcement volatility in all of these tests.

As noted by Rogers et al. (2009), under the "expectations adjustment hypothesis" of Ajinkya and Gift (1984), managers are more likely to provide guidance when investors' earnings expectations differ from their own. Although our tests thus far control for the amount and sign of earnings news, in additional (untabulated) robustness tests we control for managers' use of guidance to adjust gaps in investors' expectations of earnings by limiting analysis to firm-quarter observations in which (1) firms report no current-quarter earnings surprise and (2) managers either remain silent or bundle a neutral/confirming forecast with the current-quarter, no surprise earnings news (i.e., no "expectation adjustment").

In these "no news" firm-quarters, we find that managers are still more likely to bundle a confirming forecast (as opposed to remain silent) in the presence of an abnormal run-up in volatility.[17] In other words, an abnormal increase in uncertainty explains when managers bundle verbal indications of their agreement with the market's expectations of their future earnings versus when managers tacitly confirm their agreement with the market's expectations via silence.

Further, we continue to find that the abnormal rundown in volatility is greater when managers bundle verbal indications of their agreement with the market's expectations of their

[17] Consistent with the notion that focusing on "no news" firm-quarters (as measured by the absence of a current-quarter earnings surprise and either the absence of a bundled forecast or the presence of a neutral confirming forecast) holds constant contemporaneous news, we detect no significant differences in the means, medians or standard deviations of the 3- or 5-day abnormal return surrounding the report date of quarterly earnings when we compare the bundled (i.e., neutral/confirming guidance) quarters to the non-bundled (silent) quarters.

future earnings than when managers tacitly confirm their agreement with the market's expectations via their silence. Consequently, we view this evidence as supporting the notion that explicit (verbal) guidance that confirms the consensus has a volatility benefit that exceeds the benefit of implicit (non-verbal) agreement with the prevailing consensus.

8. Conclusion

In this study, we consider the interplay between guidance and volatility after separating pre-earnings run-ups in volatility from post-earnings declines in volatility. Our motivation for this investigation comes from the tension between the theoretical and empirical literature that links disclosure to various information environment benefits and recent academic evidence indicating that guidance increases volatility and crash risk (Rogers et al. 2009).

Consistent with the notion that volatility does indeed factor into managers' decisions to provide earnings guidance, we find that abnormal run-ups in volatility predict the quarters in which guiding firms choose to guide. And what happens to share price volatility after the guidance release? In contrast to recent work, we find no evidence that guidance increases volatility. In fact, our evidence indicates that earnings releases bundled with guidance are associated with abnormally large post-announcement reductions in volatility.
Thus, consistent with managers' perceptions (as reflected in survey evidence regarding the perceived benefits of disclosure) as well as theoretical work, guidance appears to reduce share price volatility. This finding, along with recent work connecting guidance to meaningful improvements in liquidity, reductions in litigation risk and the attraction of analyst coverage, speaks to the potential benefits of guidance.

Given the endogeneity of managers' disclosure decisions, in our analyses we control for various determinants of managers' disclosure decisions documented by prior work and augment these models to control for other factors—including firms' guiding histories, as well as the presence of "disclose-or-abstain" insider trading incentives. Although the explanatory power of our models examining the quarterly decision to guide improves upon existing models by greater than 50%, we cannot completely rule out alternative factors at play in this setting. Nevertheless, we execute a number of additional robustness tests in an effort to address concerns that the volatility patterns we document merely reflect investors' anticipation of forthcoming guidance. In so doing, our results are robust: (1) when we hold constant the expectation of guidance by focusing on subsamples of likely and unlikely/unexpected guiders, (2) when we examine uncontaminated (and seemingly unexpected) instances of unbundled guidance, and (3) when we examine backward-looking measures of *realized* volatility and abnormal news items. Thus, while these findings do not (and cannot) suggest the absence of anticipation effects at play in our setting, we believe these findings do offer compelling evidence of the presence of a reaction effect. That is, our evidence consistently and robustly supports the notion that, on average, managers react to rising volatility with guidance and that those efforts ultimately do positively shape their firms' information environment.

Appendix A ■ Variable definitions

We assemble a sample of 107,307 firm-quarter observations for the period of 2001 through 2010 with available Compustat, CRSP, I/B/E/S and First Call data. In our main tests, we focus on the 47,947 firm-quarter observations associated with firms with guidance in their recent history (i.e., ***recent_guider*=1**) and with standardized option data available from OptionMetrics. We winsorize all continuous firm-quarter observations at the 1% and 99% levels. We code industry fixed effects based on 2-digit SIC codes.

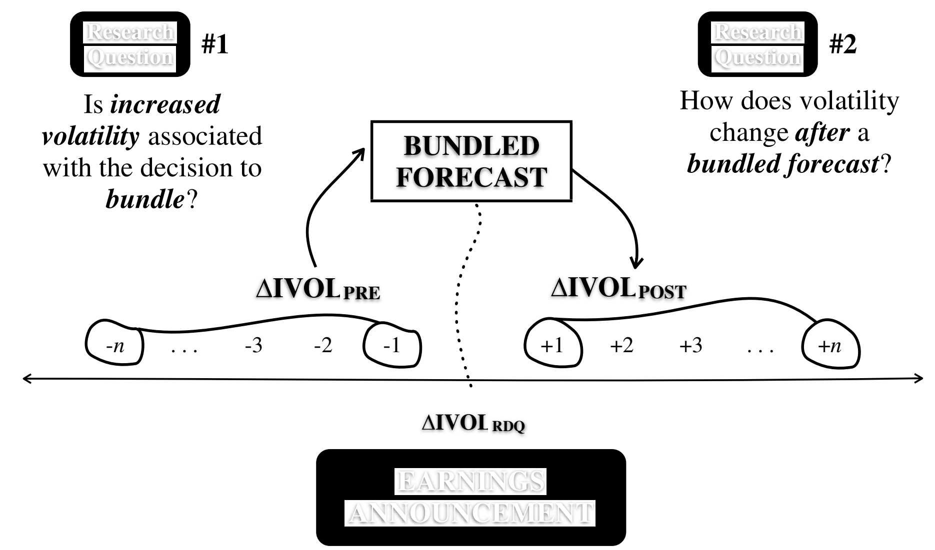
bundle	An indicator variable set to 1 if the firm provided an earnings forecast during the 5-day window surrounding the report date of quarterly earnings.
negative_bundle	An indicator variable set to 1 if ***bundle=1*** and the forecast estimate is less than the pre-forecast prevailing median analyst estimate.
positive_ bundle	An indicator variable set to 1 if ***bundle=1*** and the forecast estimate is greater than the pre-forecast prevailing median analyst estimate.
neutral_ bundle	An indicator variable set to 1 if ***bundle=1*** and the forecast estimate is equal to the pre-forecast prevailing median analyst estimate.
guide_cqtr	An indicator variable set to 1 if the firm previously provided earnings guidance for the current quarter's earnings.
bundle_prior	An indicator variable set to 1 if the firm issued an earnings forecast during the 5-day window surrounding the report date of quarterly earnings last quarter.
bundle_sqly	An indicator variable set to 1 if the firm issued an earnings forecast during the 5-day window surrounding the report date of quarterly earnings same quarter of last year.
unbundled	An indicator set to 1 if the firm provided any unbundled guidance during the current quarter.
recent_guider	An indicator set to 1 if the firm is a guiding firm, as measured by the presence of at least 3 pieces of guidance in the prior 12 quarters.
likely_guider	An indicator set to 1 if the firm is a guiding firm (***recent_guider=1***) and the firm bundled in the prior quarter (***bundle_prior=1***) and bundled in the same quarter of last year (***bundle_sqly=1***).
unlikely_guider	An indicator set to 1 if the firm is a guiding firm (***recent_guider=1***) but the firm did not bundle in the prior quarter (***bundle_prior=0***) and did not bundle in the same quarter of last year (***bundle_sqly=0***).
unexpected_guider	An indicator set to 1 if the firm is in the lowest quartile of firm-quarters of the full sample where bundled guidance is least likely to be expected in the current quarter based on the prediction model tabulated in Table 3.
surprise	Actual earnings minus the prevailing median analyst estimate, deflated by stock price 3 trading days prior to the report date of quarterly earnings.
p_surprise	An indicator variable set to 1 if this quarter's earnings surprise exceeds +0.0001.
n_surprise	An indicator variable set to 1 if this quarter's earnings surprise falls below -0.0001.
loss	An indicator variable set to 1 if actual earnings is less than 0.
dispersion	The standard deviation of prevailing analyst estimates for the current period's earnings.
prior_ret	The cumulative stock return over the 90-day period ending 3 trading days prior to the report date of quarterly earnings.
mve	The market value of equity (i.e., price multiplied by shares outstanding) measured 3 trading days prior to the report date of quarterly earnings.

numest	The number of analysts with outstanding estimates 3 trading days prior to the report date of quarterly earnings.
propmb	The proportion of the previous 4 quarters that the firm's reported earnings met or exceeded analysts' prevailing median consensus estimates.
insidertrade$_{qtr}$	The total insider trades (i.e., sales + purchases) of directors and officers (scaled by shares outstanding at the beginning of the quarter) during the current quarter.
insidertrade$_{post15d}$	The total insider trades (i.e., sales + purchases) of directors and officers (scaled by shares outstanding at the beginning of the quarter) during the 15 days after the report date of quarterly earnings.
ceo/cfo_trade$_{qtr}$	The total insider trades (i.e., sales + purchases) of the CEO and CFO (scaled by shares outstanding at the beginning of the quarter) during the current quarter.
ceo/cfo_trade$_{post15d}$	The total insider trades (i.e., sales + purchases) of the CEO and CFO (scaled by shares outstanding at the beginning of the quarter) during the 15 days after the report date of quarterly earnings.
abnews15d	The percentage change in **news** in the last 15 days of the current quarter compared to news in the last 15 days of the same quarter of last year (**news15_sqly**).
abnews30d	The percentage change in **news** in the last 30 days of the current quarter compared to news in the last 30 days of the same quarter of last year (**news30_sqly**).
abnews90d	The percentage change in **news** in the 90 days of the current quarter compared to news in the 90 days of the same quarter of last year (**news90_sqly**).
svol_level	The standard deviation of daily stock returns over the 90-day period ending 3 trading days prior to the report date of quarterly earnings.
abnormal_rvol_pre15d	The standard deviation of daily returns in the 15 days prior to the report date of quarterly earnings for the current quarter less the standard deviation of daily returns in the 15 days prior to the report date of quarterly earnings for the same quarter of last year.
ivol_level	The average level of implied volatility (**ivol**) for a 30-day duration, at-the-money option in the 5 trading days prior to the report date of quarterly earnings.
Δivol_pre15d	The natural logarithm of the ratio of **ivol** (for a 30-day duration standardized option) measured at the close of the day prior to the report date of quarterly earnings to **ivol** measured 15 days prior to the report date of quarterly earnings (i.e., the change in ivol in the 15 days prior to the earnings release).
Δivol_rdq	The natural logarithm of the ratio of **ivol** (for a 30-day duration standardized option) measured at the close of the report date of quarterly earnings to **ivol** measured at the close of the day prior to the report date of quarterly earnings (i.e., the change in ivol on the day of the earnings release).
Δivol_post15d	The natural logarithm of the ratio of **ivol** (for a 30-day duration standardized option) measured 15 days after the report date of quarterly earnings to **ivol** measured as of the close of the report date of quarterly earnings (i.e., the change in ivol in the 15 days following the earnings release).
avgΔivol_pre15d$_{4q}$	The average of **Δivol_pre15d** for the prior 4 quarters.
avgΔivol_post15d$_{4q}$	The average of **Δivol_post15d** for the prior 4 quarters.
Δivol_pre15d_unbundled	The natural logarithm of the ratio of **ivol** (for a 30-day duration standardized option) measured at the close of the day 15 days prior to the issuance of an

	unbundled forecast to **ivol** measured 1 day prior to the issuance of an unbundled forecast (i.e., the change in ivol in the 15 days prior to an unbundled forecast). **Δivol_pre15d_prior** is **Δivol_pre15d_unbundled** measured in the same time of the prior quarter. **Δivol_pre15d_sqly** is **Δivol_pre15d_unbundled** measured in the same time of the same quarter of last year.
vix_level	The level of the Chicago Board Options Exchange Volatility Index on the report date of quarterly earnings.
Δvix	The natural logarithm of the ratio of **vix_level** measured 1 day after the earnings announcement to the **vix_level** measured 1 day prior to the earnings announcement.

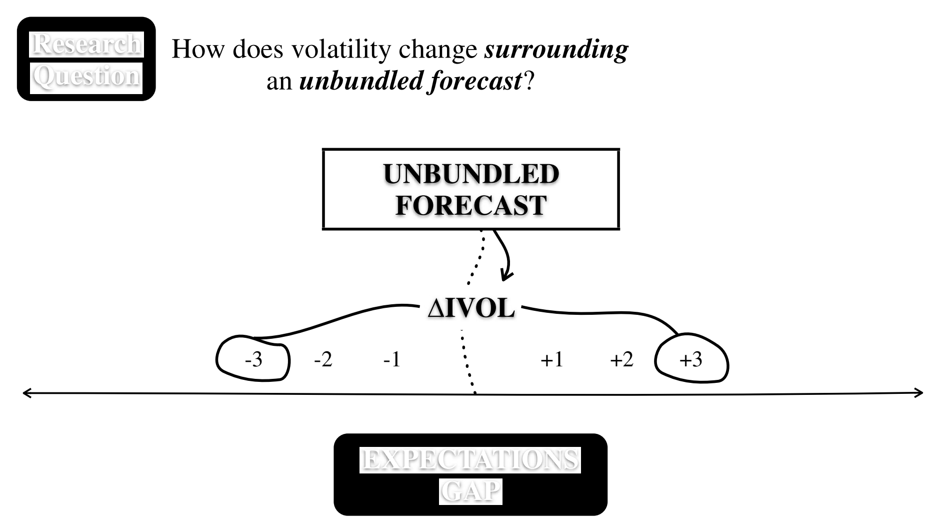
Figure 1 ■ Timeline and Setup

Panel A: This Study



We calculate volatility changes in windows leading up to (RQ #1) and windows following an earnings announcement (RQ #2) in bundled versus unbundled quarters for guiding firms.

Panel B: Rogers, Skinner and Van Buskirk (2009)



Rogers, Skinner and Van Buskirk (2009) calculate the change in volatility in the 7-day window surrounding an unbundled forecast and compare that to the change in volatility for non-forecasting firms facing similar gaps in earnings expectations.

Table 1 ■ Descriptive statistics

The sample consists of 107,307 firm-quarter observations from 2001 through 2010. This table provides descriptive statistics for the full sample partitioned based on the presence of bundled forecast. •••,••,• denote instances where the subsamples differ significantly at the 1%, 5%, and 10% level, respectively, for two-tailed tests. Please refer to the Appendix A for variable definitions.

Table 3 ■ Increased uncertainty and the likelihood of supplying a forecast

This analysis tests the likelihood that an earnings announcement is bundled with a forecast. We expect that pre-earnings announcement ***increases*** in uncertainty are associated with an increased likelihood of bundled guidance. The full sample consists of 107,307 firm-quarter observations from 2001 through 2010; the availability of OptionMetrics data reduces sample size (as indicated) in all specifications that include implied volatility measures. In specification [1], ***vol_level=svol_level***. In specifications [2] and [3], ***vol_level=ivol_level***. Note: ***bundle_prior*** and ***guide_cqtr*** are highly correlated. Following Rogers and Van Buskirk (2013) we include both in our tabulated regressions. All of our results remain when we re-estimate our regressions excluding either ***bundle_prior*** or ***guide_cqtr***. •••,••,• denote significance at the 1%, 5%, and 10% level, respectively, for two-tailed tests. Refer to Appendix A for variable definitions.

Table 4 ■ Is the run-up in volatility related to the market's expectation of guidance?

Panel A: Is the run-up in volatility greater when the market is more likely to expect guidance? Is the run-up in volatility greater when the firm actually gives guidance?

In this analysis, we test whether the run-up in volatility prior to earnings announcements (as measured by Δ***ivol_pre15d***) is greater when bundled guidance is actually given in the current quarter (i.e., ***bundle*****=1** as compared to ***bundle*****=0**) after we narrow our focus to firm-quarters in which investors are ***likely*** to expect guidance or to firm-quarters in which investors are ***unlikely*** to expect guidance. If run-ups in volatility are driven by investors' expectations of forthcoming guidance, we expect to see greater run-ups when guidance is ***likely*** (i.e., [a]>[b]). In contrast, if run-ups in volatility reflect managers' reactions to rising volatility, we expect to see greater run-ups for the firm-quarters where guidance is actually given (i.e., [1]>[3]; [2]>[4]), regardless of the expectation of guidance. •••,••,• denote significance at the 1%, 5%, and 10% level, respectively, for two-tailed tests. Refer to Appendix A for variable definitions.

Table 4 (cont.) ■ Is the run-up in volatility related to the market's expectation of guidance?

Panel B: Holding constant the expectation of guidance

This analysis tests the likelihood that an earnings announcement is bundled with a forecast. In an effort to limit variation in the extent to which investors might reasonably anticipate guidance (i.e., to hold constant the market's expectation of guidance), we examine subsamples where investors are ***likely/unlikely*** to anticipate the presence of the guidance. In all cases, we expect that ***increases*** in uncertainty (as measured by Δ***ivol_pre15d***) are associated with an increased likelihood of bundled guidance. ***LIKELY TO EXPECT GUIDANCE:*** In [1], we focus on the firm-quarters where investors are ***likely*** to expect guidance. In particular, we examine firm-quarters where managers of guiding firms bundled in the same quarter of last year and they also bundled in the prior quarter (***bundle_sqly*=1 and *bundle_prior*=1**); in this subsample, managers guide 87.2% of the time. ***UNLIKELY TO EXPECT GUIDANCE:*** In specification [2], we focus on the firm-quarters where investors are ***unlikely*** to expect guidance. In particular, we examine firm-quarters where managers of guiding firms did not bundle in the same quarter of last year and they also did not bundle in the prior quarter (***bundle_sqly*=0 and *bundle_prior*=0**); in this subsample, managers guide only 24.2% of the time. In specification [3], we use the prediction model in Table 3 to generate the quartile of firm-quarters of the full sample where bundled guidance is least likely to be expected in the current quarter; in this bottom quartile of firm-quarters, managers guide only 2.5% of the time. •••,••,• denote significance at the 1%, 5%, and 10% level, respectively, for two-tailed tests. Refer to Appendix A for variable definitions.

Dependent variable = BUNDLE.

Table 5 ■ Is there a run-up in *realized* volatility prior to guidance?

This analysis tests the likelihood that an earnings announcement is bundled with a forecast. In these tests we replace our forward-looking implied volatility measure of uncertainty (i.e., ***Δivol_pre15d***) with a backward-looking realized volatility measure of uncertainty (i.e., ***abnormal_rvol_pre15d***). Specifically, ***abnormal_rvol_pre15d*** equals the standard deviation of daily returns in the 15 days prior to the report date of quarterly earnings for the current quarter less the standard deviation of daily returns in the 15 days prior to the report date of quarterly earnings for the same quarter of last year. If the increase in implied volatility solely reflects investors' anticipation of guidance, then backward-looking realized volatility should not be associated with an increased likelihood of bundled guidance. If the increase in implied volatility reflects a managerial reaction to rising uncertainty, we expect that abnormal realized volatility is associated with an increased likelihood of bundled guidance. •••,••,• denote significance at the 1%, 5%, and 10% level, respectively, for two-tailed tests. Refer to Appendix A for variable definitions.

Table 6 ■ Is there a run-up in volatility prior to *unbundled* guidance?
In this analysis, we test whether the run-up in volatility prior to an unbundled forecast (as measured by Δ***ivol_pre15d_unbundled***) is greater than the run-up in volatility during the same time in the prior quarter (as measured by Δ***ivol_pre15d_unbundled_prior***) or than the run-up in volatility during the same time in the same quarter last year (as measured by Δ***ivol_pre15d_unbundled_sqly***). If unbundled guidance is unexpected by the market, then evidence of a significant difference between the run-up prior to an unbundled forecast as compared to the run-up during the same time last quarter (i.e., [a]>[b]) or same time in the same quarter of last year (i.e., [a]>[c]) supports the hypothesis that managers react to rising volatility with guidance. We identify contaminating news events in the 3-day window prior to the date of unbundled guidance using the Key Developments database from Capital IQ. Because of data limitations from Capital IQ, we limit this analysis to 6,197 unbundled forecasts occurring after 2004. Of those 6,197 forecasts, 3,655 (59%) contain a contaminating news item in the 3-day window prior to and including the date of the forecast, leaving an uncontaminated sample of 2,542 forecasts. If the same time in the prior quarter or same time in the same quarter last year also includes a contaminating event, we move the window to the closest uncontaminated window. If *uncontaminated* unbundled guidance is unexpected by the market, then evidence of a significant difference between the run-up prior to an unbundled forecast as compared to the run-up during the same time last quarter (i.e., [a]>[b]) or same time in the same quarter of last year (i.e., [a]>[c]) supports the hypothesis that managers react to rising volatility with guidance. •••,••,• denote significance at the 1%, 5%, and 10% level, respectively, for two-tailed tests. Refer to Appendix A for variable definitions.

Return dispersion

ABSTRACT

Recent research shows that high return dispersion (RD) is associated with economic conditions characterized by high discount rates, which are not conducive to growth and investment. We propose that RD risk can explain the accrual and investment anomalies. We conduct asset-pricing tests that include RD as a potential risk factor and show that low-accrual and low-investment firms have significantly higher exposure to the risk captured by RD. RD significantly explains future returns and the excess returns to accrual and investment hedge portfolios shrink in magnitude and become insignificant during periods of low RD. We conclude that risk explains the accrual and investment anomalies.

1. Introduction

The accrual anomaly is one of the most long-standing asset-pricing anomalies [see Kothari (2001) and Richardson et al. (2010) for comprehensive reviews of the phenomenon]. Since Sloan (1996) first documented abnormally low (high) stock returns for high-accrual (low-accrual) stocks, the literature has sought to explain the accrual anomaly and its pervasiveness.[1] While some argue that it went away in the years leading up to the financial crisis triggered in 2008 (Green et al., 2011), its subsequent reappearance has reopened the debate about its underlying source. Two main competing explanations have been put forth: (1) investors fixate on bottom-line earnings and do not understand how the persistence of the cash flow and accrual components differs (Sloan, 1996; Richardson et al., 2005) and (2) accruals matter because they capture investment and growth information, which can affect returns because of a general growth mispricing effect (Fairfield et al., 2003) or because of rational risk pricing (Khan, 2008; Wu et al., 2010). Disentangling a mispricing effect from risk pricing in

[1] The accrual anomaly is one of the most robust anomalies documented to date. Fama and French (2008) identify it as one of the anomalies that they cannot explain, persistent in all size groups and using both sorts and regression analyses. Avramov et al. (2013) highlight it as the only exception in their list of anomalies that is robust among high and low credit risk firms in all credit conditions.

Please cite this article as: Chichernea, D.C., et al., Does return dispersion explain the accrual and investment anomalies? Journal of Accounting and Economics (2014), http://dx.doi.org/10.1016/j.jacceco.2014.08.001

the context of the accrual anomaly is difficult and remains an open debate (Lewellen, 2010), especially given the fact that the firm-level investment and accrual measures are intrinsically correlated (Richardson et al., 2010).

We contribute to this debate by providing a risk-based explanation for both the accrual and investment anomalies. We show that the profitability of the accrual and investment strategies varies systematically over time and that this variation is significantly related to cross-sectional return dispersion (RD), which is a macroeconomic variable linked with other growth-related anomalies. Low-accrual and low-investment portfolios carry a positive risk premium as compensation for RD risk and after 2008, as RD increases, profits from the accrual and investment strategies regain significance. Our results support the notion that accruals contain fundamental investment and growth information and that returns to both the accrual and investment strategies are consistent with rational risk pricing.

The link between RD, aggregate states of the economy, and stock returns has been formally established by models proposed by Gomes et al. (2003) and Zhang (2005). These models predict that RD can be a useful macroeconomic state variable, as it contains information related to general investing conditions faced by firms. High RD periods indicate economic states with higher discount rates, which are not conducive to investment or growth. Jiang (2010) shows, theoretically, that RD is priced in the cross section and argues that the variable captures risk associated with aggregate economic growth and fundamental economic restructuring. Empirical literature provides evidence that RD indicates general macroeconomic conditions and that it is a useful proxy for growth and restructuring-related risk.[2]

If RD efficiently reveals macroeconomic states with high growth-related risks and accruals reflect growth information, then we expect that periods of higher (lower) RD correspond to higher (lower) returns from an accrual-based strategy. Furthermore, we expect that RD explains the time series variation in the profitability of an investment-based strategy, which is exposed to the same type of growth-related risks. Therefore, we hypothesize that both strategies are driven by the same macroeconomic conditions, which can be captured by RD. Empirically, our proposition implies that low-accrual and low-investment firms have higher exposure to RD risk and, thus, generate higher expected returns as a compensation for this risk. We further hypothesize that the profitability of these strategies is time varying and positively correlated with RD. Our results support both of these hypotheses.

Our analysis begins by examining the performance of hedge accrual and investment portfolios (low minus high quintiles). For the entire sample period (1965–2011), the accrual and investment strategies produce annualized raw returns of 7.34% and 12.93%, respectively. Consistent with Green et al. (2011), returns from the accrual strategy peak prior to 1995 (when Sloan first documented the anomaly), partly dissipate from 1996 to 2003, and then become essentially zero between 2004 and 2008. However, when the sample is extended to between 2009 and 2011, significant positive returns reappear. Subsample analysis reveals that the investment strategy exhibits very similar behavior. The reappearance of the accrual and investment anomalies after 2008, when RD has significantly increased, is consistent with our proposed explanation.

We confirm that RD indicates risk by showing that it is significantly priced in the cross section of individual stock returns. Using a two-stage Fama and MacBeth (1973) procedure, we find that RD carries a positive and significant premium under different model specifications. Furthermore, RD is positively priced among the accrual and investment portfolios in the cross section, which is consistent with the idea that low-accrual and low-investment portfolios have significantly higher exposure to the risk captured by RD.

We further examine whether RD can explain the time series variation in the profitability of the accrual and investment strategies. First, we show that accrual and investment hedge portfolios have significant exposure to RD, meaning that low- (high-) accrual and investment portfolios have significantly higher (lower) RD loadings. Specifically, a 1% increase in return dispersion generates a 7.7 basis points increase in the returns of the accrual hedge portfolio and a 12 basis points increase in the investment hedge portfolio. To put this into perspective, the average return of the accrual (investment) hedge portfolio over our sample period is 57 (100) basis points per month. In the presence of RD, the intercepts for the accrual hedge portfolio become insignificant, and for the investment hedge portfolio, they substantially shrink. The explanatory power of RD is not subsumed by other commonly used macroeconomic variables, such as dividend yield, term spread, default spread, and short-term interest rates.

Second, we quantify the economic significance of the RD effect for raw and risk-adjusted returns by documenting the incremental magnitude of the accrual and investment strategies during economic states of high RD. The accrual premium is almost five times higher during states with high RD. The investment premium produces 1.37% per month during high return dispersion states and essentially zero if return dispersion is low. The differences between the risk-adjusted returns present approximately the same magnitudes.

Documenting a significant relation between RD and the accrual and investment anomalies offers at least two distinct contributions to the literature. First, the interpretation of results showing a link between the accrual and investment anomalies is subject to intense debate. For example, Wu et al. (2010) argue that the q-theory (e.g., Tobin, 1969) provides a risk-based explanation for the accrual anomaly, suggesting that its driving force is real investment. However, Richardson et al. (2010) dispute these findings, noting that investment and accruals are mechanically correlated and, thus, that the investment proxy proposed by Wu et al. (2010) cannot be used to explain the accrual anomaly.[3] Our approach of using a

[2] RD is related to unemployment rates (Loungani et al., 1990), business cycles (Christie and Huang, 1994), momentum (Connolly and Stivers, 2003), turnover and macroeconomic news (Connolly and Stivers, 2006), and risk associated with fundamental restructuring (Demirer and Jategaonkar, 2013).

[3] Richardson et al. (2005) make the point that the link between accruals and growth/investment by itself is not sufficient to distinguish between mispricing and risk-based explanations. For example, on the one hand, papers such as Fairfield et al. (2003), Bradshaw et al. (2006), and Dechow et al.

macroeconomic state variable such as RD to explain both of these phenomena allows us to investigate the investment hypothesis as a risk-based explanation for the accrual puzzle without being subject to the mechanical correlation caveat. Second, we explain the predictive power of accruals and investments by relating a model of aggregate risk to these firm characteristics. In doing so, our results contribute to the difficult task of disentangling risk from mispricing explanations for the accrual and investment anomalies as discussed by Lewellen (2010). We provide an economic intuition grounded in theory that lends support to a risk-based explanation for both anomalies, thus unifying seemingly inconsistent results from the literature.

The paper proceeds as follows. In Section 2, we discuss the related literature and present our hypotheses. Section 3 describes our sample, variables, and methodology. In Section 4, we present our main empirical results and discuss their implications. Section 5 discusses the robustness of our conclusions to the use of alternative measures and specifications, and Section 6 concludes.

2. Background and hypotheses development

This section describes the background for our study and develops our testable hypotheses concerning the roles of risk and RD for the accrual and investment anomalies. Section 2.1 discusses the concept of return dispersion. Section 2.2 reviews the relevant literature on the accrual anomaly and its connection with investments and RD, and it develops our testable hypotheses.

2.1. What is return dispersion?

Recent theoretical and empirical work finds that the stock market's cross-sectional dispersion in returns is a leading countercyclical indicator of aggregate market states. The theoretical link between RD, the state of the aggregate economy, and growth has been established by Gomes et al. (2003). By explicitly modeling the production and investment decisions of firms in a general equilibrium framework, the authors show how the cross section of stock prices and returns depends on the state of the economy. Their model has two sources of risk: aggregate productivity shocks (such as changes in the general productivity state of the economy that determine the common productivity of all available projects) and idiosyncratic productivity shocks (such as changes in firm-specific characteristics that determine the productivity of a given firm).

The basic idea is that the cross-sectional distribution of expected returns is determined by a number of aggregate variables as well as a number of firm-specific characteristics.[4] During good economic states, differences among firms are less likely to matter, as low discount rates generate an increase in the overall scale of production, and, in turn, an overall increase in stock prices (hence, a low dispersion among firms' returns). During bad aggregate states, the difference between firm characteristics becomes more important, as firms face different adjustment costs. This results in a high dispersion among firms' risks and, in turn, high dispersion among their returns. The net result is that variation in the cross-sectional dispersion of stock returns indicates variation in the state of the economy; i.e., RD is higher in low productivity states and lower in high productivity states.[5]

The Jiang (2010) theoretical model presents additional intuition for including RD directly in the pricing kernel. This study argues that RD captures two dimensions of systematic risk. One is homogenous and is directly linked with aggregate economic growth and market states, and the other is heterogeneous and relates to fundamental economic restructuring (reallocation of resources), which is associated with future aggregate economic growth and fluctuation.

Empirical literature validates the role of RD as a meaningful variable reflecting macroeconomic conditions and capturing risk related to growth and restructuring. Loungani et al. (1990) provide evidence that RD predicts high unemployment rates, suggesting that RD may be related to economic restructuring. Christie and Huang (1994) find that RD is associated with the business cycle (RD is higher during economic recessions). Connolly and Stivers (2003) show that momentum (reversal) is positively (negatively) related to future RD. Stivers (2003) and Connolly and Stivers (2006) find that RD contains incremental information about the future idiosyncratic volatility and market volatility and relate RD to turnover and macroeconomic news. Demirer and Jategaonkar (2013) present results supporting Jiang's argument that RD captures shocks related to fundamental economic restructuring. Overall, theoretical and empirical literature finds that RD contains information about economic states or economic transitions which is not captured by commonly used risk factors.

(*footnote continued*)
(2008) propose that investors overreact to growth information contained in accruals and, therefore, support a mispricing hypothesis. On the other hand, studies such as Wu et al. (2010) and Zhang (2007) interpret this link in the context of a risk-based hypothesis.

[4] The size of the firm and the ratio of the firm's production scale to its market value are examples of such firm-specific characteristics. These can be empirically proxied by the book-to-market ratio or the earnings-to-price ratio.

[5] The Gomes et al. (2003) model not only introduces a link between RD and aggregate productivity states, but also implies that returns to factors such as size and book-to-market will be negatively related to these aggregate states (and, therefore, positively related to RD). To the extent that accruals reflect a firm's investment and growth characteristics, the returns from the accrual strategy will exhibit the same pattern (i.e., positive relation to RD).

Please cite this article as: Chichernea, D.C., et al., Does return dispersion explain the accrual and investment anomalies? Journal of Accounting and Economics (2014), http://dx.doi.org/10.1016/j.jacceco.2014.08.001

2.2. Accruals, investments, and return dispersion

The interpretation of the accrual anomaly has sparked intense debate in the literature, with explanations for the phenomenon generally falling into one of two categories: mispricing or risk. On the surface, the accrual anomaly suggests that the market misunderstands the financial accounting information that firms report. Proponents of the earnings fixation hypothesis, which is advocated by Sloan (1996) and other scholars, theorize that investors fixate on bottom-line income and are unable to differentiate between cash earnings and non-cash earnings (accruals). Other studies such as Fairfield et al. (2003), Bradshaw et al. (2006), and Dechow et al. (2008) propose that investors, in general, overreact to growth information contained in accruals. Regardless of the exact channel, the common hypothesis in this strain of literature is that mispricing generates the accrual effect in returns.

Several other studies suggest that the accrual anomaly may reflect risk pricing. For example, Zhang (2007) finds that the magnitude of the accrual anomaly is increasing with the investment information contained in accruals (proxied by the covariance between accruals and employee growth). Wu et al. (2010) present an optimal investment hypothesis consistent with rationality. Khan (2008) shows that a four-factor asset pricing model, which includes cash flow news and discount rate news factors, explains a significant amount of the accrual anomaly. The common hypothesis in this literature track is that the returns to the accrual strategy reflect a premium for the risk associated with low accruals.[6]

Consistent with the inherent link between accruals and asset growth, several studies investigate the relation between the accrual anomaly and growth. For example, Fairfield et al. (2003) interpret accruals as growth in short-term net operating assets (NOA) and argue that the accrual anomaly is a special instance of a more general anomaly that is based on growth in net operating assets. However, Richardson et al. (2005) argue that the results are consistent with the persistence hypothesis of Sloan (1996), as both accruals and growth in long-term NOA are highly subjective (less persistent) and, hence, negatively related to future stock returns. Zhang (2007) shows that accruals reflect fundamental investment information that co-varies in accordance with the other growth attributes of firms and, therefore, finds that the accrual anomaly is consistent with the investment hypothesis. Wu et al. (2010) also argue that real investment is the driving force behind the accrual anomaly and propose an optimal investment hypothesis.

We argue that the growth risk captured by RD is relevant for the accrual and investment anomalies. A necessary but not sufficient condition for our argument is that RD is positively priced in the cross section of returns (i.e., stocks with higher RD risk exposure require a positive risk premium). If that is the case, we can argue that the higher performance of low-accrual and low-investment portfolios is justified by their higher exposure to RD risk. Hence, our first hypothesis relates to the cross section of returns.

H1. RD carries a positive and significant risk premium in the cross section of accrual and investment portfolios.

RD serves as a macroeconomic state variable that contains growth-related information. If the accrual and investment information reflect growth risk (instead of mispricing), theory suggests that returns from these strategies will depend on states of aggregate productivity in the economy as captured by RD. Therefore, returns from an accrual strategy will be related to states of aggregate productivity in the economy (assuming that accruals matter because they contain investment- or growth-related information). Furthermore, returns from an investment strategy will behave similarly to returns from an accrual strategy in terms of their relation with RD. Our second hypothesis, therefore, relates to the time series variation in these anomalies.

H2. The accrual and investment excess returns vary systematically with states of the economy as captured by RD.

The second hypothesis implies that we expect to observe significant differences between the returns of accrual (investment) strategies during periods of high RD relative to periods of low RD (that is, their profitability should be stronger during periods of high RD and weaker or nonexistent during periods of low RD). In addition, the predictive ability of accruals and investments for returns should vary significantly with states of RD, thus generating the time variation in the profitability of these strategies. Supporting evidence for H1 and H2 would suggest that the link with investment and growth is consistent with a risk-based explanation.[7] The accruals (investment) premium is observed because firms with low accruals (investments) have higher exposure to RD risk relative to firms with high accruals (investments).

3. Data and methodology

We obtain financial statement data from the annual Compustat file, and stock return data are obtained from the monthly CRSP files for the period from 1965 to 2011. Consistent with previous research, we drop financials (SIC codes 6000–6999) and utilities (SIC codes 4900–4999), as these two industries are highly regulated and the measures of accruals and

[6] The connection between accruals and conditional equity premiums has also been studied at the aggregate level. Guo and Jiang (2011) find that accruals are closely correlated with the determinants of conditional equity premiums at both the firm and aggregate levels. Our results and interpretation are consistent with their paper.

[7] Under the persistence or mispricing framework, no obvious reason exists to expect a relation between the accrual anomaly and a macroeconomic state variable, such as RD. Furthermore, no obvious reason exists to expect that investments and accrual strategies present similar behavior in relation with RD.

Please cite this article as: Chichernea, D.C., et al., Does return dispersion explain the accrual and investment anomalies? Journal of Accounting and Economics (2014), http://dx.doi.org/10.1016/j.jacceco.2014.08.001

investments differ significantly from those in other industries. We also eliminate firms with a negative book value of equity. Following Sloan (1996), we calculate total accruals using the indirect balance sheet method as the change in non-cash current assets less the change in current liabilities excluding the change in short-term debt and the change in taxes payable minus depreciation and amortization expense and deflated by lagged total assets[8]:

$$\text{Accrual}_t = \big[(\Delta\text{Current Assets}_t - \Delta\text{Cash}_t) - (\Delta\text{Current Liabilities}_t - \Delta\text{Short}-\text{term Debt}_t - \Delta\text{Taxes Payable}_t) \\ -\text{Depreciation and Amortization Expense}_t\big]/\text{Total Assets}_{t-1} \quad (1)$$

Our investments-to-assets measure is built following Wu et al. (2010) and Lyandres et al. (2008), as the annual change in gross property, plant and equipment plus the annual change in inventories divided by the lagged book value of assets:

$$I/A_t = (\Delta\text{PPE\_Gross}_t + \Delta\text{Inventories}_t)/\text{Total Assets}_{t-1} \quad (2)$$

Our final Compustat sample includes 141,152 firm-year observations with non-missing accruals. We report descriptive statistics on the final Compustat annual data set, in which we annualize the corresponding returns.

The descriptive statistics for the variables of interest presented in Panels A and B of Table 1 are comparable with the results from previous studies (see Zhang (2007), for accruals and Wu et al. (2010), for investments). We follow the literature and annually winsorize variables at 1% and 99% to avoid the effect of outliers (e.g., Zhang, 2007). Accruals tend to be negative, with a mean of −0.026 and a median of −0.031 (compared with −0.023 and −0.030, respectively, presented by Zhang (2007)). Investments-to-assets have a mean of 0.11 (compared with 0.17 presented by Wu et al. (2010)). Future stock returns (defined as buy-and-hold annual returns beginning from the fifth month after a firm's fiscal year end) have a mean of 13.6% and a median of 4%. Similar to Zhang (2007), our correlation matrix shows that returns and growth variables are negatively correlated and that accruals and growth variables are positively correlated (which can be interpreted as preliminary evidence supporting the argument that accruals capture some aspect of growth).

To calculate monthly RD, we use CRSP to obtain returns for all ordinary common shares (share code 10 or 11) traded on NYSE, AMEX and NASDAQ during the period from July 1963 to December 2011. We define RD based on individual stock returns as

$$\text{RD}_t = \sqrt{\frac{1}{n-1}\sum_{i=1}^{n}(R_{i,t}-R_{M,t})^2} \quad (3)$$

where n is the number of stocks in the market, $R_{i,t}$ is the return of individual stock i in month t, and $R_{M,t}$ is the equal-weighted average market return. Although this measure is similar to those proposed by Jiang (2010) and Stivers and Sun (2010), some important differences exist. Stivers and Sun (2010) use one hundred size and book-to-market portfolios instead of individual stocks for their RD, and Jiang (2010) uses individual stocks that are listed on NYSE and AMEX and excludes the stocks in the lowest size decile. These conditions effectively reduce variation in RD and, thus, eliminate potentially useful information. We argue that a measure that is based on the full universe of individual stocks is more informative for the cross section of returns.[9]

To control for the market return, we construct a relative return dispersion monthly measure (RRD) that is orthogonal to the simple monthly market return and the absolute market return. Following Stivers and Sun (2010), we define RRD as the estimated residual (ε_t) from the following regression:

$$\text{RD}_t = \gamma_0 + \gamma_1 R_{M,t} + \gamma_2 |R_{M,t}| + \varepsilon_t, \quad (4)$$

where RD_t is the simple monthly RD from Eq. (3), $R_{M,t}$ is the concurrent market-level stock return (we use the CRSP value-weighted market index), $|R_{M,t}|$ is the absolute value of the market-level return, and the γs are coefficients to be estimated. Because estimating Eq. (4) over the full sample can introduce a look-ahead bias (an analyst will not have the future market information to obtain the errors in that fashion), we estimate this equation using expanding windows.[10] Following Stivers and Sun (2010), we build three-month moving-average expressions for RD and RRD (RD_{13} and RRD_{13}, respectively, with subscript 13 referring to months $t-1$ to $t-3$). Our main tabulated results pertain to RRD. We report descriptive statistics of our return dispersion measures in Panel C of Table 1 and graph the evolution of RD_{13} and RRD_{13} in Fig. 1 (for comparison with previous literature).

A couple of elements are worth discussion when comparing our RD measures with those used in the literature. First, the mean values are significantly higher than those presented by Jiang (2010) and Stivers and Sun (2010), and this difference is

[8] For robustness, we repeat our analysis using the direct method based on the statement of cash flows, as advocated by Hribar and Collins (2002). The results lead to similar implications as our main analysis (see Section 5).

[9] A counter-argument to our measure is that, while it captures more information because it is based on individual stocks, it is disproportionately affected by small stocks. To mitigate this concern, we repeat our main analysis using the Stivers and Sun (2010) relative return dispersion measure, and we show that this measure is also positively priced among the accrual and investment portfolios in the cross-section.

[10] Specifically, we set our starting point as January 1945, and for each month t, we use observations from the starting point up to month t to estimate Eq. (4) and retain the last error as the RRD for month t. Although our starting point appears to be arbitrarily chosen, we selected it to ensure that we have a sufficient number of observations for the first estimation. Given that we have no reason to expect a structural change in the relation between RD and market return, expanding windows allows us to use more information relative to rolling windows, thus ensuring the stability of the distribution and minimizing the effect of outliers. (Expanding windows are commonly used in the context of controlling for look-ahead bias; see, for example, Guo et al., 2014).

RRD_{13}	5.20	3.68	3.00	4.67	6.62	0.92	0.80	0.67

Panel A presents descriptive statistics of various firm characteristics. Our sample includes all US firms except for utilities (SIC codes 4900–4999), financial firms (SIC codes 6000–6999), and firms with a negative book value of equity, from 1965 to 2011. RET = raw buy-and-hold annual returns beginning from the fifth month after a firm's fiscal year-end; MV = market value at fiscal year-end (PRCC_F*CSHO); MB = market-to-book ratio, which is measured as the market value divided by the book value of equity (SEQ); ACC = total accruals, which is measured as $(\Delta CA-\Delta Cash)-(\Delta CL-\Delta STD-\Delta TP)-DEPEXP$ scaled by average total assets, where ΔCA = change in current assets (ACT), $\Delta Cash$ = change in cash and cash equivalents (CHE), ΔCL = change in current liabilities (LCT), ΔSTD = change in short-term debt (DLC), ΔTP = change in tax payable (TXP), and DEPEXP = depreciation and amortization expense (DP); *I/A* = investment-to-assets, measured as $(\Delta PPE+\Delta INV)/TA_{t-1}$, where ΔPPE is change in gross property, plant and equipment (PPEGT), ΔINV is change in inventories (INVT) and TA_{t-1} is the lagged book value of total assets (AT); TA_GR = growth in total assets, which is measured as $(TA_t–TA_{t-1})/TA_{t-1}$, where TA is total assets (AT); and CAPEXP = capital expenditures scaled by net property, plant, and equipment. All variables are annually winsorized at 1% and 99%. Panel B reports the correlations for firm characteristics (Pearson correlations are shown above the diagonal, and Spearman correlations are shown below). Panel C reports the summary statistics for our primary cross-sectional return dispersion measures (RD and RRD). RD is the cross-sectional standard deviation across the monthly returns of individual stocks (only ordinary stocks with share codes 10 or 11 are included). The monthly relative return dispersion (RRD) is constructed to be orthogonal to the simple and absolute monthly stock market returns by controlling for the look-ahead bias using expanding windows, as described in Section 3. For each one of our measures of return dispersion, we build three-month moving-average expressions calculated over months $t-1$ to $t-3$ (RD_{13} and RRD_{13}, respectively).

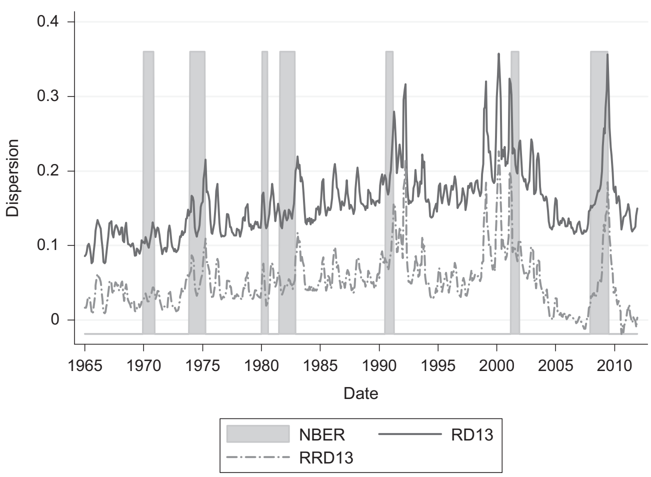

Fig. 1. Return dispersion. This figure presents the three-month moving average of cross-sectional stock returns dispersion (RD_{13}) and the three-month moving average of relative return dispersion (RRD_{13}) defined as residuals from Eq. (4). Shaded areas represent recessions as defined by NBER.

Please cite this article as: Chichernea, D.C., et al., Does return dispersion explain the accrual and investment anomalies? Journal of Accounting and Economics (2014), http://dx.doi.org/10.1016/j.jacceco.2014.08.001

expected, given our use of the entire cross-section of individual stocks (our mean RD is 15.73%; Stivers and Sun report 3.02% and Jiang reports 9.971%). The standard deviation of our RD measure is also significantly higher than the values that these authors obtained (5.28% versus 1.28% and 2.09%, respectively). Given that we are attempting to capture changes in macroeconomic conditions, we believe that it is important to include all information in our estimations. Second, the mean of our RRD measure is not zero (as reported by Stivers and Sun) because of our expanding window estimation relative to the full sample estimation that is employed by Stivers and Sun (2010). The time series of our three-month RD moving-average expressions displayed in Fig. 1 presents slightly higher autocorrelation (which we control for in our tests using autocorrelation-robust standard errors). The extreme high realizations in 2000 and 2008 correspond to the transitions from the technology boom to the bear market and the financial crisis, respectively.[11]

We perform most of our risk return analysis at a monthly level. To ensure that the accounting information is available to investors prior to portfolio formation and return accumulation periods, we match CRSP stock return data from $t+5$ through $t+16$ (12 months) with accounting information as of time t. For each cross section, we sort stocks into quintiles based on their accruals and investments-to-assets levels. We form portfolios in May of each year t and calculate monthly buy-and-hold returns of these portfolios from June of year t to May of year $t+1$.[12] We calculate the monthly return from an accrual-based strategy as the return to a zero cost portfolio that goes long on low-accrual stocks (Quintile 1) and short on high-accrual stocks (Quintile 5). We refer to this monthly hedge return as ACC_Hedge_t. We follow the same procedure to build investment buy-and-hold hedge strategies (IA_Hedge_t). Table 2 presents the returns distribution characteristics for each accrual and investment quintile portfolios and the respective hedge strategies.

Over our entire sample period, the average raw returns of a buy-and-hold equal-weighted accrual strategy going long on stocks in the lowest accrual quintile and short on stocks in the highest accrual quintile are 0.57% on a monthly basis – the equivalent of 7.34% for a 12-month holding period.[13] The corresponding numbers for the investment strategy are 1% on a monthly basis, corresponding to 12.93% for an annual holding period.

Fig. 2 displays the time series behavior of the annualized payoffs for the accrual and investment strategies, and it illustrates that the hedge portfolios exhibit very similar time series behavior. Both the graph and Panel B of Table 2 document substantial variations in the payoffs for both accrual and investment strategies over time. The first three subperiods (Panel B) correspond to those used by Green et al. (2011) and identify (1) the period before Sloan (1996) was published, when the accrual anomaly was known to few practitioners; (2) the early post-Sloan subperiod (1996–2003), during which the accrual anomaly was well known to both academics and practitioners; and (3) the late post-Sloan period (2004 to 2008), during which the accrual anomaly was highly exploited by various hedge funds. The fourth period (2009–2011) represents the period after the sample considered by Green et al. (2011). Although the period between 2004 and 2008 shows accrual payoffs that are not significantly different from zero [and justifies the conclusion in Green et al. (2011) regarding the demise of the accrual anomaly], these payoffs become significantly positive again after 2008. Interestingly, the payoffs of the investment strategy present very similar behavior in terms of time variation. Fig. 3 focuses on the significant positive returns for both the accrual and investment strategies over the last period in our sample.

These results indicate that the accrual and investment anomalies have reappeared in the most recent period, and they suggest that inferences based on the results presented in Green et al. (2011) appear to be premature.

4. Empirical results

4.1. Return dispersion and expected returns

We start our empirical investigation by showing that RD is generally priced in the cross section of individual stock returns and that the accrual and investment portfolios, in particular, are exposed to the risk captured by RD.

Following Jiang (2010) and Demirer and Jategaonkar (2013), we consider an asset pricing model that directly includes RD into the pricing kernel.[14] The authors argue that one of the sources of risk associated with RD is channeled via fundamental restructuring, which is particularly important for firms with different growth potential. Based on this argument, stocks with

[11] To make sure that our variables contain the same type of information as those in the literature, we replicate the findings of Stivers and Sun (2010) for the value payoff strategy using our measures of cross-sectional dispersion. Untabulated results confirm that our measures can predict the value payoff strategy in a similar manner to the ones proposed by Stivers and Sun (2010). We also repeat their predictive regressions for the accrual and investment payoffs and show that RD/RRD can successfully predict future payoffs for both strategies after controlling for all other macroeconomic variables.

[12] We choose the month of May to form our portfolios because of our timing for matching the accounting information with the stock return data. Because the majority of firms in the sample have December 31 fiscal year-ends and we allow a five-month gap to ensure that accounting information is available to investors, using information as of May to form our portfolios means that the sort considers the latest accounting data for most firms. Results remain qualitatively similar if we allow for different timing for matching the accounting information with the returns data (alternatively we use 3, 4, and 6 months gaps) or if we restrict the sample to only December 31 year-end firms.

[13] We use buy-and-hold returns because this scheme avoids the likely bid-ask biases induced by rebalanced equal-weighted portfolios and does not overweight large stocks as would result from using a value-weighting scheme. For robustness checks, we show that using alternative weighting (return- and value-weighted) schemes for our portfolios also results in insignificant intercepts for the accrual and investment hedge portfolios in the presence of RD/RRD (see the discussion in Section 5).

[14] Depending on the theoretical justification used, one can motivate both the inclusion of levels or of innovations in the macroeconomic variables in the pricing kernel. For example, an ICAPM argument would be more consistent with the use of innovations in the state variables (see, for example, Petkova, 2006; Chen and Petkova, 2012). The use of the level of RD is consistent with the theoretical model and justification provided by Jiang (2010). For robustness

This table reports summary statistics for our main portfolios/strategies. All return statistics are presented in percentages. Portfolio returns are buy-and-hold returns with a May formation month. We sort stocks into quintiles based on their accrual (investments) levels at the beginning of May, and we hold these portfolios for 12 months. ACC1–ACC5 (IA1–IA5) represent the monthly returns of accrual (investments) quintiles. ACC_Hedge represents the difference between low-accrual (ACC1) and high-accrual (ACC5) portfolios at the monthly level. (IA_Hedge is the corresponding monthly investments strategy.) Panel A presents return statistics for the entire sample period, which covers the months from January 1965 to December 2011. Panel B presents the accrual and investment strategies' raw returns by subperiods. (For each subperiod, we report the mean and the *t*-statistic tests that indicate whether the mean is significantly different from zero).

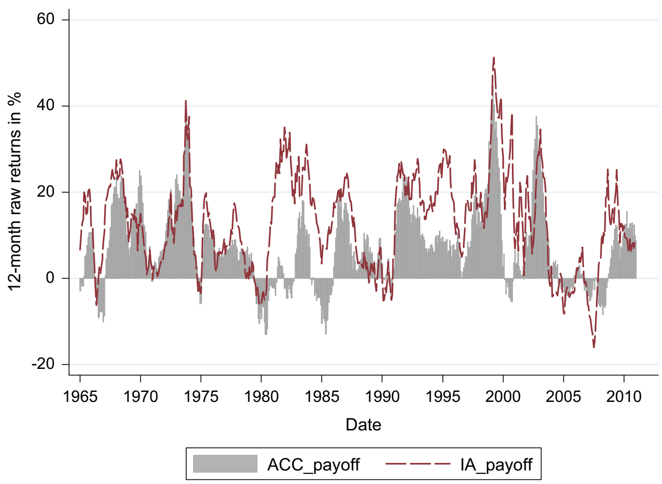

Fig. 2. Time series of accrual and investment strategies payoffs. This figure plots the monthly series of annualized raw returns of an accrual (investment) buy-and-hold hedge return strategy that goes long on stocks in the lowest accrual (investment) quintile and short on stocks in the highest accrual (investment) quintiles. For every month t, returns are annualized with a holding period over months t to $t+11$ (using the portfolios as described in Table 2).

(*footnote continued*)
purposes, we repeat our analysis, run the Fama and MacBeth (1973) cross-sectional regressions using innovations in RD, and obtain qualitatively similar results (see the discussion in Section 5).

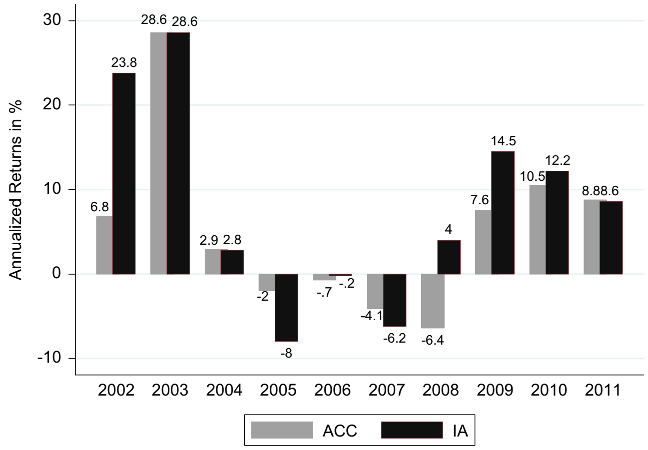

Fig. 3. The accrual and investment strategies by year. This figure presents the average annual returns from an accrual (investment) hedge strategy that goes long on stocks in the lowest accrual (investment) quintile and short on stocks in the highest accrual (investment) quintiles. The returns in the figure are expressed in percentages. ACC represents the annualized accrual hedge portfolio, and IA represents the annualized investments hedge portfolio.

higher sensitivities to RD should carry a positive risk premium, especially during bad times. The expected returns thus are modeled as a function of RD across assets (along with the market return and other common risk factors).

We follow the two-step cross-sectional regression procedure introduced by Fama and MacBeth (1973) to estimate the risk premium associated with RD.[15] In the first stage, we perform time-series regressions to estimate beta loadings for each factor (for example, $\hat{\beta}_{i,RD}$ corresponds to the beta loading of i on the RD macro-variable). We then use these beta loadings from the first stage to estimate the risk premiums in the cross section. Recent literature discusses the choice of appropriate test assets for this type of cross-sectional tests (i.e. portfolios versus individual stocks). Lewellen et al. (2010) and Daniel and Titman (2012) show that using portfolios as test assets (and in particular, the Fama and French 25 size and book-to-market portfolios) can produce spurious correlations and misleading results and therefore suggest using individual stocks for a more rigorous test. Ang et al. (2010) further support this point showing that the most efficient estimates of cross-sectional risk premium in linear factor models are obtained using individual stocks. We therefore present our main results using individual stocks as test assets in the cross-sectional regressions.[16] Table 3 presents the results of this analysis.

We start by estimating a benchmark model (Model 1) that includes the market and the Fama–French factors, and we find that the market premium is the only factor that is priced in the cross section of individual stock returns. We augment this base model to include RD and RRD and, consistent with our prediction, document that both of them carry a positive risk premium. According to Model 2 (3), the risk premium for the RD (RRD) variable is 0.397 (0.294) with a t-statistic of 2.25 (1.82). Moreover, the economical and statistical magnitude of the RD variable is not subsumed by commonly accepted macroeconomic variables (Models 4 and 5). Our results support the hypothesis that RD carries a strong positive and significant premium in the cross section of individual returns.

These results provide general evidence that RD is priced in the cross-section of returns, but they do not specifically address whether accrual and investment portfolios have significantly different exposure to the risk captured by RD. We follow the same two-stage Fama and MacBeth (1973) procedure to estimate the risk exposure of accrual and investment portfolios in the cross-section.[17] To make sure that our results are not driven by the choice of a particular set of test assets, we apply this methodology to three different sets of portfolios by sorting the sample into 25 accrual portfolios, 25 investment portfolios, and 25 (5x5) portfolios sorted on accruals and investments independently.[18]

Table 4 shows that the market premium (γ_{MKT}) tends to be negatively priced across all three sets of portfolios, which is not an uncommon result (see, for example, Frazzini and Pedersen, 2014).[19] More important, we document that the RRD

[15] Among others, the same approach is employed by Jagannathan and Wang (1996), Harvey and Siddique (2000), Lettau and Ludvigson (2001), Ang et al. (2006), Petkova (2006), Sadka (2006), Watanabe and Watanabe (2008), Liu and Zhang (2008), and Jiang (2010).

[16] However, using individual stocks as test assets in cross-sectional regressions can exacerbate the errors-in-variable problem. We use the methodology suggested by Shanken (1992) to correct for this issue. In addition, Asparouhova et al. (2010) makes the point that the cross section of individual firm returns may be biased by bid-ask effects and suggest weighting by lagged returns as a solution. Untabulated results show that using the weighted least square methodology (based on lagged returns weights) with individual stocks produces qualitatively similar results.

[17] For brevity, the remainder of our main tests uses the RRD variable. RD produces qualitatively similar results for every test, which are available upon request.

[18] Our conclusions remain qualitatively similar when we expand the set of test assets to include the Fama and French 25 size and book-to-market portfolios for a total of 50 portfolios. Because our investigation relates to whether RD can explain the accrual and investment anomalies, we do not focus on the cross section of the Fama and French 25 portfolios alone, as it will not directly inform on the ability of RD to explain the relation between accruals/investments and returns.

[19] Beta is positively priced when individual stocks are used as test assets (Table 3) and negatively priced when portfolios are used as test assets (Table 4). Core et al. (2008) document a similar switch in sign for the pricing of beta between portfolios and individual stocks in their Table 4.

This table presents Fama and MacBeth (1973) cross-sectional regressions using the excess returns on individual stocks. For each individual stock, we estimate a time series regression in which we regress the excess returns on the Fama–French three factors and various state variables (including RD/RRD). Following Petkova (2006), we use five state variables. The dividend yield (DIV) is calculated as the difference between the stock market's returns with and without dividends from CRSP; the term spread (TERM) is the difference between the yield of 10-year and 1-year T-bonds; the default spread (DEF) is the yield difference between Moody's BAA and AAA bonds obtained from the Federal Reserve Database; and the short-term T-bill (RF) is the 30-day risk-free rate. In addition, we consider RD/RRD as a state variable (calculated as described in Section 3 and Table 1). The full sample loadings (βs) from the first-stage time series regression are then used in second-stage cross-sectional regressions as independent variables using variations of the following model:

$$R^e_{i,t} = \gamma_0 + \gamma_{MKT}\,\hat{\beta}_{i,MKT} + \gamma_{SMB}\,\hat{\beta}_{i,SMB} + \gamma_{HML}\,\hat{\beta}_{i,HML} + \gamma_{RD}\,\hat{\beta}_{i,RD} + \gamma_{DIV}\hat{\beta}_{i,DIV} + \gamma_{TERM}\,\hat{\beta}_{i,TERM} + \gamma_{DEF}\,\hat{\beta}_{i,DEF} + \gamma_{RF}\,\hat{\beta}_{i,RF} + \eta_{i,t}.$$

The gamma coefficients from the second-stage cross-sectional regressions represent prices of risk. The t-statistics in parentheses are adjusted for errors in variables following the procedure of Shanken (1992). *, **, and *** indicate significance at the 10%, 5% and 1% level, respectively. The sample period is from January 1965 to December 2011.

variable is positively priced in the cross section for each set of test assets. The RRD premium varies between 1.8% and 2.9%. Alternatively, the RRD variable is insignificant in Model 4, possibly because the value and investment premiums are closely related (this high correlation would make HML subsume the power of RRD when the test assets are 25 investment portfolios). Overall, the results suggest that RRD is positively related to the accrual and investment premiums and can explain a significant portion of their profitability.

4.2. Return dispersion and variation in the profitability of accrual and investment strategies

A primary objective of this study is to examine whether RD can explain time series variation in the payoffs to the accrual and investment anomalies. We present two sets of results pertaining to the connection between RD and the variation in profitability of the accrual and investment anomalies. First, we show that accrual and investment hedge portfolios have significant exposure to RRD in the time series. Second, we quantify the effect of RRD by documenting the incremental magnitude of these strategies during states of high RRD.

Our first set of results examines whether firms with low accruals (investments) have significantly different exposure to RRD when compared with firms with high accruals (investments). Given that RRD contains information regarding the production states of the economy, if accruals contain growth information, then we expect that low-accrual (high-accrual) firms will more (less) sensitive to RRD. Because low-accrual and low-investment firms have more assets in place, it makes it more difficult for these firms to adjust during times of low aggregate productivity with higher discount rates, which makes them even riskier in these states. This generates higher returns for the accrual and investment strategies during times of low aggregate productivity states captured by high RRD.

We run time series regressions of buy-and-hold portfolio returns on commonly accepted asset-pricing factors and the RRD variable (portfolios are obtained based on sorts on accruals and investments as described in Section 3).[20] We expect to observe higher RRD beta loadings for portfolios made up of low-accrual and low-investment firms and lower RRD loadings

[20] Our results and conclusions are robust to using alternative weighting schemes as suggested by Asparouhova et al. (2010). See Section 5 for details.

N	564	564	564	564	564	564

This table presents the coefficients from the second stage of two-stage Fama and MacBeth (1973) cross-sectional regressions. We use the following sets of test assets: 25 accrual-sorted portfolios (Models 1 and 2), 25 investment-sorted portfolios (Models 3 and 4), and 25 portfolios based on a 5 × 5 sort by accruals and investments (Models 5 and 6). For each set of test assets, we estimate a time series regression in which we regress the excess returns on the Fama–French three factors and relative return dispersion (RRD). The full sample loadings (βs) from the first-stage time-series regression are then used in second-stage cross-sectional regressions as independent variables using the following model:

$$R^e_{i,t} = \gamma_0 + \gamma_{MKT}\hat{\beta}_{i,MKT} + \gamma_{SMB}\hat{\beta}_{i,SMB} + \gamma_{HML}\hat{\beta}_{i,HML} + \gamma_{RRD}\hat{\beta}_{i,RRD} + \eta_{i,t}.$$

The gamma coefficients reported are the coefficients obtained from the second-stage cross-sectional regressions. The betas used as explanatory variables are loadings obtained in the first stage on the three Fama–French factors (MKTRF, SMB, and HML) as well as RRD, which is defined as described in Table 1. The t-statistics in parentheses are adjusted for errors in variables following the procedure of Shanken (1992). ** and *** indicate significance at the 5% and 1% level, respectively. The sample period is from January 1965 to December 2011.

This table reports the factor loadings for each of the quintile buy-and-hold accrual portfolios and the low-minus-high accrual strategy (ACC_Hedge). For each portfolio i, we estimate variations of the following time series model:

$$R^e_{i,t} = \beta_0 + \beta_{i,MKT}\,\mathrm{MKT}_t + \beta_{i,SMB}\,\mathrm{SMB}_t + \beta_{i,HML}\,\mathrm{HML}_t + \beta_{i,RRD}\,\mathrm{RRD}_t + \varepsilon_{i,t},$$

where R^e_t are excess returns of accrual portfolios at time t and MKTRF, SMB, and HML are the Fama–French three factors (expressed as percentages). Relative return dispersion (RRD) is calculated as described in Section 3 and Table 1 (expressed as percentages). Panel A presents the results pertaining to the Fama–French three-factor benchmark model, and Panel B presents the results from the Fama–French model augmented with the RRD state variable. The corresponding t-statistics in parentheses are corrected for autocorrelation and heteroskedasticity using the Newey–West estimator with three lags. *, **, and *** indicate significance at the 10%, 5% and 1% level, respectively. The sample period is from January 1965 to December 2011.

This table reports the factor loadings for each of the quintile buy-and-hold investments portfolios and the low-minus-high accrual strategy (IA_Hedge). For each portfolio i, we estimate variations of the following time-series model:

$$R^e_{i,t} = \beta_0 + \beta_{i,MKT}\ \mathrm{MKT}_t + \beta_{i,SMB}\ \mathrm{SMB}_t + \beta_{i,HML}\ \mathrm{HML}_t + \beta_{i,RRD}\ \mathrm{RRD}_t + \varepsilon_{i,t},$$

where R^e_t are excess returns of investment portfolios at time t and *MKTRF, SMB, and HML* are the Fama–French three factors. RRD is calculated as described in Section 3 and Table 1. Panel A presents the results pertaining to the Fama–French three factor benchmark model, and Panel B presents the results from the Fama–French model augmented with the RRD state variable. The corresponding t-statistics in parentheses are corrected for autocorrelation and heteroskedasticity using the Newey–West estimator with three lags. ** and *** indicate significance at the 5% and 1% level, respectively. The sample period is from January 1965 to December 2011.

for high-accrual and high-investment portfolios. For every portfolio, we run the following time series regression:

$$R^e_{i,t} = \beta_0 + \beta_{i,MKT}\ \mathrm{MKT}_t + \beta_{i,SMB}\ \mathrm{SMB}_t + \beta_{i,HML}\ \mathrm{HML}_t + \beta_{i,RRD}\ \mathrm{RRD}_t + \epsilon_{i,t}, \tag{5}$$

where $R^e_{i,t}$ is the excess return of portfolio i at time t and RRD is the relative return dispersion at time t. MKT_t, SMB_t, and HML_t represent the Fama and French (1993) factors controlling for market, size and value premiums, respectively. We conduct our analysis separately for accruals and investment portfolios and present the results in Tables 5 and 6, respectively.

Panel A of Table 5 documents time-series loadings for accrual portfolios using the benchmark Fama–French model. These results suggest that including the three Fama–French risk factors does not explain the differential returns between low and high accrual portfolios. The alphas from the three-factor model almost monotonically decrease across accrual portfolios, and the alpha representing the abnormal returns of the accrual hedge portfolio (ACC_Hedge) is significant, with a magnitude of approximately 56 basis points per month (comparable to 74 basis points of abnormal performance documented by Wu et al., 2010). Comparing Models 1 and 5 of Panel A, market risk exposure is similar for low- and high-accrual firms. In both cases, it is statistically significant and close to one. Similarly, we document that the exposure to the size factor is U-shaped, which suggests that firms in high- and low-accrual portfolios (ACC1 and ACC5, respectively) tend to be small. The difference in exposure to SMB between low- and high-accrual firms is not significant and therefore cannot explain this anomaly.[21]

Panel B of Table 5 presents the same analysis after adding the relative return dispersion variable to our benchmark model. Model 6 shows that the accrual hedge portfolio (ACC_Hedge = ACC1 − ACC5) has positive and significant exposure to RRD, indicating that the low accrual portfolio has relatively higher exposure to the RRD factor compared with the high accrual portfolio. The RRD betas are 0.278 (with a t-statistic of 5.86) and 0.201 (with a t-statistic of 4.43) for low- and high-accrual firms, respectively. More important, according to Model 6, the RRD beta spread is positive and significant (0.0770 with a t-statistic of 2.87).[22]

We repeat the above analysis in the context of buy-and-hold investment-sorted portfolios and present the results in Table 6. While the low-investment portfolio has statistically lower market risk, it has relatively higher exposure to size and

[21] Although both high and low accrual groups are smaller than the rest, untabulated results show no significant difference in the sizes of these extreme accrual groups.

[22] The coefficient on RRD is not monotonic. Given the U-shaped pattern of the coefficient on SMB, one potential concern is that our results for RRD are driven by firm size and that accruals are related to firm size, which is not fully captured by SMB. Our results (untabulated) are robust when we repeat our analysis after eliminating the bottom decile of stocks in terms of size (market capitalization).

value factors, implying that in this case the low-investment portfolio is comprised of relatively smaller and value firms. However, similar to accrual portfolios, Panel A of Table 6 illustrates the inability of the three-factor benchmark model to explain the investment premium (the alphas from the benchmark model monotonically decrease across investments portfolios). Model 6 shows an abnormal performance of the investment hedge portfolio of 94.8 basis points with a t-statistic of 8.97.

Panel B of Table 6 presents the results from the model that includes the RRD variable. Similar to the accrual portfolio analysis, we observe that the low-investment portfolio is also more sensitive to general macro-economic conditions as measured by the RRD variable. In particular, the RRD beta for the IA1 (IA5) portfolio is 0.270 (0.150) with a t-statistic of 7.56 (2.93). More important, as expected, the RRD beta spread between these two portfolios is statistically significant. (Model 6 shows that the hedge investment portfolio presents a coefficient on RRD of 0.121 with a t-statistic of 3.38.)

Overall, these empirical findings suggest that both the investment and accrual premiums are positively related to the risk captured by RRD, supporting our hypothesis that shareholders of low-accrual and low-investment firms face higher risk during low productivity states. Furthermore, including the RRD variable substantially reduces the magnitude of the intercept of the accrual and investment hedge strategies (Models 6 in Panel B of Tables 5 and 6, respectively).[23] Untabulated results confirm that this effect is not subsumed by other commonly used macroeconomic variables. (RRD consistently stays positive and significant for the accrual and investment hedge portfolios even after we include controls for dividend yield, term spread, default, and the risk-free rate.)

Our next question relates to the economic significance of the RRD effect, so we follow a methodology geared toward quantifying the magnitude of the RRD effect for the accrual and investment strategies' returns. Specifically, we split the months in our sample into states based on the realized level of RRD during the month. Following Petkova and Zhang (2005) we define four states of the world: State 1 (Low) corresponds to the 10% lowest observations for RRD; State 2 corresponds to below-average RRD, excluding the 10% lowest observations; State 3 corresponds to above-average RRD excluding the 10% highest observations; and State 4 (High) corresponds to the 10% highest observations for RRD. We then document raw and risk-adjusted returns of the accrual and investment hedge portfolios in each state, and we test whether the difference in performance between high and low RRD states is statistically significant. Table 7 presents the results of this analysis.

The accrual premium monotonically increases from good (low RRD) states (conducive to growth) to bad (high RRD) states (less conducive to growth). Specifically, while the accrual strategy generates 20.5 basis points per month during states with low RRD, it produces 92.4 basis points during periods when RRD is high. The difference in performance of the accrual hedge portfolio between periods with low and high RRD is both economically and statistically significant. Similarly, we find that the investment hedge portfolio generates 136 (-1) basis points during high (low) RRD periods, and the difference in raw returns of the investment strategies between high and low RRD states is economically and statistically significant.

In Panel B of Table 7, we estimate the economic significance of the RRD effect for risk- adjusted returns using the same definition for states. To capture the abnormal (risk-adjusted) performance we run time series regressions of the hedge portfolios for each state on the Fama–French three factors. The abnormal performance of the accrual strategy monotonically increases with states of RRD – specifically, during low (high) states of RRD the abnormal performance of the accrual premium is 23.7 (88.9) basis points. Similarly, the abnormal returns of the investment strategy are higher during high RRD states – the investment hedge portfolio has no significant abnormal performance during low RRD states and a significant performance of 126 basis points in high RRD states. To test whether the difference in abnormal returns between high and low RRD states is statistically significant, for each strategy (accruals/investments) we estimate a regression in which we consider the low RRD state (State 1) as the base state, and we include two dummies identifying the high RRD state (State 4) and everything else (States 2 and 3), respectively. The last column of Panel B reports the coefficient of the dummy variable for the high state (which represents the difference in intercepts between the high and low states) and the coefficients of the State 4 interaction dummies for each of the Fama–French factors (which represent the difference in loadings between the high and low states). During high RRD states the accrual (investment) strategy produces risk-adjusted returns that are 65 (125) basis points higher than during low RRD states (in both cases, the differences are statistically significant). High RRD states also present significantly lower loadings on the HML factor for the accrual strategy and significantly lower loadings on the market factor (and higher loadings for the SMB factor) for the investment strategy.

One potential caveat for the methodology used is that it involves sorting firms into portfolios based on a particular characteristic, which may reflect biases due to transaction costs and bid-ask bounce (as discussed in Asparouhova et al., 2010). As an alternative method, we estimate characteristic rank regressions at an individual firm level (following Mashruwala et al., 2006). We test whether the cross-sectional relation between accruals/investments and returns is dependent on RRD in a pooled panel setting, using the Petersen (2009) methodology to allow for two-way cluster-robust standard errors. Results (untabulated) confirm that the predictive ability of accruals and investments varies significantly with the state of RRD. Specifically, in high RRD states, the magnitude of the negative relation is significantly larger.

[23] Given that RRD is not a return-scaled risk factor, interpreting the intercept as abnormal excess returns may be problematic. However, econometrically, the intercept does represent the unexplained portion in the hedge portfolios' returns, which is significantly reduced after the inclusion of the RRD explanatory variable (and becomes insignificant in the case of accruals).

We sort calendar months into groups based on the relative return dispersion (RRD) level realized during each month. Following Petkova and Zhang (2005) we define four states of the world: State 1 (Low) corresponds to the 10% lowest observations for RRD; State 2 corresponds to below-average RRD, excluding the 10% lowest observations; State 3 corresponds to above-average RRD excluding the 10% highest observations; and State 4 (High) corresponds to the 10% highest observations for RRD. Panel A reports the average monthly accrual and investment hedge raw returns (percent) for each state. The last column in Panel A presents the difference in returns (percent) between high and low RRD regimes. Panel B presents risk-adjusted returns, obtained as follows. For each expected RRD state, we regress the accrual and investment hedge portfolios (percent) on the Fama–French factors (percent). The *t*-statistics that correspond to the loadings are presented in parentheses and are corrected for autocorrelation and heteroskedasticity using the Newey–West estimator with three lags. The last column of Panel B presents the differences in risk-adjusted returns and coefficients between the high and low states, obtained as follows. For each strategy (accruals/investments) we estimate a regression in which we consider the low state (State 1) as the base state, and include dummies identifying the high state (State 4) and everything else (States 2 and 3). We report the coefficient of the dummy variable for the high state (which represents the difference in intercepts between the high and low states) and the coefficients of the State 4 interaction dummies for each of the Fama–French factors (which represent the difference in loadings between the high and low state). *, **, and *** indicate significance at the 10%, 5% and 1% level, respectively. The sample period is from January 1965 to December 2011.

5. Robustness checks

We run a battery of robustness checks to ensure that our results are not specific to the sample, methodology, and proxies presented in our main tabulated results. For the sake of brevity, we do not tabulate these results.

The first concern is whether the results are sensitive to the proxies that we use for calculating return dispersion and for measuring accruals. We repeat all results presented in the main tables using RD instead of RRD as a measure for cross-sectional return dispersion. In addition, we use measures of relative return dispersion calculated based on portfolios instead of individual stocks (following Stivers and Sun, 2010) and based on individual stocks after excluding small firms (following Jiang, 2010). Results continue to show a significant relation between return dispersion and the returns to accrual and investment hedge portfolios. Also, one may argue that the indirect method of calculating accruals (based on balance sheet information) is subject to measurement errors in accruals, as described by Hribar and Collins (2002). We repeat our main analysis on the post-1988 sample using the direct method for accruals advocated by Hribar and Collins (2002) and confirm that RD explains the payoffs from accrual-based strategies.

Asparouhova et al. (2010, 2013) make the point that cross-sectional tests for individual returns may be biased by bid-ask effects and propose a lagged return-weighting scheme to address this microstructure bias. We repeat our individual stock level tests using a weighted least squares methodology with the proposed weighting scheme and confirm that RD/RRD significantly explains future returns. At the portfolio level, we confirm that if we use value-weighted or return-weighted portfolios, the accrual and investment hedges vary significantly with our RD/RRD variables, and that their intercepts become insignificant in the presence of RD/RRD.

To ensure that RD captures risk, we repeat our main set of tests using innovations in return dispersion (instead of levels). Specifically, we follow the VAR methodology proposed by Campbell (1996) and Petkova (2006) to obtain innovations in return dispersion, controlling for innovations in other macroeconomic variables. The results show that innovations in RD (RRD) are positively priced in the cross section of individual stock returns and that low-accrual and low-investment firms have higher exposure to innovations in return dispersion measures. Generally, the introduction of macroeconomic variables in cross-sectional asset pricing models can be motivated either (1) as additional risk factors that help to price the cross section of returns by capturing additional sources of risk (see Chen et al., 1986; Maio and Philip, 2013) or (2) as state variables that predict changes in the investment opportunities set (see Campbell, 1993; Chen, 2002). If RD matters because it captures deteriorations in the investment opportunity set, then innovations in this variable will be negatively priced in the cross section.[24] Our cross-sectional results (untabulated) show that innovations in RD/RRD are positively priced, which supports the idea that this macro-variable captures risk, rather than a countercyclical hedging component.[25]

Moreover, our (untabulated) tests provide only weak support for the accrual and investment strategies being countercyclical.[26] We conclude that the connection with accruals/investments is driven by the information related to fundamental economic restructuring, rather than cyclicality. Specifically, RD is likely to capture the uncertainty associated with economic transitions and the flexibility of adaptability to fundamental economic restructuring [in line with Pastor and Veronesi (2009) and Demirer and Jategaonkar (2013)], rather than shocks related to the business cycle.

Another question relates to whether alternative mispricing hypotheses can explain our documented results. For example, Sloan (1996) argues that investors' inability to differentiate between the persistence of earnings and cash flows explains the accrual anomaly, but it is unclear that this will vary systematically with macroeconomic conditions. Systematic variation in the accrual anomaly could be observed under this scenario only to the extent that arbitrageurs' ability to eliminate the accrual mispricing varies with general market conditions.[27] Mashruwala et al. (2006) argue that barriers to arbitrage stemming from the absence of close substitutes (idiosyncratic risk) and transaction costs (in particular, low trading volume) prevent arbitrageurs from driving away accrual-related mispricing. If these barriers to arbitrage vary systematically with RRD, then this would be consistent with our documented results. However, robustness checks indicate that our results are not driven by liquidity or a bid-ask spread bias (consistent with the limits to arbitrage argument). Quantifying the extent to which systematic variation in barriers to arbitrage generates systematic variation in the accrual anomaly is an interesting avenue that we leave open for future research.

6. Conclusion

This paper links return dispersion–a macroeconomic variable that captures states of the aggregate economy–to the accrual and investment anomalies. We document that a positive RD risk premium exists in the cross section of returns and that low-accrual and low-investment firms have higher exposure to this risk. In the time series, the accrual and investment premiums are positively correlated with return dispersion and the predictive ability of the accrual and investment characteristics is significantly stronger in high return dispersion states. The results persist in portfolios and individual stock level tests, and they are robust to a battery of alternative proxies, choice of test assets, sample periods, and control variables.

We argue that our results support a risk-based interpretation for the accrual and investment anomalies. The fact that both strategies present a similar relation to RD implies that the risk that RD captures is related to the growth characteristics of the firms. This supports our claim that the accruals matter in the cross section of returns because they reflect information relevant to the growth/investment characteristics of firms.

Our results have important implications for both academics and practitioners. From an academic perspective, evidence that accruals and investments may be leading indicators of firm growth can explain why accruals and investments are informative with regard to equity premiums at both the aggregate and firm levels. From a trading perspective, we show that the profitability of accrual and investment strategies will strongly co-vary with return dispersion, which is of interest to practitioners attempting to implement such strategies.

[24] Maio and Santa-Clara (2012, p. 587) succinctly summarize the restrictions imposed by ICAPM on the time-series and cross-sectional behavior of state variables and factors: “If a state variable forecasts positive (negative) changes in investment opportunities in time-series regressions, its innovation should earn a positive (negative) risk price in the cross-sectional test of the respective multifactor model.”

[25] It is difficult to argue that high accrual and/or high investment firms are good hedges (and therefore have lower returns), because that would imply that these firms perform well in bad times, which is not the case. Instead, these firms are the ones that are less flexible and more likely to be negatively affected in periods of high RRD (supported by the fact that the accrual and investment anomalies are stronger in high RRD states, as shown in Table 7).

[26] Wu et al. (2010) present predictive regressions, which suggest (weak) support for the accrual and investment anomalies being countercyclical. We replicate the predictive regression results obtained by Wu et al. (2010), and we also investigate the magnitude of the accrual and investment anomalies conditioning on the National Bureau of Economic Research business cycles. Both methods provide weak evidence in support of the countercyclical nature of these strategies.

ABSTRACT

This paper investigates whether the initiation of trading in credit default swaps (CDSs) on a borrowing firm's outstanding debt is associated with a decline in that firm's reporting conservatism. CDS investments can modify lenders' payoffs on their loan portfolios by providing insurance on negative credit outcomes. The onset of CDS trading reduces lenders' incentives to continuously monitor borrowers and also their demand that borrowers report conservatively. Additionally, borrowers expect CDS-insured lenders to be more intransigent in renegotiations triggered by defaults and covenant violations. Since conservatism can trigger earlier covenant violations, borrowers have heightened incentives to report less conservatively in the post-CDS period. Using a differences-in-differences research design, we observe a decline in borrowing firms' reporting conservatism after CDS trade initiation. This effect is more pronounced when reputation costs lenders face from reducing monitoring are lower, when debt contracts outstanding at the time of CDS trade initiation have more financial covenants, and when lenders who monitor borrowers more regularly in the pre-CDS period enter into CDS contracts to hedge their credit exposures.

1. Introduction

This paper investigates the influence of financial developments in the capital markets on accounting practices. Financial market developments can affect the payoffs and incentives of existing contractual parties to the firm. Since contractual considerations can influence accounting practices (Watts and Zimmerman, 1986), an altered contractual environment can potentially induce changes in these practices. The financial market innovation we focus on is credit default swaps (CDSs), widely used in recent times to manage lenders' credit risk exposures and their regulatory capital. The accounting practice we study is conservatism, in the context of the borrower–lender relationship. Our primary interest is in examining whether the advent of CDS trade initiation on a firm's outstanding debt is associated with a change in that firm's reporting conservatism.

The credit default swap is a contract in which the buyer, generally called the protection buyer, makes a series of payments to the seller, generally called the protection seller. In exchange, the protection buyer receives a payoff from the protection seller if a credit instrument (such as a loan or a bond) goes into default or experiences any other “credit event” specified in the CDS contract (such as restructuring, bankruptcy, or credit-rating downgrade). By acquiring a CDS contract, the protection buyer transfers the credit risk associated with its investment (such as a loan or a bond) to the protection seller, while retaining legal ownership of the investment. The risk-shifting via CDS contracts allows lenders, particularly banks, to better manage their regulatory capital since the risk weight assigned to a loan can be based on the credit rating of the counter-party in the CDS contract rather than the original borrower.[1] As an example, AIG discloses in its Annual Report that $150 billion of its notional CDSs outstanding at the end of 2009 reflected contracts it wrote to provide regulatory capital relief to financial institutions for their corporate loans (Saretto and Tookes, 2013). The overall CDS market has grown tremendously in recent years, with the notional amount increasing from $180 billion in 1998 to $57 trillion at the end of June 2008 (Stulz, 2010).[2]

Investments in CDS contracts by banks can potentially have an influence on the reporting practices of those clients. Upon granting a loan, lenders generally face an asymmetric payoff on their investment: if the borrowing firm remains solvent, lenders receive their principal and earned interest, while bankruptcy entitles them to the orderly liquidation value of the borrower. The literature argues that this asymmetric payoff underlies lenders' demand for conservatism in the financial statements of borrowers (Watts and Zimmerman, 1986; Watts, 2003). Under conservative reporting, which requires stricter verification standards for recognizing good news in earnings relative to bad news, the book value of a firm provides lenders with a lower-bound estimate for the firm's orderly liquidation value. Ensuring that borrowers do not deviate from conservative reporting practices post-loan-initiation arguably requires continuous monitoring by lenders over the life of the loan. Indeed, continuous lender monitoring, in particular by banks, seems to be a salient feature of the traditional lender–borrower relationship (Gorton and Khan, 1993; Roberts and Sufi, 2009; Acharya et al., 2014).

The availability of CDS contracts alters lenders “downside” payoffs and can thus influence the lender–borrower relationship. In the event of borrower insolvency (in practice, any pre-specified credit event in the CDS contract), lenders are now entitled to settlement payouts from CDS sellers. Coverage from a CDS contract thus reduces the asymmetry in the payoffs to lenders' claims, and provides them greater bargaining power upon the occurrence of pre-specified credit events such as defaults and violations (Bolton and Oehmke, 2010). Lenders' less asymmetric claim structure post-CDS, and their higher bargaining power in renegotiations, potentially diminish their reliance on continuous monitoring to protect the value of their claims and relatedly, their demand for conservatism in borrowers' financial reports. Furthermore, lenders' reduced reliance on continuous monitoring is expected to be accompanied by higher intransigence on their part in renegotiations with borrowers who experience credit events (Fink, 2004; Hu and Black, 2006; Bolton and Oehmke, 2010; Stulz, 2010; Subrahmanyam et al., 2014). Since conservative accounting policies are associated with earlier covenant violations (Zhang, 2008; Nikolaev, 2010), borrowers have increased incentives to report less conservatively after CDS trade initiation, because they anticipate tougher renegotiations if they trigger covenant violations. The joint effect of borrowers' incentives to avoid renegotiations and lenders' incentives to avoid monitoring costs can lead to less conservative reporting by borrowers after CDS trade initiation.

A post-CDS reduction in borrowers' reporting conservatism need not necessarily be a foregone conclusion as it can make third parties such as CDS sellers apprehensive about borrowers' credit quality. Note that CDS sellers do not own control rights with respect to the underlying loan and typically eschew any direct contractual involvement with borrowers. Nevertheless, it is possible that lenders maintain their demand for conservatism, to avoid reputation costs (for example, with CDS sellers) arising from negative credit event realizations that are attributed to their reduced monitoring of financial statements. Further, it may be difficult for borrowers to deviate from past conservatism for the sake of maintaining reporting consistency. Other stakeholders to the firm unprotected by CDS investments, such as shareholders and lenders, may step up their monitoring to ensure that borrowers continue to report conservatively. These alternative scenarios illustrate the importance of empirically investigating changes in borrowers' reporting conservatism upon CDS trade initiation.

---

[1] BASEL II states that guarantees issued by or protection provided by entities with a lower risk weight than the counterparty exposure is assigned the risk weight of the guarantor or protection provider.

[2] The size of the CDS market fell sharply in the second half of 2008 in the wake of the financial crisis, but was still high at $41 trillion at the end of 2008. The Bank for International Settlements (BIS) has statistics on the CDS market since the end of 2004 based on survey data. See http://www.bis.org/statistics/derstats.htm.

We identify a sample of 529 firms who experience CDS trade initiation between 2002 and 2009. The empirical exercise involves the identification of an event, CDS trade initiation, and an examination of whether there is a change in conservatism around this event. To control for selection bias and endogeneity, we follow the Ashcraft and Santos (2009) matched-sample design. In the first stage of this analysis, we predict CDS trade initiation based on credit rating, leverage, profit margin, size, return volatility and market-to-book.[3] In the second stage, we use the CDS-trade-initiation probability-estimates yielded by the first stage model to construct a sample of 525 unique matched firms from the same industry as the treatment firms, but with no CDS trading throughout the sample period. Finally, in a difference-in-difference regression, we compute the change in conservatism for CDS firms from the two years prior to CDS-trade-initiation to the two years after, and compare that change to the corresponding change for matched non-CDS firms.

We define conservatism as the asymmetric requirement of weaker verification standards for recognizing losses than for recognizing gains. We measure conservatism as the greater timeliness of earnings with respect to negative returns relative to positive returns (Basu, 1997). Our results indicate that the initiation of CDS trading is on average associated with a decline in the financial reporting conservatism of underlying borrowers. The specific coefficients imply that asymmetric timeliness of loss recognition declines by around 20% after the onset of CDS trading. The decline seems economically significant and is statistically significant at the 5% level.

In cross-sectional analyses, we test predictions on when a post-CDS decline in conservatism is more likely. We reason that a decline in reporting conservatism should be more prominent when the underlying borrowers are ex ante more informationally opaque and riskier. Among such borrowers, lenders are likely to face higher monitoring costs prior to CDS trade initiation, and lower reputation costs from the potentially adverse consequences of reducing their demand for conservatism after CDS trade initiation (Parlour and Winton, 2013; Ashcraft and Santos, 2009). Further, if lenders reduce their demand for conservatism in financial statements, then borrowers with poorer *ex ante* credit quality are expected to be more responsive to such a reduction. The evidence indicates that the decline in conservatism is concentrated among borrowers that are smaller and carry speculative-grade credit ratings prior to CDS trade initiation.

Our cross-sectional tests also indicate a greater decline in conservatism at the time of CDS trade initiation when borrowers' outstanding private debt at that time includes more financial covenants. Since conservative reporting is hypothesized to accelerate covenant violations (Zhang, 2008), our finding is consistent with borrowers having higher incentives to avoid violations after CDS trade initiation, presumably because they expect greater lender-intransigence in the associated renegotiations.

We reason that the influence of lenders' incentives to avoid monitoring costs in the post-CDS period will manifest more in firms that are subject to continuous lender monitoring in the pre-CDS period. Banks represent the class of lenders most likely to continuously monitor borrowers, via their sophisticated and timelier private insights into various aspects of a firm's managerial practices, including their reporting choices. Banks also provide the data necessary in their Y-9C reports to identify those among them with a greater likelihood of having entered into CDS contracts on their clients. We find that a decline in conservatism after CDS trade initiation is more pronounced among borrowers with loans outstanding from banks that are likely to have hedged their credit exposures via CDS contracts.

Additional tests examine the possibility that the observed association between CDS trade initiation and a decline in conservatism is endogenous, in the sense that lenders are motivated to enter into CDS contracts when they anticipate a decline in reporting conservatism at the borrower. Our empirical analysis indicates that the decline in borrower conservatism we observe is unlikely driven by the change in conservatism anticipated at the time of CDS trade initiation. Indeed this result is confirmed again when we substitute the matched-sample method with a Heckman two-stage procedure to control for selection bias, and when we employ an expanded prediction model for CDS trade initiation that incorporates banks' tendency to offload credit risk (Minton et al., 2009). Our results are not sensitive to alternative identification of matched control firms. Finally, they are also robust to using a conservatism measure that relies on earnings time-series properties (Basu, 1997) and not on equity returns.

The primary contribution of our study is in providing evidence that financial market developments influence financial reporting practices because they alter contractual parties' payoffs and incentives. In particular, CDS trade initiation in a firm's outstanding debt leads to a decline in its reporting conservatism because it alters the firm's relationship with its lenders.

The rest of the paper proceeds as follows. Section 2 discusses related literature and develops testable hypotheses. Section 3 describes sample selection and presents descriptive statistics. Section 4 introduces variable measurement and empirical methods. Section 5 reports empirical findings. We conclude in Section 6.

2. Related literature and hypothesis development

2.1. The CDS market

Single-name CDSs are typically written on specific securities issued by firms, for example public bonds outstanding. CDS buyers make payments to CDS sellers via insurance premiums expressed as an annualized percentage of the notional value

[3] The first-stage model indicates that CDS trade initiation is more likely for firms with higher credit rating, leverage, profit margin and size, and lower return volatility, consistent with adverse selection concerns in the CDS market creating a bias towards firms with higher credit quality and transparency.

of the transaction. For example, if the CDS spread of the underlying firm is 0.5%, a bank buying $10 million worth of protection from the CDS seller must pay the seller $50,000 annually. The payments continue until either the CDS contract expires or until the occurrence of a pre-specified credit event (e.g., default, bankruptcy, credit-rating downgrade or restructuring). See Appendix A for a sample CDS contract. There are typically two types of CDS sellers: (a) monoline insurers such as AIG and Ambac who primarily operate on the sell-side and (b) financial institutions and hedge funds including J.P. Morgan and Goldman Sachs who serve as market-makers. Both types of CDS sellers hedge their open risk exposures on CDSs across various derivative instruments and across numerous investors in each instrument (Weistroffer, 2009).

CDS contracts provide a convenient channel for hedging to lenders, even though the loans responsible for lenders' credit risk exposures to the underlying borrowers are distinct from the specific securities (i.e., bonds) that CDS contracts are written on.[4] The CDS protection benefits banks with respect to regulatory requirements. BASEL II states that by entering into CDS contracts, a bank can substitute the credit risk of the borrower by the credit risk of the CDS seller in computing risk-weighted assets (BASEL II, page 49, Article 141). CDS purchases can therefore allow for lower commitment of regulatory capital to the loan, which in turn frees funds for alternative productive investments. The CDS insurance also allows originating lenders to maintain lending relationships with their borrowers while reducing the risk profile of their loan portfolios (Venokur et al., 2008; Saretto and Tookes, 2013).

CDSs are derivative instruments, and hence are available for trade not only to lenders seeking insurance on their loan exposures, but also to speculators (Stulz, 2010; Lewis, 2010). Nonetheless, there is evidence that banks are increasingly using the CDS market to hedge the credit exposures they originate through their lending business.[5] In 2006, banks entering into CDS contracts related to their loan portfolios constituted 20% of the market for CDS purchases. By comparison, banks writing CDS contracts on their loan portfolios constituted only 9% of total CDS selling, implying that banks in general maintain net purchase positions, reflecting their incentives to use CDSs for hedging and managing regulatory capital (British Bankers Association (BBA), 2006, also see Appendix B).

2.2. CDS contracts, lender monitoring and borrowers' conservatism: primary hypothesis

CDS contracts allow loan originators to "economize" on their regulatory capital and share their risk exposures with the rest of the economy (Deutsche Bank Research, 2009). The literature has investigated whether lenders pass on the benefits from CDS investments to their clients. Ashcraft and Santos (2009) fail to find evidence that CDS trade initiation is associated negatively with interest spreads that lenders demand from their corporate borrowers. However, Saretto and Tookes (2013) document that S&P 500 firms with CDS contracts trading on their debt are able to maintain higher leverage ratios and longer debt maturities, consistent with such firms benefiting from fewer supply-side frictions in lending.

A traditional lender–borrower relationship is typically characterized by lending institutions, in particular banks, continuously monitoring borrowers after loan initiation (Fama, 1985; James, 1987; Roberts and Sufi, 2009; Acharya et al., 2014). A key question in the literature has been whether the development of the CDS market weakens lenders' incentives to monitor borrowers (Duffee and Zhou, 2001; Morrison, 2005; Ashcraft and Santos, 2009; Marsh, 2009; Stulz, 2010; Parlour and Winton, 2013). A similar issue exists with other credit-risk-transfer mechanisms such as loan sales in the primary and secondary market (Pennacchi, 1988; Gorton and Pennacchi, 1995; Ball et al., 2008; Bushman and Wittenberg-Moerman, 2012). The CDS market, however, differs from the loan sale market in some important respects. In a loan sale, both the risk exposure on the loan and control rights, including the right to monitor and administer the loans, are typically transferred to the loan buyer.[6] Even in cases that loan sales are partial, as when lead arrangers bring in syndicate participants, the latter are in a better position to detect any shirking in monitoring by the originating lender than CDS sellers, who do not have any direct access to the borrower. In contrast, in a CDS contract, the credit risk transfers to the CDS seller, but control rights remain with the original lender. Thus, the agency issues are potentially more severe with CDS contracts (Parlour and Winton, 2013).

CDS availability significantly alters the lender–borrower dynamic. Consider a bank that invests in a CDS contract on an underlying borrower's bonds. Upon the occurrence of a pre-specified credit event, for example a payment default, renegotiations are less crucial for the bank to preserve the value of its claim, because of its existing CDS insurance. This provides the bank incentives to (a) be more inflexible in renegotiations and (b) rely on credit event triggers rather than continuous monitoring to ensure the value of its claim. Hu and Black (2006) and Bolton and Oehmke (2010) refer to this as the phenomenon of the "empty creditor." Subrahmanyam et al. (2014) document that bankruptcy probability and credit risk assessments by rating agencies both increase with CDS trade inception, a finding that persists after controlling for selection bias therein, as well post-CDS changes in firm fundamentals such as leverage. They attribute the heightened financial risk of borrowers to lenders' intransigence in the post-CDS period.

In the context of the traditional lender–borrower relationship, accounting conservatism is hypothesized to provide an efficient means for debt-holders to monitor their credit risk (Watts and Zimmerman, 1986; Basu, 1997; Watts, 2003; Frankel

[4] For example, JP Morgan Chase reports $48 billion in notional CDS purchases to hedge the credit risk of its loan portfolio in its 2009 Annual Report (Saretto and Tookes, 2013).

[5] According to a survey by the British Bankers Association (2006) half of the protection banks bought in the CDS market in 2005 and 2006 were to cover exposures resulting from their lending activities.

[6] Loan sales without recourse constitute the vast majority of transactions (see Gupta et al., 2008).

and Litov, 2008; Zhang, 2008; Nikolaev, 2010; Ahmed et al., 2002; Gormley et al., 2012; Tan, 2013; Donovan et al., 2014). Conservative financial reporting, by recognizing economic losses in a timely manner and deferring the recognition of economic gains, ensures that borrowers' net asset values are understated. Thus, under conservatism, net asset values provide a lower bound on borrowers' ability to repay their debt obligations (Roychowdhury and Watts, 2007). Further, asymmetrically timely loss recognition under conservative reporting is expected to accelerate debt covenant violations and facilitate timelier transfer of control to debt-holders (Zhang, 2008; Nikolaev, 2010). Borrowers' incentives to report less conservatively after loan origination to avoid covenant violations are typically mitigated by continuous monitoring of their financial statements by lenders.

If lenders shift away from continuous monitoring because their claims are insured via CDSs, borrowers now have incentives to report less conservatively. Firms do not necessarily observe the timing of their lending banks' investments into specific CDS contracts, but they can observe CDS trade initiation on their own outstanding bonds. Further, lenders' weakened incentives to monitor the conservatism in borrowers' financial statements can manifest in several ways, including fewer requests for timely financial statements, fewer clarification requests regarding those statements and less frequent on-site visits to verify reported numbers.[7] The reduced scrutiny from lenders seeking to lower monitoring costs provides borrowers the opportunity to report less conservatively. The expected intransigence of lenders in post-CDS renegotiations makes violations particularly unattractive for borrowers and provides them with incentives to report less conservatively.[8]

Systematic empirical evidence regarding a decline in lender monitoring upon CDS trade initiation is limited. Marsh (2009) documents a less positive stock return reaction to borrowers announcing new loans from banks known to transfer credit risk via collateralized loan obligations (CLOs), consistent with the market anticipating weaker monitoring by such banks.[9] Ashcraft and Santos (2009) find that debt financing costs are higher for risky and informationally opaque firms after the onset of CDS trading, which they interpret as evidence of a reduction in lender monitoring among this subset of firms.

Wang and Xia (2014) document that firms borrowing from banks active in loan securitizations (via CLOs) enjoy looser covenants at loan origination, and appear to take on more risk than those borrowing from non-securitization banks. They conclude that banks exert less monitoring effort after loan securitizations, but do not investigate CDSs. Inconsistent with Wang and Xia (2014), Sustersic (2012) finds that new debt agreements in the post-CDS period are more likely to include financial covenants, with less "slack," relative to those initiated in the pre-CDS period. Interestingly, Sustersic (2012) finds no evidence of increased covenant violation probability in the post-CDS period; her results raise the possibility that borrowers report less conservatively after CDS trade initiation, and thus avoid an otherwise higher level of covenant violation, given the more numerous and tighter covenants. To our knowledge, the specific issue of whether lenders reduce their scrutiny of their borrowers' financial statements upon acquiring CDS contracts, or whether borrowers exhibit any change in their reporting practices, is unaddressed in the literature. Our paper tests the following null hypothesis:

H1 (null). The onset of CDS trading in a firm is not associated with a reduction in the firm's reporting conservatism.

H1 is stated in null form because other economic forces exist that could possibly influence the change in lender monitoring and borrower conservatism upon CDS trade initiation, but the net influence of these forces is often ambiguous. For example, it is possible that the demand for conservatism arising from parties other than banks is also altered with the availability of CDS contracts. Parties such as shareholders (with the board of directors and auditors as their fiduciary agents) and public debt-holders not invested in CDSs possibly increase their monitoring of financial statements and their demand for conservatism in anticipation of reduced lender monitoring. However, it is not clear that such parties can completely substitute for the expert monitoring by lenders, in particular banks. Further, CDS contractual provisions can specify that the bank's claim on the underlying firm is junior to those of other parties, motivating banks to retain their demand for conservatism (Sufi, 2007). In spite of this, such modifications in practice tend to be rare; CDS counterparties typically rely on the International Swaps and Derivatives Association Master Agreement to draw up contracts (see Deutsche Bank Research, 2009, and the discussion of standard CDS contracts in Appendix A). Similarly, on the one hand, it is possible that the responsibility for monitoring of financial statements passes from lenders to CDS sellers. On the other hand, the absence of private contractual agreements between CDS sellers and underlying borrowers limits the ability of the former to monitor borrowers on an ongoing basis after CDS trade initiation. Rather, CDS sellers, the largest of whom are monoline insurers, typically establish diversified portfolios of credit risk in which losses generated by one contract are compensated by premiums earned from other contracts. Finally, CDS sellers can price-protect in anticipation of reduced lender monitoring and can also increase CDS prices for lenders if they observe heightened post-CDS borrower default. Nevertheless, the implications of price-protection by CDS sellers are far from obvious. CDS-sellers typically price-protect only on average

[7] As Arping (2012) argues, managers at borrowing firms can typically detect any weakening of monitoring intensity in general.

[8] Other factors can also motivate managers at borrowing firms to report less conservatively in the absence of lender monitoring. Managerial compensation is often linked to earnings, for example via bonus plans. Conservative reporting, by delaying the recognition of gains relative to losses, introduces a deferred component to managers' compensation (Leone et al., 2006). It is also argued that reporting conservatism restricts managers' ability to operate or invest in projects that are potentially detrimental to the firm's health but generate private benefits for managers (Ball and Shivakumar, 2005). In addition, Roychowdhury (2010) points to the possibility that conservative reporting can weaken managers' incentives to invest in risky projects.

[9] Marsh (2009) does not observe the same evidence with banks investing in CDSs, but cautions that his sample is not appropriate for the test, since it excludes firms actively traded in the CDS market.

across both lenders and speculators *ex ante*, and cannot always attribute *ex post* borrower defaults to reduced lender monitoring. We test this latter possibility in our cross-sectional analysis, discussed next.

2.3. CDS contracts and underlying borrowers' conservatism: cross-sectional hypotheses

2.3.1. The role of reputation costs

If lenders reduce their demand for conservatism after acquiring CDSs, they may face reputation costs with CDS sellers and other loan syndicate participants (in cases that the lenders are also lead arrangers) if the loan subsequently performs poorly. This can respectively manifest in higher CDS prices in subsequent transactions with CDS sellers and/or lower willingness of potential syndicate participants to participate in future loans. Thus, lenders' propensity to lower monitoring of financial statements after entering into CDS contracts is expected to be greater when reputation effects are weaker.

Parlour and Winton (2013) argue that reputation effects in the CDS market will be weaker when riskier borrowers are involved. The intuition is as follows: if borrowers already deemed to be riskier were to default or experience any other credit event, it is more difficult for external parties to attribute this negative outcome to a lack of lender monitoring. Consequently, CDS-protected lenders are more likely to reduce monitoring of riskier borrowers. The evidence in Ashcraft and Santos (2009) suggesting a more pronounced decline in lender monitoring among riskier borrowers post-CDS-trade initiation is consistent with Parlour and Winton (2013). In the loan syndication market, Gopalan et al. (2011) find that the reputation loss suffered by lead arrangers in the event of borrower bankruptcies is lower when outstanding loans to the insolvent borrowers already have high yields (consistent with these loans being deemed as high-risk).

Furthermore, since continuous monitoring of riskier and opaque borrowers should be costlier, we expect that lenders protected by CDS investments will find it more efficient to rely on pre-specified credit events to trigger renegotiations or payments by CDS sellers. In turn, riskier borrowers will generally tend to be closer to triggering covenant violations and renegotiations, and hence are expected to be more responsive to any decline in lenders' demand for conservatism. Thus, we expect any decline in conservatism after CDS-trade initiation to be more pronounced for riskier borrowers with more opaque information environments. We identify firms that are smaller in size and have credit ratings below investment grade as riskier firms with lower-quality information environments. Thus, we test the following prediction:

H2 (alternate). A decline, if any, in conservatism after the onset of CDS trading is more pronounced for smaller borrowers and borrowers with credit rating below investment grade.

2.3.2. The role of covenants

Zhang (2008) documents that firms who report more conservatively are timelier in violating covenants upon the realization of a negative event, proxied for by a negative price shock. Nikolaev (2010) documents a positive association between conservatism and the presence of financial covenants in public debt contracts, interpreting this as evidence of the complimentary role they play in facilitating timely transfer of control to lenders. In general, the literature suggests that conservatism is more likely to facilitate transfer of control to lenders in the presence of financial covenants. Upon CDS trade initiation, we expect borrowers to have greater incentives to lower conservatism in response to reduced lender scrutiny when their existing debt contracts include more financial covenants. This is particularly true because borrowers rationally expect lenders to be more inflexible in renegotiations triggered by covenant violations when lenders are CDS-protected (Hu and Black, 2006; Bolton and Oehmke, 2010; Subrahmanyam et al.,2014). In formulating our hypothesis, we focus on the number of financial covenants in private debt contracts with banks. Private debt contracts are much more likely to include financial covenants than public debt (Begley and Freedman, 2004; Chava and Roberts, 2008), and banks/financial institutions are also more likely to hedge their underlying exposures via sophisticated derivative instruments such as CDSs (Acharya and Johnson, 2007).

H3 (alternate). A decline, if any, in conservatism after the onset of CDS trading is more pronounced for borrowers with a larger number of financial covenants in their existing private debt contracts at the time of CDS trade initiation.

2.3.3. Lender identity and continuous monitoring

CDS trade initiation and its influence on lenders' monitoring of financial statements is relevant only when the lender–borrower relationship is characterized by continuous monitoring in the first place. In other words, if post-loan initiation, lenders rely not on continuous monitoring but on credit events such as defaults or violations to trigger further scrutiny of borrowers even in the pre-CDS period, then CDS investments have little scope of altering lenders' monitoring strategy. We identify borrowers that are subject to regular monitoring by their lenders in the pre-CDS period by focusing on CDS firms that have loans outstanding to banks. Fama (1985) describes banks as providers of "inside debt", in that they have the greatest access to private information and are most likely class of lenders to monitor the firm closely after loan initiation. Consistent with this James (1987) finds a positive equity return upon the announcement of new bank credit agreements. Additionally, consistent with continuous monitoring after loan initiation, Roberts and Sufi (2009) document that a large majority (75%) of private credit agreements are renegotiated, with only a small minority (18%) of these renegotiations motivated by defaults and/or covenant violations. Data available for banks also enables us to identify whether lending banks exhibit a greater likelihood of having invested in CDS contracts on underlying borrowers upon CDS availability. This identification provides the additional advantage of isolating instances when CDS investments are made by banks hedging underlying loans, rather than by traders assuming speculative positions.

In summary, we test the following hypothesis:

H4 (alternate). A decline, if any, in conservatism after the onset of CDS trading is more pronounced among borrowers whose banks exhibit a greater likelihood of having hedged their respective loan exposures via CDS contracts upon CDS availability.

3. Sample selection

3.1. Firms with traded CDS contracts

CDS contracts are traded in the over-the-counter (OTC) market, almost entirely populated by institutional investors. Unlike an organized exchange such as the NYSE, the information on CDS trading must be gathered from market participants on the basis of their voluntary participation in periodic surveys. We collect information on CDS contracts from Datastream. Datastream covers approximately 13,000 single-name CDS contracts for firms domiciled in 70 countries. Among U.S. firms, there are 8,041 single-name CDS contracts with either senior debt (93%) or subordinated debt (7%) as the underlying securities.[10] Datastream collects CDS data from two main sources: CMA Datavision CDS series and Thomson Reuters CDS series. We only focus on the CMA CDS series because Mayordomo et al. (2014) find that CMA database quotes lead the price discovery process relative to quotes provided by other databases including Markit, GFI, Reuters EOD and JP Morgan. CMA in turn collects data directly from the trading desks of buy-side CDS market participants. Note that the CMA series are no longer offered through Datastream after the 3rd quarter of 2010. This change does not affect our empirical analysis, as our sample of CDS trade initiations ends in 2009.

We identify 1,193 U.S. firms that have single-name CDS contracts traded between January 2002 and December 2009. The CDS sample ends in 2009 to facilitate computation of asymmetric timeliness of loss recognition after CDS trade initiation for all firms in the sample. For each of these firms, we identify the first fiscal year that the firm trades at least one US-dollar-denominated CDS contract. We merge these 1,193 firms with Compustat and CRSP to collect financial variables used in the subsequent empirical analyses.[11] After deleting financial firms and requiring all firms to have at least one observation during both pre- and post-CDS trade-initiation periods, we are left with 529 unique U.S. non-financial firms with required financial variables.

3.2. Matched control firms

The initiation of CDS contracts balances credit risk preferences between the protection seller and the protection buyer. In particular, firms' credit risk and growth opportunities potentially influence the demand and supply of CDS contracts (Ashcraft and Santos, 2009). To address this sample selection issue, we follow Ashcraft and Santos (2009) and implement the matched-sample design developed in the literature. Specifically, we augment the model in Ashcraft and Santos (2009) and estimate the following logistic model to predict the initiation of CDS trading (firm subscripts are suppressed for brevity):

$$\begin{aligned}\text{Prob}(\text{CDS}_t = 1) = \Phi(&\beta_0 + \beta_1 \text{INVESTMENT GRADE}_{t-1} + \beta_2 \text{RATING}_{t-1} + \beta_3 \text{LEV}_{t-1} + \beta_4 \text{PROFIT MARGIN}_{t-1} \\ &+ \beta_5 \text{SIZE}_{t-1} + \beta_6 \text{RETURN VOLATILITY}_{t-1} + \beta_7 \text{MB}_{t-1}) + \varepsilon_t \end{aligned} \tag{1}$$

where CDS is an indicator variable equal to one for firms with CDSs traded between 2002 and 2009, and zero otherwise. We include INVESTMENT GRADE, RATING, LEV, and PROFIT MARGIN to account for firms' credit risk. INVESTMENT GRADE is an indicator variable equal to one if a firm has an S&P credit rating above BB+, and zero otherwise. RATING is an indicator variable equal to one if a firm has an S&P credit rating, and zero otherwise.[12]

LEV is book leverage, equal to a firm's total debt (short-term debt plus long-term debt) scaled by total assets. PROFIT MARGIN is net income scaled by sales. We also include firm size (SIZE), return volatility (RETURN VOLATILITY), and market-to-book ratio (MB) to consider the effect of overall information environment and growth opportunities on the demand and supply of CDS contracts. SIZE is the natural logarithm of market value of equity. RETURN VOLATILITY is the standard

[10] Single-name CDS contract is one where there is just one reference entity. The reference entity can be any borrower, but is most often one of a few hundred widely traded companies (corporate or financials) or a handful of governments (sovereigns). The CDS contract that we are interested in is the single-name one where the reference entity is a corporation. In addition to the single-name CDSs, there are basket default swaps (BDSs), index CDSs, and funded CDSs (also called a credit-linked notes) etc.

[11] The 1,193 firms include multiple subsidiaries for the same parent holding firms. For such firms, we collect financial variables for the parent holding firms only when merging with the Compustat and CRSP databases.

[12] We have tested robustness to using an ordinal variable capturing the credit rating of the firm, in lieu of the indicator variables INVESTMENT GRADE and RATING. All our subsequent results are robust to this alternative specification of the first stage model.

Table 1
Logistic regression results on probability of CDS trade initiation.

Dependent variable = Prob(CDS = 1)			
Variable	Coeff. Est.		p-Value
Intercept	−6.485		< 0.001
INVESTMENT GRADE	0.691		< 0.001
RATING	1.356		< 0.003
LEV	1.476		< 0.001
PROFIT MARGIN	0.106		< 0.001
SIZE	0.439		< 0.001
RETURN VOLATILITY	−2.201		< 0.001
MB	0.023		0.331
Pseudo R^2		0.46	
Model significance	1,940.55		< 0.001
Likelihood ratio	21,145.97		< 0.001
Percent concordant		91.50%	
Percent discordant		8.11%	
Number of firm-years		138735	

This table reports coefficient estimates from estimating a logistic model to predict the onset of credit default swap (CDS) trading. The dependent variable, CDS, is equal to 1 if a CDS is traded on a firm, and 0 otherwise. Independent variables include INVEST GRADE, an indicator variable equal to 1 if a firm has a S&P credit rating above BB+, and 0 otherwise; RATING, an indicator variable equal to 1 if a firm has a S&P credit rating, and 0 otherwise; SIZE, natural logarithm of market value; MB, the ratio of market value of equity to book value of equity; LEV, leverage equal to total debt scaled by total assets; PROFIT MARGIN is net income scaled by sales; RETURN VOLATILITY is standard deviation of monthly stock return within a fiscal year. The sample period spans 1997–2009, containing firms without CDS traded and firms with CDS traded during this period. For firms with CDS traded, only firm-years prior to the onset of CDS trading are included in the sample. Robust standard errors are estimated and are clustered at the firm level.

deviation of monthly stock return within a fiscal year, and MB is the ratio of market value of equity to book value of equity. We use all Compustat firms with available information during the period 1997–2009.[13]

Table 1 reports regression results of estimating Eq. (1). As shown, the model specified in Eq. (1) predicts the onset of CDS trading well, as evidenced by good model fit, high proportion of concordant pairs (91.5%) and low proportion of discordant pair (8.1%). The results indicate that firms with higher credit rating, leverage, profit margin and market cap, along with lower stock return volatility are more likely to have CDS trade initiation during the sample period. These findings are generally in line with an adverse selection explanation: given banks (potential protection buyers) possess superior private information about the debt instruments that they originated, the protection seller is more likely to offer CDS contracts for firms with less credit risk (firms with higher credit rating and higher profit margin) and a more transparent information environment (larger firms). The positive relation between leverage and the likelihood of CDS trade initiation suggests greater market demand of credit risk protection (via CDS contracts) for high-leverage firms.

Next, we utilize a matching procedure to construct a control sample of non-CDS firms (i.e., firms with no CDSs trade during the sample period). Specifically, based on the estimation results of Eq. (1), we obtain the estimated likelihood of CDS trade initiation for all Compustat firms. For each CDS firm (i.e., firms with a CDS trade during the sample period), we identify three non-CDS firms within the CDS firm's two-digit SIC industry that have the closest estimated likelihood to the CDS firm. The comparison of estimated likelihoods is made in the fiscal year prior to the year of CDS-trade-initiation.[14] We allow the same non-CDS firm to be matched to multiple CDS firms to minimize the distance in their estimated probability of CDS trade initiation.[15] However, once assigned as a match, a control (i.e., non-CDS) firm enters the sample only once every year, even if it serves as a match for more than one treatment (i.e., CDS) firm; thus, every control firm-year observation is unique. The matched-sample design generates 525 unique non-CDS-firm matches for the 529 CDS firms.

3.3. Descriptive statistics

Table 2 Panel A presents the sample distribution based on the CDS-trade-initiation year for the CDS sample and the matched non-CDS sample. The year 2004 witnessed the largest number of firms with CDS trade initiation (297 firms, or 56.1% of the CDS sample). The number of CDS trade initiations quickly declined afterwards for two reasons. First, since we select only the first traded CDS contract for each underlying firm, by construction we will observe a decline in the number of

[13] Our results are robust to setting the initial year of prediction to 2002, that is, the year of the first CDS trade initiation in our sample (and using corresponding explanatory variables from 2001) and therefore estimating the model parameters over 2001–2009.

[14] Our process of identifying more than one matching non-CDS firm for every CDS firm is similar to that in Lee (1997) and Chen and Martin (2011).

[15] We limit the distance in their estimated probability of CDS trade initiation to within 20% points. As a result, some CDS firms may have fewer than three matching non-CDS firms.

Table 2
Sample distribution.

Panel A: Sample distribution by CDS onset year for both CDS and non-CDS firms

	CDS		Non-CDS	
Year	*N*	%	*N*	%
2002	1	0.19	2	0.38
2003	128	24.2	237	45.14
2004	297	56.14	184	35.05
2005	41	7.75	32	6.1
2006	13	2.46	17	3.24
2007	41	7.75	43	8.19
2008	3	0.57	5	0.95
2009	5	0.95	5	0.95
Total	529	100	525	100

Panel B: Sample distribution by industry

	CDS		Non-CDS	
Industry (based on 1-digit SIC)	*N*	%	*N*	%
Mining, mineral and construction	57	10.78	40	7.62
Food, apparel, petroleum refining, and paper and printing	122	23.06	113	21.52
Rubber, stone, computer, transportation equipment	125	23.63	130	24.76
Railroad transportation and electric and gas	107	20.23	121	23.05
Retail and wholesale	55	10.40	51	9.72
Business service	47	8.88	55	10.47
Public service	13	2.46	12	2.28
Government service	3	0.57	3	0.58
Total	529	100	525	100

This table reports sample distribution by the CDS onset year in Panel A and by industry in Panel B, for both CDS firms and their matched firms (Non-CDS). For the match firms, the CDS onset year is assumed from their matched CDS firms.

Table 3
Summary statistics.

Panel A: Pre-CDS trading period

	CDS		Non-CDS		Mean diff
Variable	Mean	Median	Mean	Median	
EPS	0.033	0.055	0.023	0.050	0.010*
R	0.178	0.153	0.186	0.153	−0.008
D	0.273	0.000	0.293	0.000	−0.021
SIZE	8.849	8.770	8.123	7.969	0.726***
MB	1.142	0.884	1.240	0.920	−0.099**
LEV	0.297	0.268	0.291	0.270	0.005

Panel B: Post-CDS trading period

	CDS		Non-CDS		Mean diff
Variable	Mean	Median	Mean	Median	
EPS	−0.007	0.042	−0.010	0.038	0.003
R	0.093	0.057	0.094	0.059	−0.001
D	0.429	0.000	0.432	0.000	−0.003
SIZE	8.424	8.307	7.627	7.480	0.798***
MB	1.112	0.786	1.333	0.817	−0.221***
LEV	0.328	0.309	0.325	0.308	0.003

This table reports sample mean and median for main variables in the empirical analysis for both CDS firms and their matching firms (non-CDS) for both pre-CDS onset period and post-CDS onset period. The pre-CDS onset period covers two years prior to the onset of CDS and the post-CDS onset period covers two years after the onset of CDS. For non-CDS firms, the onset year is assumed from their matching firms. The sample period spans 2000–2011. EPS is net income scaled by prior year market value of equity; *R* is 12 month compounded returns starting 9 months before the fiscal year end. *D* is an indicator variable coded 1 if *R* is less than 0, and 0 otherwise. SIZE, natural logarithm of market value; MB, the ratio of market value of equity to book value of equity; LEV, leverage equal to total debt scaled by total assets.

Table 4
Pearson and Spearman correlations between selected variables.

	Variables	(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)

(8)	POST	**0.16**	**0.13**	**−0.15**	**0.14**	**0.08**	**−0.09**	**−0.05**	1.00

This table reports Pearson (above diagonal) and Spearman (below diagonal) corrections among variables used in the empirical analysis. The sample period spans 2000–2011. EPS is net income scaled by prior year market value of equity; *R* is 12 month compounded returns starting 9 months before the fiscal year end. *D* is an indicator variable coded 1 if *R* is less than 0, and 0 otherwise. SIZE is natural logarithm of market value of a firm; MB is market value of equity to book value of equity of a firm; LEV is leverage equal to total debt scaled by total assets; CDS is an indicator variable equal to 1 if a firm has a CDS traded over the sample period. POST is an indicator variable equal to 1 if a year falls in the two years after the onset of CDS trading, and 0 if a year falls in the two years before the onset of CDS trading for CDS firms. The match firms take on the same value of POST as the matched CDS firms in the pre- and post-CDS-trade-initiation year, respectively. Bold figures indicate significant level less than 1%.

CDS trade initiation over time. Second, the drastic decline may also foreshadow the looming financial crisis—by the end of 2008, CDS trades were initiated on only 3 new firms (0.6% of the CDS sample). By construction, we observe similar distribution for non-CDS firms. Table 2 Panel B reports the sample distribution by industry. As shown, CDS firms are primarily concentrated in the rubber, stone, computer, and transportation equipment industries (23.6% of the CDS sample). In addition, 23.1% of all CDS firms belong to the food, apparel, petroleum refining, and paper and printing industries, while 20.2% belong to the railroad transportation and electric and gas industries.

Table 3 reports descriptive statistics of variables used in subsequent analyses across the CDS sample and the matched non-CDS sample. The two samples exhibit characteristics that are generally similar in economic magnitudes. However, there are a few statistically significant differences between the two samples. During the two-year period prior to CDS trading, CDS firms have slightly better earnings performance. In addition, CDS firms are significantly larger in market capitalization and exhibit lower growth potential (lower MB).[16] The differences in firm size and growth between CDS firms and non-CDS firms are similar during the two-year period *after* the onset of CDS trading, although earnings performance becomes statistically similar between these two groups of firms. The similar magnitudes of differences between firm characteristics across CDS and non-CDS firms in Panels A and B suggest that these characteristics are unlikely to be driving the increasing difference in conservatism between CDS and non-CDS firms as one moves from Panel A to Panel B.

We report Pearson and Spearman correlations among variables used in our empirical tests in Table 4. As shown in Column (7), the correlations between CDS (an indicator variable equal to one for CDS firms, and zero for non-CDS firms) and earnings performance, firm size, growth, and leverage confirm the univariate patterns observed in Table 3.

4. Empirical methodology

4.1. Measurement of accounting conservatism

The aspect of conservatism we are interested in is the asymmetric timeliness of earnings in recognizing losses versus gains. We measure conservatism following Basu (1997), that is, the greater timeliness of earnings with respect to negative returns relative to positive returns. In particular, we estimate the following pooled cross-sectional model with standard errors clustered at the firm level (firm subscripts are suppressed for brevity):

$$EPS_t = \beta_0 + \beta_1 D_t + \beta_2 R_t + \beta_3 D_t \times R_t + \varepsilon_t \tag{2}$$

where EPS is net income for fiscal year t scaled by year-beginning market value of equity; *R* is the 12-month compound stock returns ending three months after the end of fiscal year t; *D* is a indicator variable equal to one if *R* is negative, and zero otherwise.

In the above model, the sensitivity of earnings to economic gains is captured by β_2 and the sensitivity of earnings to economic losses is captured by $(\beta_2 + \beta_3)$. If verification standards imposed for recognizing losses are lower than those imposed for recognizing gains, earnings will recognize economic losses in a timelier manner than economic gains. Hence, the association between earnings and stock returns should be incrementally higher when stock returns are negative, i.e., $\beta_3 > 0$ (Basu, 1997). We thus use β_3 to measure the extent to which earnings are reported conservatively. In the robustness tests, we also use Basu (1997)'s earnings time-series model to measure asymmetric timeliness of loss recognition.

[16] The probability-score-match controls only for the extent to which a combination of these firm characteristics (SIZE, MB, LEV) contribute to the probability of CDS trade initiation, rather than the individual characteristics.

4.2. Research design

We use the difference-in-difference method in all empirical tests. Specifically, to examine the influence of CDS trade initiation on accounting conservatism, we expand Basu's (1997) baseline model as specified in Eq. (2) by including two indicator variables: the first identifies whether a firm has at least one CDS traded over the sample period and the second captures whether a firm-year observation falls in the two-year period after CDS trade initiation. We estimate the following model using ordinary least square regression:

$$\begin{aligned}\mathrm{EPS_t} = {} & \beta_0+\beta_1 R_t+\beta_2 D_t+\beta_3 D_t\times R_t+\beta_4\mathrm{CDS}+\beta_5\mathrm{CDS}\times R_t\\ & +\beta_6\mathrm{CDS}\times D_t+\beta_7\mathrm{CDS}\times D_t\times R_t+\beta_8\mathrm{POST}+\beta_9\mathrm{POST}\times R_t\\ & +\beta_{10}\mathrm{POST}\times D_t+\beta_{11}\mathrm{POST}\times D_t\times R_t+\beta_{12}\mathrm{CDS}\times\mathrm{POST}\\ & +\beta_{13}\mathrm{CDS}\times\mathrm{POST}\times R_t+\beta_{14}\mathrm{CDS}\times\mathrm{POST}\times D_t\\ & +\boldsymbol{\beta}_{15}\mathbf{CDS}\times\mathbf{POST}\times\mathbf{D_t}\times\mathbf{R_t}+\sum_{j=1}^{N}\lambda_j\mathrm{ADDITIONAL\ CONTROLS_j}\\ & +\sum_{i=1}^{K}\gamma_i\mathrm{INDUSTRY_i}+\sum_{m=1}^{N}\delta_m\mathrm{YEAR}_m+\varepsilon_t\end{aligned} \tag{3}$$

where CDS is an indicator variable equal to one for firms with a CDS traded during the sample period, and zero for matched control firms. POST is an indicator variable equal to one (zero) if an observation falls in the two-year period following (preceding) CDS trade initiation for both the CDS firm and its matched control firms. Since sample CDS trade initiations span 2002 to 2009, the examination of change in conservatism from two years before to two years after CDS trade initiation implies that the overall period of our analysis extends from 2000 to 2011. Industry and year fixed effects are included. Standard errors are clustered at the firm level to account for serial correlation within a firm (Petersen, 2009).[17] All the other variables are as defined in Eq. (2). To ensure that the results are not entirely driven by matched control firms, we also estimate Eq. (3) for CDS firms only (thereby dropping all terms relating to the indicator variable CDS).

Prior studies suggest that firm size, market-to-book ratio, and leverage may affect accounting conservatism (e.g., Basu, 1997; LaFond and Roychowdhury, 2008; LaFond and Watts, 2008). Therefore, we include these firm characteristics and their interactions with the three terms in Basu's (1997) model in Eq. (3) as additional control variables.

Our primary interest is the effect of CDS trade initiation on asymmetric timeliness of loss recognition (H1). Hence, we test whether the coefficient β_{15}, which captures the change in accounting conservatism of CDS firms relative to their matched firms, is significantly different from zero.

5. Empirical results

5.1. Primary tests

Table 5 reports regression results on the change in asymmetric loss recognition timeliness around the onset of CDS trading. The first two columns of Table 5 summarize results of estimating Eq. (3). As shown, the coefficient on $D\times R$ is significantly positive (coefficient=1.216, p-value <0.001), suggesting that non-CDS firms are more timely in recognizing economic losses than economic gains in the two-year period prior to CDS trading. The coefficient on CDS $\times D\times R$, which captures the difference in conservatism between CDS and non-CDS firms prior to the initiation of CDS trading, is positive and statistically significant (coefficient=0.231, p-value=0.015). Hence, prior to CDS trading, CDS firms exhibit higher levels of accounting conservatism than their matched non-CDS firms.

Comparing the pre-trading period with the post-trading period, non-CDS firms appear to have no change in the timeliness of recognizing economic losses in the two-year period after CDS trading, as evidenced by the statistically insignificant coefficient on POST $\times D\times R$ (coefficient $=-0.012$, p-value=0.884). Importantly, we find a significantly negative coefficient on CDS × POST $\times D\times R$ (coefficient $=-0.295$, p-value=0.036), suggesting that relative to matched control firms, CDS firms reduce asymmetric timeliness in loss recognition after the onset of CDS trading. The combined coefficient on CDS × POST $\times R$ and CDS × POST $\times D\times R$ (-0.254) is significantly negative, indicating that CDS firms also experience a significant decline in overall (and not just asymmetric) timeliness of loss recognition after CDS trade initiation compared to their match firms. These findings reject the null and support the notion that CDS firms experience a decline in accounting conservatism around the initial years of CDS trading. Economically, the incremental decline in asymmetric timeliness for CDS firms relative to non-CDS firms is about 20% of the accounting conservatism level of the CDS firms before the onset of CDS trading (=0.295/(1.216+0.231)).[18]

Next, we estimate Eq. (3) for CDS firms only to ensure that our findings are not driven by the change in accounting conservatism for matched control firms. We therefore exclude all terms related with the indicator variable CDS and control

[17] Results are quantitatively similar if we cluster the standard errors at the year and two-digit SIC industry levels.

[18] This decline of 20.3% represents a net amount, inclusive of a 21.2% decline in the conservatism of CDS firms around CDS trade initiation. The matched non-CDS firms exhibit a (statistically insignificant) decline of 0.09% in their conservatism around the pseudo-CDS-trade-initiation dates assigned to them. For a comparison of magnitudes, Ettredge et al. (2012) findings imply a 46% increase in asymmetric timeliness of earnings following earnings restatements.

This table reports multivariate regression results on the relation between Basu's (1997) measure of asymmetric loss recognition timeliness and the onset of CDS trading. The sample period spans 2000–2011. Firms in financial industries are excluded. The dependent variable is EPS, defined as net income scaled by prior year's market value of equity. *R* is twelve-month buy-and-hold returns starting nine months before the fiscal year end. *D* is an indicator variable equal to one if *R* is negative, and zero otherwise. CDS is an indicator variable equal to one if a firm has a CDS contract traded over the sample period, and zero for matched control firms. The control sample is chosen based on the matched-sample design, using the estimated probability of CDS trade initiation as described in Table 1. POST is an indicator variable equal to one if a year falls in the two-year period after the CDS-trade-initiation year, and zero if a year falls in the two-year period prior to the CDS-trade-initiation year for CDS firms. The match control firms take on the same value of POST as the matched CDS firms in the pre- and post-CDS-trade-initiation year, respectively. Additional controls include firm size, market-to-book ratio, book leverage, and their corresponding interaction terms with *R*, *D*, and *D* × *R*. Year and industry fixed effects are included. *P*-values are derived based on robust standard errors clustered at the firm level.

for several firm attributes that may affect accounting conservatism. The last two columns of Panel A report the results. We find that the coefficient on POST × *D* × *R* is significantly negative, supporting the notion that CDS firms experience a decline in accounting conservatism after the onset of CDS trading.

Taken together, results presented in Table 5 suggest that regardless of whether CDS firms are benchmarked with matched control firms or are used as their own controls, they become less asymmetric timely in reporting economic losses after the onset of CDS trading. Thus, CDS trade initiation has a net negative effect on accounting conservatism of borrowing firms.

5.2. Cross-sectional tests

5.2.1. The role of reputation costs

To test H2, we examine whether the change in accounting conservatism around CDS trading initiation varies with firm size, and credit rating. We partition our sample of treatment and control firm-years into two groups based on size and credit rating and estimate Eq. (3) within each subsample.

Table 6, Panel A presents results for two sub-samples partitioned based on size – specifically, firms below median market value of equity and those above. As shown, the coefficient on CDS × POST × *D* × *R* is significantly negative for firms with below median market value (coefficient = −0.518, *p*-value = 0.005), but insignificant for firms with above median market value (coefficient = 0.132, *p*-value = 0.544). An *F*-test of the statistical difference in this coefficient estimate across these two subsamples yields a *p*-value of 0.037.

Panel B presents results for two sub-samples partitioned based on S&P long-term credit rating – specifically, firms below investment-grade rating and those above. We find that the coefficient on CDS × POST × *D* × *R* is significantly negative for firms with below investment grade ratings (coefficient = −0.377, *p*-value = 0.023). We observe a smaller and insignificant

This table reports cross-sectional analysis of firm size, credit rating, and the common factor constructed based on the former two variables on the relation between asymmetric timely loss recognition and the onset of CDS trading. The sample period spans 2000–2011. Firms in financial industries are excluded. The dependent variable is EPS, defined as net income scaled by prior year's market value of equity. In Panel A, the sample is partitioned into large firms and small firms based on the full sample median market value of equity prior to the year of CDS onset. In Panel B, the sample is partitioned into firms with investment-grade credit rating and firms without investment-grade credit rating prior to the year of CDS onset. In Panel C, the sample is partitioned into high lender reputation and low lender reputation based on the full sample median lender reputation factor. Lender reputation factor is derived from the principal component analysis based on the two variables: natural logarithm of firm market value of equity and long-term S&P credit rating. Credit rating is defined by an ordinal variable ranging between 1 (AAA) and 19 (CCC-) for firms with S&P long term debt rating; we assign a value of 20 for firms in default stage, and 21 for firms with no debt rating. R is twelve-month buy-and-hold returns starting nine months before the fiscal year end. D is an indicator variable equal to one if R is negative, and zero otherwise. CDS is an indicator variable equal to one if a firm has a CDS contract traded over the sample period, and zero for matched control firms. The control sample is chosen based on the matched-sample design, using the estimated probability of CDS trade initiation as described in Table 1. POST is an indicator variable equal to one if a year falls in the two-year period after the CDS-trade-initiation year, and zero if a year falls in the two-year period prior to the CDS-trade-initiation year for CDS firms. The match control firms take on the same value of POST as the matched CDS firms in the pre- and post-CDS-trade-initiation year, respectively. Additional controls include firm size, market-to-book ratio, book leverage, and their corresponding interaction terms with R, D, and $D \times R$. Year and industry fixed effects are included. P-values are derived based on robust standard errors clustered at the firm level.

decline in conservatism for firms with credit rating above investment grade (coefficient = −0.089, p-value = 0.603). The difference in the decline in conservatism between the two groups is significant at the 10% level.

In Panel C we construct a common factor, Reputation Factor, based on both firm size and credit rating using principle-components. Size is defined as natural logarithm of market value of equity. Credit rating is defined by an ordinal variable ranging between 1 (AAA) and 19 (CCC-) for firms with S&P long term debt rating; we assign a value of 20 for firms in default stage, and 21 for firms with no debt rating. The common factor thus captures the contribution of both size and credit rating to ex ante risk of borrower default, which is expected to be associated negatively with lenders' incentives to maintain post-CDS monitoring out of concern for reputation costs. As constructed, Reputation Factor varies positively with size and negatively with credit rating. We partition the sample based on whether the value of Reputation Factor for a particular firm-year is above or below the median value for that year. The results show that the coefficient on CDS × POST × $D \times R$ is significantly negative for firms with low Reputation Factor (coefficient = −0.585, p-value < 0.005), but insignificant for firms with high Reputation Factor (coefficient = 0.177, p-value = 0.478). An F-test of the statistical difference in this coefficient estimate across these two subsamples yields a p-value of 0.014. The decline in conservatism for CDS firms when their lenders are likely to bear lower reputation costs is about 35% of their conservatism level in the pre-CDS period (= (−0.585 + 0.024)/(0.342 + 1.241)).

The results in Panels A, B and C collectively indicate that the post-CDS decline in borrower conservatism is more pronounced when banks entering into CDS contracts face lower reputation costs (as in borrowers with smaller size and

This table reports cross-sectional analysis based on financial covenants in loan contracts to the firms in our sample. The sample period spans 2000 to 2011. Banks lending to CDS and non-CDS firms in the sample are identified using data obtained from the LPC (Loan Pricing Corporation)'s Dealscan database. Loan contracts that are outstanding at least two years prior to the CDS trade initiation date but mature at least two years after that date are identified from the LPC database. Among all loans outstanding, the number of financial covenants is measured for the loan with the maximum number of financial covenants in the year prior to the onset of CDS trading. The sample is partitioned into more (few) covenants groups in which firms have loans contracts outstanding with the number of financial covenants exceeding 3 (below 2). The dependent variable is EPS, defined as net income scaled by prior year's market value of equity. *R* is twelve-month buy-and-hold returns starting nine months before the fiscal year end. *D* is an indicator variable equal to one if *R* is negative, and zero otherwise. CDS is an indicator variable equal to one if a firm has a CDS contract traded over the sample period, and zero for matched control firms. POST is an indicator variable equal to one if a year falls in the two-year period after the CDS-trade-initiation year, and zero if a year falls in the two-year period prior to the CDS-trade-initiation year for CDS firms. The match control firms take on the same value of POST as the matched CDS firms in the pre- and post-CDS-trade-initiation year, respectively. Additional controls include firm size, market-to-book ratio, book leverage, and their corresponding interaction terms with *R*, *D*, and $D \times R$. Year and industry fixed effects are included. *p*-Values are derived based on robust standard errors clustered at the firm level.

poorer credit ratings) from reducing monitoring. We do not observe any evidence of a decline in conservatism among larger firms with higher credit ratings, suggesting either lenders do not reduce their demand for conservatism among such firms or borrowers maintain their consistency with respect to conservative accounting practices (presumably to satisfy the demands of other stakeholders).

5.2.2. *The role of covenants*

In examining the role of covenants (H3), we first identify the number of financial covenants in firms' private debt contracts from the LPC (Loan Pricing Corporation)'s Dealscan database. Due to data availability requirements, we are left with a smaller sample size of 3,074 firm-years containing 417 unique CDS firms and 317 unique matched non-CDS firms. We next identify all loan contracts outstanding in the fiscal year *prior* to CDS trade initiation and maturing *after* CDS trade initiation. Among these loan contracts, we consider the one with the maximum number of financial covenants because this number likely represents the binding covenant intensity. Subsequently we partition the sample based on whether the number of loan covenants exceeds the sample top quartile (i.e., number of covenants > 3) or whether that number is below the bottom quartile (i.e., number of covenants < 2). Table 7 reports results for this partition. Firms exhibit a much more prominent decline in conservatism when the number of financial covenants in existing loan contracts at the time of the CDS trade initiation is above the 75th percentile. From an economic perspective, the accounting conservatism of CDS firms declines about 45% relative to their pre-CDS trade initiation period. When the number of financial covenants in existing loan contracts at the time of the CDS is below the 25th percentile, firms do not exhibit a significant decline in conservatism.

5.3. The issue of lender identity

We first identify banks with outstanding loans to the CDS firms and the matched control firms in our sample. The partial effect for a bank of investing in a CDS contract on a borrower would be to lower the risk weight assigned to the loan on that borrower and to increase the bank's CDS holdings.[19] However, it is difficult to observe the effect of a CDS contract on a single borrower on the bank's risk-weighted assets or on its CDS portfolio. Therefore, we employ a reverse approach. For each bank, we can observe whether there is a change in the proportion of total assets bearing a risk weight lower than 100% in a given year, and also whether their overall CDS holdings increases/decreases in any given year. We reason that banks for whom the proportion of assets weighted at lower than 100% rises, or banks that exhibit an increase in overall CDS holdings, *in the same year as* CDS trade initiation on an underlying borrower are more likely to have hedged their exposure to the specific borrower via the newly available CDS contracts.

Table 8 presents results of testing H4. In Panel A we present results for two sub-samples partitioned based on whether there was an increase in the proportion of banks' assets risk-weighted at lower than 100% in the same year as CDS trade initiation. We identify banks lending to CDS and non-CDS firms in our sample using data obtained from the LPC (Loan Pricing Corporation) Dealscan database, and the risk weights on banks' assets from Federal Reserve's Y-9C reports. We find that the coefficient on $\text{CDS} \times \text{POST} \times D \times R$ is significantly negative for firms whose banks exhibit an increase in the proportion of assets that bear risk weights lower than 100% (coefficient$=-0.452$, p-value$=0.003$), but is actually positive and statistically significant for firms whose banks do not exhibit an increase in the proportion of assets that bear risk weights lower than 100% (coefficient$=0.286$, p-value$=0.028$). An F-test of the statistical difference in this coefficient estimate across these two subsamples yields a p-value of 0.003.

Table 8, Panel B presents results for two sub-samples partitioned on whether banks exhibit an increase in CDS portfolio holdings in the same year as CDS trade initiation on underlying borrowers. CDS portfolio holdings of banks are obtained from Federal Reserve's Y-9C reports. As shown, the coefficient on $\text{CDS} \times \text{POST} \times D \times R$ is significantly negative for firms whose banks exhibit an increase in CDS holdings in the year of CDS trade initiation (coefficient$=-1.020$, p-value$=0.000$), but insignificant for firms whose banks do not exhibit an increase in CDS holdings (coefficient$=-0.113$, p-value$=0.310$). An F-test of the statistical difference in this coefficient estimate across these two subsamples yields a p-value of 0.100.

Finally, Panel C presents results based on identifying firms whose banks exhibit either an increase in the proportion of assets bearing risk weights below 100% or an increase in CDS holdings. We find that the coefficient on $\text{CDS} \times \text{POST} \times D \times R$ is significantly negative when either condition is satisfied (coefficient$=-0.522$, p-value$=0.000$). Economically, the decline in conservatism for CDS firms when their lenders are likely to enter into CDS contracts for hedging is about 27% of their conservatism level in the pre-CDS period ($=(-0.522+0.022)/(0.245+1.584)$). In contrast, the conservatism level for CDS firms relative to their counterparts when lenders unlikely enter into CDS contracts actually increases significantly in the post-CDS period relative to matched control firms (coefficient$=0.437$, p-value$=0.003$). This may be evidence of a selection bias: banks that do not hedge their exposures to underlying borrowers even when CDS contracts are available are likely to be the ones that intend to increase their monitoring of borrowers' financial statements. An F-test of the statistical difference in this coefficient estimate across the two subsamples yields a p-value below 0.000 (rounded).[20]

We conduct a variety of tests to check the robustness of our results. First, we modify the first-stage prediction model following Minton et al. (2009), to incorporate bank propensity to invest in derivative securities, including interest rate, foreign exchange, equity and commodity derivatives. The findings we obtain in Tables 5–7 with respect to both our primary and cross-sectional hypotheses are robust to using this first stage model. Second, we identify as matched control firms the *two* rather than the three nearest neighbors (with replacement) within 20% of the CDS-trade-initiation probability score for each treatment firm. We also modify the thresholds to include control firms within 5% rather than 20% of the treatment firm's CDS-trade-initiation probability score. Finally, we use a *one year* window rather than a two-year window for the pre- and post-CDS-trade-initiation analysis. The results (untabulated) are robust to all these alternative procedures.

5.4. Additional analysis

5.4.1. Endogeneity between expected change in conservatism and CDS trade initiation

In our final analysis, we examine the possibility that CDS trade initiation is more likely when lenders anticipate a decline in borrower conservatism. While existing literature does not raise this possibility, it has a testable empirical prediction: a negative association between *expected* change in conservatism and CDS trade initiation. Note that in our primary tests, we

[19] Loans to corporate entities are assigned a risk weight between 20% and 150% under the standardized approach to credit risk. The risk weight declines if the bank is hedged on its exposure to a specific borrower via CDS contracts if the credit rating of the CDS sellers is higher than that of the borrower. According to Basel II, a risk weight of 150% is assigned to loans rated below BB-, 100% to loans rated above BB- but below AA-, and 20% for loans with CDS protection where CDS sellers are rating above AA-.

[20] We repeat all our cross-sectional analyses in Section 5.2 within the sample of firms that are likely to have hedged their credit exposures via CDSs (that is, firms whose banks exhibit either an increase in the proportion of assets bearing risk weights below 100% or an increase in CDS holdings). The results on cross-sectional variation obtained in Tables 6 and 7 are robust to using this sub-sample; that is, we find a more pronounced decline in conservatism (a) when borrowers are risky and informationally opaque ex ante, and (b) when borrowers' debt contracts outstanding at the time of CDS trade initiation include a larger number of financial covenants.

This table reports cross-sectional analysis of characteristics of banks lending to the firms in our sample. The sample period spans 2000–2011. Firms in financial industries are excluded. The dependent variable is EPS, defined as net income scaled by prior year's market value of equity. Panel A presents results for two sub-samples partitioned on whether there was an increase in the proportion of banks' assets risk-weighted at lower than 100% relative to total bank assets in the same year as CDS trade initiation. Banks lending to CDS and non-CDS firms in the sample are identified using data obtained from the LPC (Loan Pricing Corporation)'s Dealscan database, and the risk weights on banks' assets are from Federal Reserve's Y-9C reports. Panel B presents results for two sub-samples partitioned based on whether banks exhibit an increase in CDS portfolio holdings in the same year as CDS trade initiation on underlying borrowers. CDS portfolio holdings of banks are obtained from Federal Reserve's Y-9C reports. Panel C presents for situations in which either the conditions in Panel A or Panel B hold. In other words, banks exhibit an increase in either lower-risk-weighted assets or an increase in CDS portfolio holdings. *R* is twelve-month buy-and-hold returns starting nine months before the fiscal year end. *D* is an indicator variable equal to one if *R* is negative, and zero otherwise. CDS is an indicator variable equal to one if a firm has a CDS contract traded over the sample period, and zero for matched control firms. The control sample is chosen based on the matched-sample design, using the estimated probability of CDS trade initiation as described in Table 1. POST is an indicator variable equal to one if a year falls in the two-year period after the CDS-trade-initiation year, and zero if a year falls in the two-year period prior to the CDS-trade-initiation year for CDS firms. The matched control firms take on the same value of POST as the CDS firms in the pre- and post-CDS-trade-initiation year, respectively. Additional controls include firm size, market-to-book ratio, book leverage, and their corresponding interaction terms with *R*, *D*, and $D \times R$. Year and industry fixed effects are included. *p*-Values are derived based on robust standard errors clustered at the firm level.

are interested in whether there is an actual *ex post* decline in conservatism after CDS trade initiation as lenders lower monitoring of financial statements. Key to distinguishing between the two possibilities is the measurement of, and the imposition of a control for, expected change in conservatism. Accordingly, we modify our empirical research design to match control firms to treatment firms based on expected change in conservatism.

To accommodate the cross-sectional nature of our conservatism measure, we develop a novel approach for measuring expected change in conservatism. Khan and Watts (2009) demonstrate that the asymmetric timeliness of earnings (i.e., the Basu measure) varies monotonically across deciles of CSCORE, a firm-specific measure of conservatism. We partition firms in the Compustat universe into quintiles of CSCORE in the year prior to CDS trade initiation, that is, year $t-1$ (where year t is the year of CDS trade initiation). We then estimate the cross-sectional Basu measure within each of these quintiles and assign the corresponding asymmetric timeliness coefficient to all firms in that quintile. Holding quintile membership constant, we measure the cross-sectional Basu measure for year $t+1$, that is, the year after CDS trade initiation. The actual change in the asymmetric timeliness coefficient for the CSCORE quintile from year $t-1$ to $t+1$ serves as a proxy for the expected change in conservatism for every firm within that quintile. Thereafter, we augment our first stage model with expected change in conservatism.

The association between CDS trade initiation and expected change in conservatism is significantly negative. Note that our measure of expected conservatism suffers from hindsight bias, since it relies on actual change in conservatism measured *ex post*. Therefore, caution is warranted in interpreting the negative association observed in the first stage as a causal relation between expected conservatism change and CDS trade initiation. This potentially reduces the power of our second-stage regression to detect an actual change in conservatism for CDS firms. Upon matching on the CDS trading probability score from the modified first stage model, we detect no difference in *expected* change in conservatism between matched and control firms. In the second stage, we still observe an actual decline in conservatism among CDS firms upon CDS trade initiation, with this decline being much more pronounced relative to the matched non-CDS firms identified earlier, as shown in Table 9.[21]

[21] The sample size reduces slightly due to the enhanced data requirements for estimating our first stage model, which adversely influences the extent to which we can find matches for CDS firms.

Table 9
Robustness analysis – change in conservatism included in the first stage model.

This table reports regression results on the relation between Basu's (1997) measure of asymmetric loss recognition timeliness and the onset of CDS trading based on a first stage model that includes expected change in asymmetric loss recognition timeliness from one year before to one year after the onset of CDS trading. For computing expected change in asymmetric timeliness, firms in Compustat are sorted into quintiles each fiscal year based on CSCORE, which in turn is computed following Khan and Watts (2009). For every firm-year, the change in the Basu coefficient from year -1 to year $+1$ for the CSCORE quintile the firm belongs to serves as that firm's expected change in conservatism. The sample period spans 2000–2011. The dependent variable is EPS, defined as net income scaled by prior year's market value of equity. R is twelve-month buy-and-hold returns starting nine months before the fiscal year end. D is an indicator variable equal to one if R is negative, and zero otherwise. CDS is an indicator variable equal to one if a firm has a CDS contract traded over the sample period, and zero for matched control firms. POST is an indicator variable equal to one if a year falls in the two-year period after the CDS-trade-initiation year, and zero if a year falls in the two-year period prior to the CDS-trade-initiation year for CDS firms. The matched control firms take on the same value of POST as the CDS firms in the pre- and post-CDS-trade-initiation year, respectively. Additional controls include firm size, market-to-book ratio, book leverage, and their corresponding interaction terms with R, D, and $D \times R$. Year and industry fixed effects are included. p-Values are derived based on robust standard errors clustered at the firm level.

5.4.2. Alternative control for selection bias in CDS trade initiation

The difference-in-difference research design used in our main analysis should mitigate the concern that our results are driven by firm characteristics that conceivably also determine CDS trade initiation. To further test the robustness of our analysis to an alternative specification, we use the Heckman two-stage procedure where the first stage models the probability of firms experiencing CDS trade initiations, and the second stage model includes the inverse mills ratio derived from the first stage to control for the selection bias. We estimate model (1) in the first stage; the second stage results are reported in column (1) Table 10. The coefficient on the inverse-mills ratio is positive, but statistically insignificant at conventional levels. The coefficient on POST $\times D_t \times R_t$ continues to be negative and statistically significant, with a p-value of 0.014. In addition, we expand the first stage model by including the expected change in accounting conservatism as discussed in the previous sub-section; the corresponding second stage results are presented in column (2). The coefficient on the inverse-mills ratio in this specification is significantly positive, indicating the presence of selection bias. Importantly, our results on a significant decline in borrower conservatism upon CDS trade initiation are robust to this alternative procedure of controlling for selection bias.

5.4.3. Robustness to using non-returns based measure of conservatism

CDS trade initiation potentially influences equity price changes (see for example Boehmer et al., forthcoming), and in turn can conceivably influence the returns-based Basu measure of conservatism. Note that the magnitude and even direction of this influence is not obvious, and it is unlikely that any influence of CDS trade initiation on stock prices can generate the collective evidence we report. Nevertheless, to check robustness to a non-returns-based measure of conservatism, we utilize an alternative measure of asymmetric loss recognition based on an earnings time-series model (Basu, 1997; Ball and Shivakumar, 2005). Specifically, we estimate the following equation using ordinary least square regression with standard errors clustered at the firm level based on the sample consisting of both CDS firms and matched

Table 10
Robustness analysis – Heckman two-stage tests.

This table reports the second-stage regression results on the relation between Basu's (1997) measure of asymmetric loss recognition timeliness and the onset of CDS trading using Heckman two-stage procedure with CDS firms only. In the first stage, the sample consists of 138,735 firm-year observations, the same sample in Table 1. In column (1), the first stage selection model includes all the explanatory variables used in the first stage model as shown in Table 1. In column (2), the first stage selection model includes all the explanatory variables used in the first stage model as shown in Table 1, as well as the expected change in asymmetric loss recognition timeliness between one year before and one year after CDS trade initiation. For computing expected change in asymmetric timeliness, firms in Compustat are sorted into quintiles each fiscal year based on CSCORE, which in turn is computed following Khan and Watts (2009). For every firm-year, the change in the Basu coefficient from year −1 to year +1 for the CSCORE quintile the firm belongs to serves as that firm's expected change in conservatism. The sample period spans 2000–2011. The dependent variable is EPS, defined as net income scaled by prior year's market value of equity. *R* is twelve-month buy-and-hold returns starting nine months before the fiscal year end. *D* is an indicator variable equal to one if *R* is negative, and zero otherwise. POST is an indicator variable equal to one if a year falls in the two-year period after the CDS-trade-initiation year, and zero if a year falls in the two-year period prior to the CDS-trade-initiation year. Additional controls include firm size, market-to-book ratio, book leverage, and their corresponding interaction terms with *R*, *D*, and $D \times R$. Year and industry fixed effects are included. *p*-Values are derived based on robust standard errors clustered at the firm level.

control firms.

$$\begin{aligned}\Delta E_t = {} & \gamma_0+\gamma_1\Delta E_{t-1}+\gamma_2 D_{t-1}+\gamma_3 D_{t-1}\times\Delta E_{t-1}\\ & +\gamma_4\text{CDS}+\gamma_5\text{CDS}\times\Delta E_{t-1}+\gamma_6\text{CDS}\times D_{t-1}+\gamma_7\text{CDS}\times D_{t-1}\times\Delta E_{t-1}\\ & +\gamma_8\text{POST}+\gamma_9\text{POST}\times\Delta E_{t-1}+\gamma_{10}\text{POST}\times D_{t-1}+\gamma_{11}\text{POST}\times D_{t-1}\times\Delta E_{t-1}\\ & +\gamma_{12}\text{CDS}\times\text{POST}+\gamma_{13}POST\times\text{CDS}\times\Delta E_{t-1}+\gamma_{14}\text{CDS}\times\text{POST}\times D_{t-1}\\ & +\boldsymbol{\gamma_{15}}\textbf{CDS}\times\textbf{POST}\times\mathbf{D}_{t-1}\times\boldsymbol{\Delta}\mathbf{E}_{t-1}+\sum_{j=1}^{N}\lambda_j\text{ADDITIONAL CONTROLS}_j\\ & +\sum_{i=1}^{K}\gamma_i\text{INDUSTRY}_i+\sum_{m=1}^{N}\delta_m\text{YEAR}_m+\varepsilon_t \end{aligned} \tag{4}$$

where ΔE_t is current year's earnings change, ΔE_{t-1} is previous year's earnings change, *D* is an indicator variable equal to one for previous earnings decline (i.e., $\Delta E_{t-1}<0$) and zero otherwise, and the other variables are as defined in Eq. (3). In the above equation, we allow earnings persistence to differ between earnings increase and earnings declines. More timely recognition of losses than gains implies that earnings increases are more persistent than earnings declines. Hence, a reduction of accounting conservatism around the CDS-trade-initiation year would require that the coefficient on $\text{CDS}\times\text{POST}\times D_{t-1}\times\Delta E_{t-1}$, γ_{15}, be significantly positive.

Results presented in Table 11 corroborate those presented in Table 5.[22] The coefficient on $\text{CDS}\times\text{POST}\times D_{t-1}\times\Delta E_{t-1}$ is significantly positive at the 5% level (coefficient = 1.308, *p*-value = 0.017), implying that reversals in earnings declines are less in the years following CDS trade initiation. Our finding reinforces the conclusion that CDS firms experience a decline in the asymmetric timeliness of loss recognition after the onset of CDS trading.

[22] There is a reduction in sample size, because we impose the requirement that for every year, enough data be available to compute earnings changes for the following year. Since CDS trade initiations span 2002 to 2009, the sample period for this test extends from 1999 to 2011, given that we require lagged data to estimate changes in the earnings time-series measure of conservatism.

Table 11
Non-returns based measure of conservatism.

Earnings time-series measure	Dependent variable = ΔEPS_t

Adjusted R^2 (%)	28.86	

This table reports multivariate regression results on the relation between an earnings time-series measure of asymmetric loss recognition timeliness and the onset of CDS trading. The sample period for this test spans 1999–2011. The period includes one extra year (1999) relative to Tables 5–10, due to the requirement of lagged data for estimation of the earnings-time-series-based measure of conservatism. Firms in financial industries are excluded. The dependent variable is ΔE_t, the change in annual earnings before extraordinary item, scaled by lagged total assets. D is an indicator variable equal to one if ΔE_{t-1} is negative, and zero otherwise. CDS is an indicator variable equal to one if a firm has a CDS contract traded over the sample period, and zero for matched control firms. The control sample is chosen based on the matched-sample design, using the estimated probability of CDS trade initiation as described in Table 1. POST is an indicator variable equal to one if a year falls in the three-year period after the CDS-trade-initiation year, and zero if a year falls in the three-year period prior to the CDS-trade-initiation year for CDS firms. The matched control firms take on the same value of POST as the CDS firms in the pre- and post-CDS-trade-initiation year, respectively. Additional controls include firm size, market-to-book ratio, book leverage, and their corresponding interaction terms with ΔE_{t-1}, D_{t-1}, and $D_{t-1} \times \Delta E_{t-1}$. Year and industry fixed effects are included. *p*-Values are based on robust standard errors clustered at the firm level.

6. Conclusion

Our paper provides evidence that the availability of CDS trades to a firm's lenders leads to a decline in that firm's reporting conservatism. Our findings are consistent with borrowers' incentives to report less conservatively after CDS trade initiation to avoid triggering violations, because they expect CDS-protected lenders to be less accommodating in renegotiations. Even in the presence of heightened incentives, borrowers would be constrained from reporting less conservatively if lenders were to maintain their monitoring. An actual decline in conservatism is thus also indicative of a slackening in lenders' post-CDS scrutiny of financial statements. The results thus imply that either (a) other stakeholders to the firm cannot replicate the monitoring by banks necessary to maintain borrowers' reporting conservatism and/or (b) that banks demand a level of conservatism higher than the equilibrium demand from other stakeholders.

It is possible that the lower reporting conservatism after CDS trade initiation encourages borrowers to also take actions that transfer wealth from debt-holders to shareholders via asset substitution, underinvestment, dividend overpayment, etc. In that sense, the structure of the CDS market during the sample period examined in this study may be off-equilibrium. On the other hand, the threat of more unfavorable renegotiations with lenders upon the occurrence of payment defaults, covenant violations and other credit events possibly disciplines borrowers *ex ante* from expanding attempts to transfer wealth from debt-holders. Thus, CDS availability potentially alters the lender–borrower relation to one that de-emphasizes continuous monitoring and financial reporting conservatism, and relies instead on the discipline imposed by the threat of lender inflexibility in renegotiations triggered by credit events. A thorough investigation into these possible scenarios following the onset of CDS trading is beyond the scope of this study, but can serve as a fertile area for future research.

Appendix A. The credit default swap contract

Credit default swaps are generally documented using industry-standard derivative master agreements and standard CDS terms. Unlike equity shares or bonds, which are traded primarily on regulated exchanges, CDS are traded mainly over-the-counter (OTC). In principle, therefore, the contracting parties can agree upon the terms and conditions of the CDS individually – such as definitions of the credit events or settlement procedures. In practice, to facilitate documentation, avoid disputes regarding the occurrence of credit events and settle contracts, CDS contracting parties generally refer to the International Swaps and Derivatives Association (ISDA) Master Agreement. These general terms and conditions – established by ISDA, the central industry body – were introduced in 1999 and have been continuously developed since then. A revised version of the agreement was released in 2003, while the latest amendments were made in 2009 (see Deutsche Bank Research, 2009).

A.1. Sample term sheet for a credit default swap (traded by XYZ Bank PLC)

Draft terms – credit default swap

1. General terms

Trade Date	Aug 5, 2003
Effective Date	Aug 6, 2003
Scheduled Termination Date	Jul 30, 2005
Floating Rate Payer ('Seller')	XYZ Bank plc, London branch
Fixed Rate Payer ('Buyer')	ABC Investment Bank plc
Calculation Agent	Seller
Calculation Agent City	New York
Business Day	New York
Business Day Convention	Following
Reference Entity	Jackfruit Records Corporation
Reference Obligation	Primary Obligor: Jackfruit Records
Maturity	Jun 30, 2020
Coupon	0%
CUSIP/ISIN	xxxxx
Original Issue Amount	USD 100,000,000
Reference Price	100%
All Guarantees	Not Applicable

2. Fixed payments

Fixed Rate Payer Calculation Amount	USD 7,000,000
Fixed Rate	0.3% per annum
Fixed Rate Payer Payment Date(s)	Oct 30, Jan 30, Apr 30, Jul 30, starting Oct 30, 2003
Fixed Rate Day Count Fraction	Actual/360

3. Floating payments

Floating Rate Payer Calculation Amount	USD 7,000,000
Conditions to Payment (Or Seller)	Credit Event Notice (Notifying Parties: Buyer Notice of Publicly Available Information: Applicable (Public Source: Standard Public Sources. Specified Number: Two)
Credit Events	Bankruptcy Failure to Pay (Grace Period Extension: Not Applicable. Payment Requirement: $1,000,000)
Obligation(s)	Borrowed money

4. Settlement terms

Settlement Method	Physical Settlement
Settlement Currency	The currency in which the Floating Rate Payer Calculation Amount is denominated
Terms Relating to Physical Settlement	
Physical Settlement Period	The longest of the number of business days for settlement in accordance with the then – current market practice of any Deliverable Obligation being Delivered in the Portfolio, as determined by the Calculation Agent, after

	consultation with the parties, but in no event shall be more than 30 days
Portfolio	Exclude Accrued Interest
Deliverable Obligations	Bond or Loan
Deliverable Obligation Characteristics	Not Subordinated Specified Currency – Standard Specified Currencies Maximum Maturity: 30 years Not Contingent Not Bearer Transferable Assignable Loan Consent Required Loan
Restructuring Maturity Limitation	Not Applicable
Partial Cash Settlement of Loans	Not Applicable
Partial Cash Settlement of Assignable Loans	Not Applicable
Escrow	Applicable

5. Documentation

Confirmation to be prepared by the Seller and agreed to by the Buyer. The definitions and provisions contained in the 2003 ISDA Credit Derivatives Definitions, as published by the International Swaps and Derivatives Association, Inc., as supplemented by the May 2003

Supplement, to the 2003 ISDA Credit Derivatives Definitions (together, the ‘Credit Derivatives Definitions’), are incorporated into the Confirmation

6. Notice and account details

Telephone, Telex and/or: Facsimile Numbers and Contact Details for Notices	Buyer Phone: Fax: Seller: A.N. Other Phone: +1 212-xxx-xxxx Fax: +1 212-xxx-xxxx
Account Details of Seller	84-7512562-85

A.2. *Risks and characteristics*

Credit risk. An investor's ability to collect any premium will depend on the ability of XYZ Bank plc to pay.

Non-marketability. Swaps are not registered instruments and they do not trade on any exchange. It may be impossible for the transactor in a swap to transfer the obligations under the swap to another holder. Swaps are customized instruments and there is no central source to obtain prices from other dealers.

Keywords
Accounting Information Transparency, Decision Making Effectiveness

Abstract

The purpose of this study is to examine the effect of accounting information transparency on decision making effectiveness via mediating influences, which include financial report quality and information advantage. The author improves novel components of accounting information transparency: disclosure, accuracy, and clarity. Data was collected from 238 Thai firms, divided into two categories: financial institutions and insurance companies. The statistics used to analysis multiple regression analysis. The result indicates that accounting information transparency has significantly positive influence on financial report quality and two of three dimensions of accounting information transparency have significantly positive influence on information advantage. Moreover, financial report quality and information advantage have significantly positive influence on decision making effectiveness.

1. Introduction

Recent crisis involves the actions taken by Toshiba Corporation in the wake of an accounting scandal. Between 2006 – 2014 Toshiba overstated operating profits by more than $1.2 billion (The Japan Times News,2015). Unethical behavior intended to break the rules and regulations to manipulate information was presented in the financial statements. The financial statements did not present accurate and useful information. Such accounting scandals weredue to the lack of financial transparency, imperfect regulations and unethical behavior (Hanson, 2003, Holzner et al., 2002). Furthermore, in the aftermath of Enron, WorldCom and other corporate scandals, the call went forth from various stakeholders for more "transparency" in accounting, auditing and corporate governance (Arya, et al., 2003). In the meantime, academic accountants began the task of identifying the attributes and mechanisms of corporate transparency (Anctil et al., 2004, Bushman et al., 2004). In the end, the US was to rule out Sarbanes-Oxley Acts to create transparency in financial reporting and business operations in a more ethical manner.Sarbanes-Oxley Act section 404 provides established internal controls and procedures for financial reporting and documents.It also tests and maintains internal controls and procedures to ensure their effectiveness. (SOX, 2002). Together, section 409 and Securities and Exchange Commission (SEC) require annual financial report disclosures for information transparency because information transparency plays an important role for its users, as most user require financial statements to support their decision making in the future (Reck, 2004). Nevertheless, not only more information transparency is needed, but also reliable information. Therefore, information transparency is an important issue for all companies because it helps to build stakeholder's confidence on their investment decisions. (Yu, 2005, Elliott et al., 2009).

The Corruption Perceptions Index 2014, ranked by Transparency International, shows the result of Thailand perceived transparency score at 38/100 and ranked at 85th from 175 countries, 12thof 28 countries in Asia Pacific (Report the Corruption Perceptions Index, 2014). The result suggests that Thailand have corruption problems as well as the lack of transparency. Furthermore, the findings in 2015 from a corporate governance assessment of 588 listed companies also shows that there is disclosure and transparency category having the score of 80 percent (Corporate Governance Report of Thai Listed Company, 2015). Thus, transparency in the preparation of financial statements helps build users' confidence and promote effective decision making. In Thailand, the concept of transparency is not a new concept although it is not widely practiced in every businesses. In financial businesses, it is believed that transparency can help attract more professionals and investors in the property market. Transparency has therefore become more significant in the financial businesses due to the demand from investors (Schulte et al., 2005).

The financial business have revealed sensitive information, accurate to stakeholders and financial decisions. Disclosure of information as an indicator of transparency in the operation, is a key factor in building confidence among all stakeholders of the financial business's operational integrity and a mechanism to monitor the implementation. (Guide governance of Government Savings Bank, 2015). This little study focuses on the transparency of financial businesses in Thailand. The literature, however, has been hampered by methodological issues over what actually constitutes "transparency", as well as the lack of a quantitative indicator which has substantial coverage across countries and time (Williams, 2014).Within accounting information, this ideal of transparency leads to an influential belief that by making financial information and processes more visible to users, related information and processes would be made more available and accessible to users, providing them with greater control and enabling enhanced decision making. (Roberts ,2009).

The aim of this study is to investigate the relationships between accounting information transparency, including three dimensions (disclosure, accuracy, and clarity) and decision making effectiveness through impact on financial report quality and information advantage.

In this study the key research questions are: (1) How does each dimension of accounting information transparency influence on financial report quality,information advantage and decision making effectiveness? (2) How does financial report quality influence on decision making effectiveness? (3) How does financial report quality and information advantage influence on decision making effectiveness?

The study is structured as follows: Firstly, the researcher provides the relevant literatures and hypotheses development. Secondly, the researcher explains the methodology, including data collection procedure and measurement, measure validation, and statistical technique. Next, the researcher discusses the results of this study, then explains the contributions. Finally, the summary is provided along with the limitation of this study.

2. Literature Review and Hypothesis Development

This study investigates the relationship between accounting information transparency and decision making effectiveness through the impact on mediators as financial report quality and information advantage. All hypotheses in this research proposed to have a positive effect. The conceptual model presents the relationship between all constructs in Figure 1.

This study explains and predicts the relationship between variables under the concept of agency theory.

One possible reason for agency problems is a result of the information asymmetry (Sengupta, 1998). The basic insight of the agency theory is that one party (principal) hires another (agent) to take charge of a specific task, but the former suffers from an information asymmetry, which introduces a problem in terms of motivating the agent. The agency problem shows that it is hard for internal agent to deliver credible information to external information users. Thus, according to Zuo, G. (2012), transparency consists of greater disclosure, high quality disclosure and understandable information. Transparency helps to reduce such agency problem as information asymmetry.

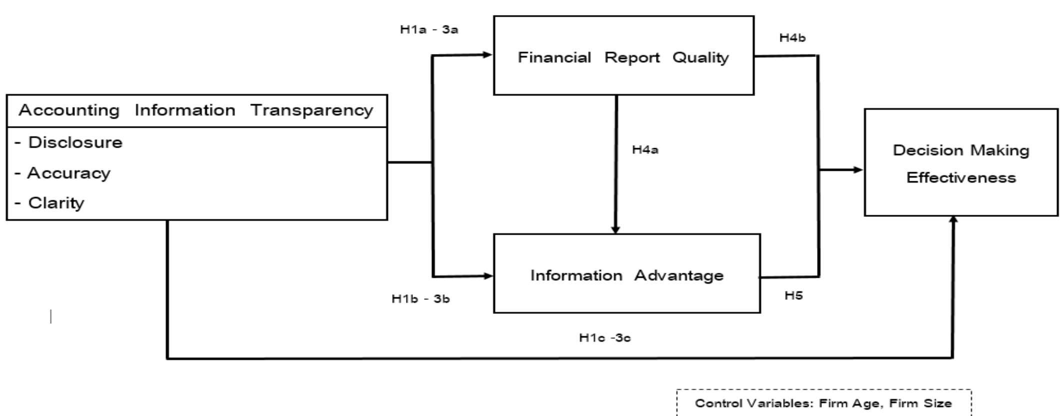

Figure 1 : Conceptual Model of Accounting Information Transparency and Decision Making Effectiveness

2.1 Accounting Information Transparency

Accounting information plays an important role for its users, especially in decision-making. Information of accounting in financial statements represents the financial effects of past events and transactions, which can be used to support decision making in the future. In addition, the non-financial information also supports decision-making for users of financial statements. According to Barth and Schipper (2008), financial reporting transparency is identified as, on the one hand, disclosure for information in the financial statements are underlying economics; on the other hand, information disclosure in the financial statements are readily understandable by internal and external information users. Florini (2007) defines transparency as the degree of information ~~is~~ available to outsiders, allowing them to make decision and/or to assess the decision of insiders. Furthermore, transparency is related to quality of information such that information needed should be easily understood, factually accurate by the intended audience and presented in a feature that promotes adoption of the desired behaviors (O'Malley and Thompson, 2009). Further definition of financial transparency is comprehensibility, clarity, and clearness, and excellent corporate governance (Hanson, 2003, Holzner et al., 2002). Accurate, clear, and disclosed information can be considered to hold a strong degree of transparency. (Schnzackenberg, 2009). In this study, accounting information transparency is defined as reliable accounting information which helps users to accurately make decisions. The characteristics of the information quality include: 1) the level of disclosed information presented, which will be available to interested parties. This disclosure must be timely appropriate, relevant and easy to understand. 2) the level of accuracy which complies with standard accounting rules. 3) clarity, focusing on the benefits of the information, which is accurate, complete, adequate, reliable and relevant to decision making. Therefore, if the company has accounting information transparency, it will enable the company to have financial report quality, information advantage to be used in effective decision making. In this study, the construct of accounting information transparency has three dimensions, consisting of disclosure, accuracy and clarity (Schnackenberg, 2009). The details of each dimension are described below.

Disclosure

Disclosures are generally defined as announcements which employ a disseminate policy, accounting technique and make somewhat verifiable forecasts (Diamond &Verrecchia, 1991). In Nada Lahrech, AbdelmounaimLahrech and Youssef Boulaksil (2014), a significant relationship between the disclosure level of quantitative and qualitative information in Islamic banking financials and the profit allocation ratio is studied. Disclosure is meant to include both the *availability* of that representation to interested parties as well as the *quantity* of information presentation. Core (2001) identifies disclosure quality as an agent to disclosure policy optimization in a firm. Such studies conclude that *quality* is a separate and identifiable element to disclosure. In this study, disclosure is defined as *timeliness,* referring to the timely presentation of financial information; *relevance* refers to the extent to which these reports provide users with the information required to make effective decisions; and *openness* refers to the understandability and accountability (Cottarelli, 2012). Therefore, firms that produce their accounting information disclosure following the timeliness, relevance and openness tend to increase the quality of financial report and reliability of the information, as well as enhance quality of decision making. Therefore, the hypotheses are posited as follows:

Hypotheses 1: The higher the disclosure is, the more likely that firms will gain greater (a) financial report quality, (b) information advantage, and (c) decision making effectiveness.

Accuracy

Accounting standards are the basic concepts focusing on the preparation and presentation of financial statements for external users (IASB, 2009).The regulations are corporate governance that reforms the firm's transparency, and the firms that follow the related regulations will increase the information's transparency (Waroonkun and Ussahawanitchakit, 2011). In this study, accuracy is defined as the accounting information that strictly follows the accounting standards, regulation and the follow up changes in those standards including constant focus on the understanding and interpretation of the accounting standards to help the organization present financial reports correctly and completely (Kohlbeck and Warfield, 2010). Therefore, firms which prepare accounting information following the standards tend to increase the quality of financial report and reliability of the information, as well as enhance quality of decision making. Therefore, the hypotheses are posited as follows:

Hypotheses 2: The higher the accuracy is, the more likely that firms will gain greater (a) financial report quality, (b) information advantage, and (c) decision making effectiveness.

Clarity

Clarity are defined as the focus on the utility of accounting information which is accurate, adequate, reliable,complete, and relevant for decision making to establish the reliability of accounting information for stakeholders. This will eventually lead to the added value of the firm. Financial information usefulness is very important for both internal and external users to support decision making related to the operations (Reck, Vernon and Gotlob, 2004).

Hypotheses 3: The higher the clarity is, the more likely that firms will gain greater (a) financial report quality, (b) information advantage, and (c) decision making effectiveness.

2.2 Financial Report Quality

Financial report quality are the accuracy, timeliness, completeness, consistency, and relevance of the used information system applied to the problem solving. Furthermore, it also covers used information, business performance, which includes role in the procedures and the operation of the business, both non-monetary and monetary (Neely and Cook, 2011). Therefore, the information will affect the operation of the business (Delone and Mclean, 2003; Chitmun, Ussahawanitchakit, 2012), resulted in the decision to take benefit from an information system in operation. In addition, financial reporting quality will affect information reliability, effectiveness of decision making, and useful information. In this study,financial report quality refers to the information comprehensiveness and support for the success of businesses, the information to assess and reflect the accuracy of situation which can be used to support better decision making than the competitors. Therefore, the hypotheses are posited as follows:

Hypotheses 4: The higher the financial report quality is, the more likely that firms will gain greater (a) information advantage, and (b) decision making effectiveness.

2.3 Information Advantage

Information advantage is defined as both the financial information and non-financial information which can reflect the actual operational condition effectively, and can be a good indicator of the profitability of the business both at present and in the future. Information advantage helps an organization's process to increase efficiency and effectiveness (Glomstead, 2001) and decision making. Information advantage is the greater qualitative characteristic of accounting information which can enhance the organization's capacity to analyze, assess, and forecast the economic events with accuracy and clarity (PWC, 2010). Financial information usefulness refers to good results of the reports that reflect the position of financial and operating results, which are accurate and reliable, and can be used to support decision making or forecasting of future performance (Fisher and Kingma, 2001).The purpose of financial information is to provide relevant and timely information for users to support decision making (Pongsatitpat and Ussahawanitchakit, 2012). Decision making is concerned with actions in the future (Bello, 2009) or financial information that is the foundation of internal financial information to assist managers to make business decisions. Krumwiede et al. (2007) and Zager and Zager (2006) state that information advantage is financial information usefulness in the context of the decision making process.

2.4 Decision Making Effectiveness

Decision making effectiveness is defined as the ability to use data to make effective, timely, and appropriate decisions to achieve the desired purpose. Accounting systems have been considered important organizational mechanisms which are critical for effective decision management and control in a business (O'Donnell and David, 2000). Successful decision making is the achievement in the selection among company choices which enables organizations to reach their objectives or goals. Ability of manager to manage relies on good decision making, which is a selection of the most efficient course of action to achieve desired objective. In selecting the most appropriate choice, a manager needs information related to alternative solutions such as cost information quality (Barfield et al., 1997). Moreover, prior research suggested that effective decision making is an assessment to the extent that the decision maker achieves the desired purpose related to business performance (Barfied et al., 1997; Ponikvar et al., 2009; Dimitratos et al., 2011). Thus, in this study, decision making effectiveness refers to companies which make accurate and timely decisions helping the organization to reach the desired goals. In this study, firms which have information advantage tend to make better decisions.Thus, the hypotheses are proposed as follows:

Hypotheses 5: The higher the information advantage is, the more likely that firms will gain greater decision making effectiveness.

3. Research Methods

3.1 Sample Selection and Data Collection Procedure

The sample of this study is financial businesses in Thailand consist of 238 firms divided into two categories: financial institutions and insurance companies. Database in this research is drawn from the Bank of Thailand and Insurance Thailand on their websites: www.bot.or.th and www.thai.insurancethailand.info. Accounting executives and accounting managers of each business are chosen as key participants. The data were collected via questionnaires, in which 228 out of 238 were returned. The mailing was 238 surveys, the returned questionnaires 10 mailing. Thus successful questionnaires mailed 228. Among the completed and returned surveys, only 78 were usable. The effective response rate was thus 34.21%. The response rate for a mailed survey with an appropriate follow-up procedure, if greater than 20%, is considered acceptable (Aaker, Kumar and Day, 2001).

3.2 Test of Non-Response Bias

Empirical research has been checked for non-response bias and to detect and consider possible problems with non-response errors, the investigation and assessment of non-response-bias are tested with the early and late wave data as recommended by Armstrong and Overton (1977). The mean of demographic variables of the two waves is tested by t-test whether the means are different between respondents. The result showed no significant differences. Thus, a non-response bias is not considered a problem in this study.

3.3 Variable Measurements

All variables were obtained from the survey and all items of the questions are measured by a five-point Likert scale, ranging from 1 (strongly disagree) to 5 (strongly agree). Constructs in the conceptual model are developed and modified from prior research. Thus, in this study, the variable measurements of the dependent variable, independent variables, mediating variable and control variables are described below.

Dependent Variable

Decision making effectiveness is defined as companies which make accurate and timely decisions helping the organization to reach the desired goals. In this study, firms which have information advantage tend to make better decision.

Independent Variables

This research consists of seven independent variables: accounting information transparency, and two outcomes. Accounting information transparency as the first one is the core construct of this study. This variable is measured by three attributes: disclosure, accuracy, and clarity. Moreover, these attributes reflect the accounting information that is in compliance with accounting standards and regulations to obtain information that is reliable and useful for decision-making, as well as to prepare information for reporting to management and stakeholders effectively. The measure of each attribute is detailed as follows:

Disclosure is defined as *timeliness,* referring to the timely presentation of financial information; *relevance* refers to the extent to which these reports provide users with the information required to make effective decisions; and *openness* refers to the understandability and accountability

Accuracy is defined as the accounting information that strictly follows the accounting standards, regulation and the follow up changes in those standards including constant focus on the understanding and interpretation of the accounting standards to help the organization present financial reports correctly and completely.

Clarity is defined as the focus on the utility of accounting information which is accurate, adequate, reliable,complete, and relevant for decision making to establish the reliability of accounting information for stakeholders.

Financial report quality is defined as the information comprehensiveness and support for the success of businesses, the information to assess and reflect the accuracy of situation which can be used to support better decision making than the competitors.

Information advantage is defined as good results of the reports that reflect the position of financial and operating results, which are accurate and reliable, and can be used to support decision making or forecasting of future performance.

Control Variables

In this study, the control variables consist of firm age and firm size.

Firm age is defined as the number of years a firm or the period of time has been in operation (Jonas and Diamanto, 2006) and there is a significant relationship between firm growth and firm age (Capelleras and

Rabetino, 2008). In this study, firm age is measured by the number of years a firm has been in operation using a dummy variable of 1, which means the firm has been in business for more than 15 years; and 0 which means otherwise.

Firm size determines the success of the organization and the value of organizational performance (Serrano-Cinca et al., 2005). In this study, firm size is measured by the total assets of the firm using a dummy variable of 1, which means the firm has total assets of more than 10,000,000,000 baht, while 0 means otherwise.

3.4 Reliability and Validity

Reliability of collected data was tested by Cronbach's alpha coefficients to measure internal reliability of respondents' answer for all items in the questionnaires which are greater than 0.70 (Nunnally and Bernstein, 1994). Cronbach's alpha coefficientsof constructs have values ranging 0.826 – 0.907. For testing the validity, this study produces an exploratory factor analysis (EFA) to test the construct validity of the instrument by examining the underlying relationships of a large number of items, and to determine whether they can be reduced to a smaller set of factors. This analysis has a high potential to inflate the component loading. Therefore, as a higher rule-of-thumb, a cut-off value of 0.40 is accepted (Hair et al., 2010). Factor loading have value ranging 0.715 – 0.939, all factor loadings greater than the 0.40 cut-off are statistically significant. Table 1 presents the results for both factor loadings and Cronbach's alpha for multiple-item scales in this study.

Table 1 : Results of Measure Validation

Items	Factor Loadings	Cronbach Alpha
Disclosure (DC)	.715 - .896	.826
Accuracy (AC)	.866 - .897	.907
Clarity (CL)	.765 - .939	.859
Financial Report Quality (FRQ)	.841 - .890	.872
Information Advantage (IA)	.766 - .933	.887
Decision Making Effectiveness (DME)	.868 - .938	.899

Table 1 shows that all variables have a factor loading score between 0.718 - 0.944 indicating that there is construct validity. Furthermore, Cronbach's alpha coefficients for all variables are presented between 0.831 - 0.921. Consequently, the reliability of all variables is adopted.

3,5 Statistical Techniques

Multiple regression analysis is an appropriate method for examining the hypothesized relationships.

In this study, the model of the relationships is depicted as follows:

Equation 1: $FRQ = \beta_{01} + \beta_1 DC + \beta_2 AC + \beta_3 CL + \beta_4 FA + \beta_5 FS + \varepsilon_1$

Equation 2: $IA = \beta_{02} + \beta_6 DC + \beta_7 AC + \beta_8 CL + \beta_9 FA + \beta_{10} FS + \varepsilon_2$

Equation 3: $IA = \beta_{03} + \beta_{11} FRQ + \beta_{12} FA + \beta_{13} FS + \varepsilon_3$

Equation 4: $DME = \beta_{04} + \beta_{14} FRQ + \beta_{15} IA + \beta_{16} FA + \beta_{17} FS + \varepsilon_4$

Equation 5: $DME = \beta_{05} + \beta_{18} DC + \beta_{19} AC + \beta_{20} CL + \beta_{21} FA + \beta_{22} FS + \varepsilon_5$

4. Results and Discussion

The descriptive statistics and correlation matrix for all variables are shown in Table 2. It can be seen that the potential problems relating to multicollinearity, variance inflation factors (VIFs) were used to provide information on the extent to which non-orthogonality among independent variables inflates standard errors. The VIFs range from 1.036 to 4.138, well below the cut-off value of 10 as recommended by Neter, Wasserman and Kutner (1985), meaning that the independent variables are not correlated with each other. Therefore, there are no substantial multicollinearity problems encountered in this study.

Table 2 : Descriptive Statistics and Correlation Matrix

Variable	DC	AC	CL	FRQ	IA	DME
Mean	4.468	4.224	4.423	4.396	3.990	4.158
S.D.	0.474	0.583	0.588	0.553	0.684	0.578
DC	1

*p<0.1, **p<0.05, ***p<0.01[a] Beta coefficients with standard errors in parenthesis.

Table 3 presents results for multiple regression of hypotheses 1a-3a, hypotheses 1b-3b, and hypotheses 1c-3c. The results of relationships among the three dimensions of accounting information transparency (including disclosure, accuracy and clarity), financial report quality, information advantage, and decision making effectiveness are shown in Eq.1, 2, and 5. Eq.1 also presents the relationships between accounting information transparency and financial report quality are provided in Table 3. The results show significant positive effects of disclosure (β_1 = 0.252, p<0.01), accuracy (β_2 = 0.255, p<0.01), and clarity (β_3 = 0.552, p<0.01) on financial report quality. These results indicate that the businesses with higher accounting information transparency consist of disclosure, accuracy and clarity will have greater financial report quality consistent with the study of Roberts (2009), IASB (2009) and Kohlbeck and Warfield (2010). Hence, **Hypotheses 1a, 2a, and 3a are supported.** However, Eq.2 presents the relationships between accounting information transparency and information advantage. The results show significant positive effects of disclosure (β_6 = 0.288, p<0.05) and accuracy (β_7 = 0.757, p<0.01) on information advantage. These results show that the businesses with higher accounting information transparency consist of disclosure and accuracy will have greater information advantage (Roberts, 2009). Thus, **Hypotheses 1b and 2b are supported and 3b is not supported**. Moreover, Eq.5 indicate that accuracy of accounting information transparency has a significant positive influence on decision making effectiveness (β_{19} = .730, p<.01). Thus, **Hypothesis 2c is supported and 1c and 3c are not supported** consistent with the study of Diamond and Verrecchia (1991), Price et al.(2011) and Reck, Vernon and Gotlob, (2004) who found that accounting information transparency has an impact on decision making.

Moreover, the finding in Eq.3 indicates that financial report quality is positively correlated with information advantage (β_{11} = 0.577, p<0.01). Thus, **Hypotheses 4a is supported**. These results suggest that the businesses with higher financial report quality will have higher information advantage consistent with the study of Delone and Mclean (2003). Finally, the findings in Eq.4 shows that financial report quality and information advantage are positively correlated with decision making effectiveness (β_{14} = 0.182, p<0.05; β_{15} = 0.759, p<0.01). Thus, **Hypotheses 4b and 5 are supported.** These results suggest that the businesses with higher financial report quality and information advantage will have higher decision making effectiveness (Fisher and Kingma, 2001;Bruce et al, 2002;Reck, Vernon and Gotlob, 2004; Zager and Zager 2006; and Krumwiede et al., 2007).

5. Contributions

5.1 Theoretical Contribution

This study provides a clearer understanding of the relationships among three dimensions of accounting information transparency and decision making effectiveness of financial businesses in Thailand via financial report quality and information advantage. The study is intended to expand on the theoretical contributions of previous knowledge and literature of accounting information transparency. Another contribution is the form of the identification of three dimensions of accounting information transparency for empirical study, which provides an important theoretical contribution expanding on all or some dimensions that are positively related to financial report quality, information advantage, and decision making effectiveness.

5.2 Managerial Contribution

This study helps accounting executives identify and justify key components of the three dimensions of accounting information transparency, which may be critical in severe market competition. In addition, this also assist them to understand the importance of accounting information transparency (disclosure, accuracy, and clarity) which may contribute to accurate, timely, and beneficial decision making of the organizations.

6. Conclusion

The purpose of this study is to examine the relationships between accounting information transparency including three dimensions (disclosure, accuracy, and clarity) and decision making effectiveness through impact on financial report quality and information advantage. The finding indicates that all dimensions of accounting information transparency have significantly positive influence on financial report quality and two of three dimensions of accounting information transparency have significantly positive influence on information advantage. However, only accuracy of accounting information transparency has significantly positive influence on decision making effectiveness. In addition, financial report quality has significantly positive influence on information advantage. Moreover, financial report quality and information advantage have significantly positive influence on decision making effectiveness.

This study has some limitation in that it focuses on only financial businesses in Thailand and the sample used is too small.

ABSTRACT

This study examines the association between the voluntary disclosure of economic and financial information and earnings management. The outlined arguments on the subject are based on the assumption that consistent voluntary disclosure policies may reduce earnings management. The analysis is conducted on a random sample of 66 non-financial Brazilian listed companies in the 2005-2012 period. To measure voluntary disclosure, the index proposed by Consoni and Colauto (2016) is used. As a proxy for earnings management, discretionary accruals (DA) are estimated based on the model by Dechow, Sloan, and Sweeney (1995). The relationship between these measurements is analyzed using a model of simultaneous equations and by the random effects regression method with panel data. A significant negative relationship was expected *a priori*; however, the main result of the study indicates that voluntary disclosure and earnings management are not simultaneously determined or associated. Although the results obtained contradict certain theoretical assumptions, there are alternative explanations for this finding. The empirical set of evidence in this research, in addition to those in previous studies, should be interpreted with caution because there is no consensus on the measures for voluntary disclosure and earnings management. Second, several companies in Brazil may not be interested in providing high-quality voluntary disclosure because most of their shareholders enjoy private benefits of control. This issue reduces the importance of the potential market demand for information, stratifies information asymmetry, and does not prevent earnings management.

Keywords: accounting information, voluntary disclosure, earnings management, emerging markets, discretionary accruals.

*Paper presented at the American Accounting Association Annual Meeting, Chicago, IL, United States of America, August 2015.

1. INTRODUCTION

Although it is well known that corporate disclosure brings advantages such as greater stock market liquidity and a lower cost of capital (Botosan 1997, 2006; Lopes & Alencar 2010; Welker 1995), managers are not always willing to increase the level of accounting disclosure. In addition to these benefits, there are most likely competing elements that may justify tighter managerial control over information, contributing to the importance of decisions about whether to disclose information.

Managers generally have access to more specific and accurate information about a company's business than do other market actors, but they may want to disclose or retain that information to serve their personal interests (Demsetz & Lehn, 1985). According to Watts and Zimmerman (1986), in deciding which information to report, managers attempt to evaluate how alternative methods will affect their wealth.

According to Dye (1988), a manager enjoys an advantage over stockholders with regard to information because it is difficult for the latter to directly observe the company's performance and therefore identify its future business prospects. In this sense, Scott (2012) observes that this information asymmetry creates ideal conditions for selective and distorted information reporting and a temptation to moral hazard. Thus, greater information asymmetry allows managers to use their discretion for the specific purpose of managing accounting results.

Information asymmetry can be reduced through voluntary disclosure and tighter regulation (Scott, 2012). However, regulation in the context of agency conflict works only if the regulator can require the disclosure of information that market participants are unwilling to disclose voluntarily (Beyer, Cohen, Lys, & Walther, 2010). According to Watts and Zimmerman (1986), the recognition, measurement, and disclosure of accounting data are not always guided by impartial decisions, but can be driven by economic incentives that maximize the expected utility of one of the interested parties. Managers overlook the fact that, in earnings management, accounting choices should be guided by the economic fundamentals of the company's business.

The guiding hypothesis of this study is that voluntary disclosure and earnings management are negatively related because this relationship is based on the relationship of each of these variables with information asymmetry. Healy and Palepu (2001), Lambert, Leuz, and Verrecchia (2007), and Verrecchia (1983) present voluntary disclosure as a factor that contributes to the reduction of information asymmetry. For Dye (1985, 1988) and Schipper (1989), among others, the information asymmetry between managers and investors is the necessary condition for earnings management. From this perspective, this study aims to investigate the relationship between voluntary disclosure of economic and financial information and earnings management in the Brazilian capital market.

Voluntary disclosure and earnings management are recurring themes in research on finance and accounting. However, there is little empirical evidence on the relationship between them that is specific to the Brazilian capital market. One example is the study by Murcia and Wuerges (2011), who explore this relationship from 2006 to 2008 using a sample of the 100 largest companies listed on the São Paulo Stock Exchange, Commodities and Futures (BM&FBOVESPA) and report a partially negative association between voluntary disclosure and earnings management.

To deepen this discussion, the time period of 2005-2012 is explored. Part of this period is marked by adjustments resulting from the process of alignment with international accounting standards starting in 2008. Consoni and Colauto (2016) present evidence that this process can be understood as an exogenous factor that had a significant positive effect on voluntary disclosure in Brazil. Therefore, the index proposed by Consoni and Colauto (2016) is adopted as a metric for voluntary disclosure and, different from that of Murcia and Wuerges (2011), the proxy for earnings management that is used is the discretionary accruals (DA) estimated using the model by Dechow et al. (1995).

The analysis performed in this study reveals that voluntary disclosure and earnings management are neither co-determined nor associated. That is, the absence of a relationship between the variables investigated suggests that disclosure decisions are not an important determinant for the practice of earnings management in Brazil. For the U.S.A. (Jo & Kim, 2007; Lobo & Zhou, 2001) and British (Iatridis & Kadorinis, 2009) markets, there is evidence of a negative association. Thus, it should be noted that different proxies for voluntary disclosure and earnings management make direct comparison difficult. Moreover, institutional differences between markets may influence both voluntary disclosure and earnings management.

Another crucial element is the understanding of voluntary disclosure as a response to information asymmetry. As observed by Francis, Nanda, and Olsson (2008), the assumption that voluntary disclosure is a determinant of the quality of earnings reported by companies ignores the fact that the voluntary disclosure may itself be based on poor-quality information. This point must be discussed and other methodologies must be used to better understand the behavior of voluntary disclosure and earnings management in the Brazilian context.

2. LITERATURE REVIEW AND HYPOTHESIS DEVELOPMENT

2.1 Voluntary Disclosure of Information

The demand for additional resources always increases when new investment opportunities appear and new investment opportunities are themselves likely to be associated with a widening gap in the information asymmetry between "insiders" and "outsiders" (Healy & Palepu, 2001). Analytical models, such as those developed by Diamond and Verrecchia (1991), Glosten and Milgrom (1985), and Kim and Verrecchia (1994), show that information asymmetry decreases as the level of voluntary disclosure of information rises because and this can reduce the adverse selection component of the bid-ask spread (the mechanism for price protection when shares are bought and sold). As a result, the trade volume and stock market liquidity increase, possibly reducing the cost of capital.

According to Grossman (1981), Milgrom (1981), and Milgrom and Roberts (1986), without information disclosure, investors would be unable to distinguish between high-quality and low-quality stocks. A lack of information would lead investors to reexamine their beliefs about the company's value and, logically, offer an average price for the entire group of stocks evaluated. In this sense, managers have an incentive to disclose all of the data at their disposal to distinguish themselves from those with less favorable data. In turn, theory about voluntary corporate disclosure has concentrated on identifying the reasons that full disclosure does not in fact occur.

Some of the research conducted by Robert E. Verrecchia and Ronald A. Dye, or research to which these authors contributed, has aimed to formulate models to explain partial voluntary disclosure. Refuting Verrecchia's thesis (2001) that there is no unified theory of voluntary disclosure, Dye (2001) demonstrates that his arguments differ from those of Verrecchia in that they consider models of voluntary disclosure to be essentially endogenous, whereas Verrecchia (2001) attributes the same status to endogenous and exogenous models.

According to Dye (2001), the idea that voluntary disclosure is efficient and contributes to efficient resource allocation in the capital market is related to the credibility of the financial data disclosed. Although Verrecchia (2001) notes managers' propensity not to disclose data that are essentially true, Dye (2001) argues that Verrecchia omits what he considers the determining factor in the disclosure's credibility, earnings management.

In this sense, Core (2001) argues that unbiased disclosure is not a manager's ideal, given that it carries a high cost. This conclusion is based on Watts and Zimmerman's understanding (1986, p. 205) that not all accounting manipulation is eliminated and that only in capital markets with rational expectations will managers fail to benefit from manipulation. The notion that it is very expensive to eliminate manipulation entirely indicates that managers can introduce some disclosure bias at a low personal cost.

In Verrecchia's model (1983), the disclosure costs that hinder full disclosure do not vary based on the information that the manager possesses. In Verrecchia's view (1983), the discretionary disclosure policy of managers is influenced by the costs of disclosing data, but the managers' only motivation for divulging information is its effect on the company's value.

In contrast, Dye (1985, 1986) claims that disclosure costs vary with the nature of what is being disclosed. If investors are uncertain whether managers withhold private information, they cannot interpret a lack of information as a sign that the company in question is withholding bad news. In the eyes of investors, Dye argues, companies with bad news are therefore indistinguishable from companies that make no disclosures.

Uncertainty over how investors will interpret a disclosure causes managers to publish data based on how they believe investors will interpret it (Dye, 1985). To correctly interpret a manager's action, it is necessary to identify the manager's incentives to disclose good or bad news and the entire set of data that the manager could have disclosed, but chose not to. Discussion of this question has led Dye (2001) to state that voluntary disclosure is a special case of Game Theory because it is not always possible to conclude that managers disclose only information calculated to raise the company's stock price and hide information that will reduce it. The reason is that bad news may be released during labor negotiations or when options are being granted and good news may be released at the time these options are exercised.

It is interesting to note that the benefits of corporate disclosure typically result in voluntary information disclosure, but not of all the information to which company management is privy. As noted by Dye (2001), the best information for the purpose of negotiating contracts is not necessarily the best information on which an investor should base a decision. Therefore, managers can strategically choose what to disclose and when to disclose it, provided that investors are uncertain as so what information the managers possess.

2.2 Earnings Management

Earnings management has been studied from many perspectives and methods. As a result, Mulford and Comiskey (2002) report that different characterizations have arisen, such as income smoothing, the reduction of current profits for the sake of future profits (big bath), creative accounting, and cosmetic financial statements (window-dressing), among others.

Healy and Wahlen (1999, p. 368) and Schipper (1989, p. 92) explain that earnings management can aim to modify both profit measures and economic and financial ratios, thereby modifying the form and content of accounting information. It is thus supposed that the practice of earnings management can interfere with the credibility of accounting data and its utility for decision-making by market actors. Thus, if earnings management is viewed as an opportunistic act, it must be viewed as reducing the quality of the published disclosure.

For Arthur Levitt (1998), former president of the Securities and Exchange Commission (SEC), earnings management stems from a decline in the quality of financial information disclosure, and measures requiring greater transparency and oversight of the financial statement disclosure process would be necessary to contain it. In Brazil, the Brazilian Securities Commission (CVM, by its Portuguese abbreviation) has also spoken on this subject. In Circular n. 480 (14 February 2007) (Comissão de Valores Mobiliários/Normas Contábeis e Auditoria/Superintendência de Relações com Empresas, 2007), the CVM declared that it considers earnings management to be an arbitrary form of discretion intended to influence or manipulate accounting numbers, though it falls within the limits of the law.

Despite the reduction in data reliability that often accompanies the practice of earnings management, there are arguments that this practice can be useful if kept within certain limits. Fields, Lys, and Vincent (2001) and Schipper (1989) argue that earnings management may reveal information about the company's value. In this sense, Subramanyam (1996) and Burgstahler, Hail, and Leuz (2006) refer to the practice of earnings management as an opportunistic behavior, but not when management's discretion is used to better communicate the company's underlying economic and financial performance. Thus, if earnings management is used responsibly, then this practice can transmit private information to the market about expectations for future corporate earnings.

According to Dechow and Skinner (2000), the different interpretations of earnings management agree that the practice requires intentional management, but it is not clear whether that intention is merely opportunistic or designed to convey private information to investors. As a result, this aspect makes it difficult to achieve a comprehensive understanding of the motivations for this practice and leads to widely differing empirical results.

According to Schipper (1989, p. 95), it is the persistence of information asymmetry that makes earnings management possible. This condition arises from a contractually established form of communication that cannot be eliminated without changing the contract. Along this same line of reasoning, Dye (1988) argues that earnings management occurs when one or more hypotheses of the Revelation Principle are violated, given that monitoring mechanisms would force managers to reveal the truth about the information that they possess.

The Revelation Principle is present in the literature on the design of mechanisms. In this context, mechanisms refer to a set of incentives that causes the agent to act in a manner that maximizes utility for the principal (Myerson, 1979). According to Lambert (2001), the premises of the Revelation Principle are related to communication, the form of the contract, and the commitment taken on. Thus, the author explains that, according to the logic of mechanisms, when agents receive private information, they have the ability to transmit the information in its fullest dimension, i.e., when there are two signals, they will be transmitted as two separate messages rather than being aggregated into a single message.

Arya, Glover, and Sunder (1998) emphasize that individuals do not blindly follow the provisions established in contracts; as a result, problems in the mechanism's design arise from the difficulty of ensuring that the contracting parties fully disclose the information in their possession. In Dye's view (1988), when the mechanism is inefficient, managers hold an informational advantage over shareholders, which leads them to exercise their discretionary power to apply accounting standards in a manner that serves their own interest, given that shareholders cannot perfectly monitor the company's performance and observe the prospects of the business environment. Dye (2001) addresses this issue, noting that Verrecchia (2001) neglects what he considers to be the determining factor in the information's credibility, earnings management.

According to Watts and Zimmerman (1986), managers sometimes have the power to determine when an event will be shown in the accounts and which transactions will affect the results reported, such as the appropriation of a certain expense, revenue, and the disposal of assets. In this sense, Bushman, Engel, and Smith (2006) explain that profit may not be a good indicator for monitoring managers' efforts. One reason is that managers may choose accounting policies to maximize their own expected utility, managing the earnings opportunistically, and/or by reducing voluntary disclosure.

As suggested by LaFond and Watts (2008, p. 450), the private benefits of control give managers incentives to use private information to transfer wealth to themselves, "even in the absence of financial-reporting-based debt and compensation contracts". Furthermore, the institutional environment can interfere and provide various incentives for the practice of earnings management. The level of protection for the investor can guide corporate choices on issues such as governance, the dividend policy, the financial structure, and the shareholder control of companies.

The literature on earnings management suggests many explanations and/or motivations for this practice, with each of the explanations being applied to particular circumstances. Healy (1996, p. 108-109) suggests that the motivations for earnings management are ambiguous, making it difficult to establish appropriate methods for analyzing a certain behavior. In any given group of companies, some may act to reduce profit to reduce their tax burden or discourage potential competition, whereas others may inflate profits to maximize bonuses, meet analysts' projections, or obtain loans. Furthermore, all of these behaviors may be present in the same company over a given period.

Due to the variety of environments in which businesses operate, it is difficult for a single explanation to cover all environments. In summary, it appears that earnings management occurs because there is no precise measure of net income and because the generally accepted accounting principles (GAAP) cannot completely constrain the subjectivity inherent in accounting policy choices and in certain practices. Many decisions about accounting choices are complex and defy a simple answer about which best informs the investor.

Therefore, the issue of information asymmetry presents itself as a link between voluntary disclosure and earnings management and supports the research hypothesis. To inform stakeholders, managers can voluntarily disclose qualitative and quantitative information that goes beyond that which is required by law.

Through voluntary disclosure, managers can show current and prospective earnings to those interested in the financial position of the company or they can clarify and explain the criteria adopted for the company's formulation of its accounting policies and estimates (Lundholm, 2003). According to Lambert et al. (2007), this effort aims to reduce information asymmetry and thereby increase investors' ability to make decisions and accurately monitor their investments.

Dye (1985, 1988) and Schipper (1989) consider the information asymmetry between managers and shareholders to be a necessary condition for earnings management. Schipper (1989) states that high levels of information asymmetry between managers and shareholders indicate a lack of sufficient resources, incentives, or access to relevant information for managers' actions to be monitored.

Trueman and Titman (1988) base their work on the assumption that voluntary disclosure increases transparency and that earnings management would therefore be more easily detected by shareholders of companies with a more consistent voluntary disclosure policy. Under these circumstances, managers would be less likely to practice earnings management because its purpose and effectiveness depend on the level of information asymmetry between managers and other market participants. Thus, managers would limit the level of voluntary disclosure if they wanted to maintain the flexibility to engage in earnings management.

Richardson (2000) explores these arguments, suggesting that the level of earnings management increases as the level of information asymmetry increases; testing this relationship, he finds a positive correlation. Richardson believes that this evidence indicates that, when information asymmetry is high, parties interested in the accounting data cannot obtain access to the information necessary to prevent accounting manipulation. Therefore, as information asymmetry increases, managers can use their discretion to manage reported earnings. Along the same lines, Iatridis and Kadorinis (2009), Jo and Kim (2007), and Lobo and Zhou (2001) find voluntary disclosure to be inversely correlated with earnings management. Based on the theoretical predictions and empirical results discussed, the research hypothesis is as follows:

H_1: as the index of voluntary disclosure of economic and financial information increases, the level of earnings management decreases.

3. METHODOLOGY

3.1 Measurement of Voluntary Disclosure

To explore what underlies the objective of this study and the specifics of the context being analyzed, as Botosan (2004) refers to it, this study employs the metric proposed by Consoni and Colauto (2016) for measuring the content of voluntary disclosures (Table 1). These researchers conceive the metric grounded in Brazilian studies and define its content based on the elements that continue to be voluntary over the time period of the study. This aspect of the methodology is relevant in the context of this analysis because, starting in 2008, Brazil began the process of aligning with the international accounting standards. In addition, in 2009, the CVM began to require companies to file a Reference Form, which replaced the Annual Information Form (IAN, by its Portuguese abbreviation), and contributed to changing the nature of disclosure and increasing the volume and detail of the disclosed information.

Table 1 *Voluntary disclosure index*

	Market view
1	Competitive analysis
2	Market share
3	Assessment of major economic trends market
4	Government influence on the company activities
	Corporate strategy
5	Plans and corporate objectives
6	Alignment of company activities with the stated objectives
7	Prospect of new investments
8	Sales forecasts
9	Earnings forecasts
10	Cash flow forecasts
	Economic and financial performance
11	Variation in the inventories of goods for sale, inputs or finished products
12	Variation in the level of receivables
13	Variation in the volume of sales
14	Variation in the level of administrative and commercial expenses
15	Variation in the level of operational earnings
16	Variation in the cost of goods sold, the products manufactured or services provided
17	Financial effect from the raising of short and long-term third-party resources
18	Financial effect from the application of own resources
19	Performance of common and preferred shares
20	Global indicators (EVA, EBITDA, MVA)
21	Cost of equity
	Operational aspects
22	Current production compared to the installed capacity
23	Operational efficiency measures
24	Dependence of technology, suppliers, customers and labor
25	Investments and divestments
26	Resources invested in human capital management
27	Resources invested in education projects, culture and social development

Source: *Adapted from Consoni and Colauto (2016).*

This metric favors economic-financial information, although voluntary disclosure is not restricted to this content. It is understood that this limitation guides the analysis and is primarily due to the difficulty of evaluating the disclosure of socio-environmental information in heterogeneous samples. Occasionally, this type of information is linked to details of corporate activities in certain segments of the market and may even be disclosed to meet regulatory requirements for that sector of the market.

The procedures for data collection are the same as those adopted by Consoni and Colauto (2016), aligning the scope of each item of the metric with the content of statements in the Management Report and, where applicable, in some sections of the IAN and Reference Form. To take advantage of the fact that some companies disclose more detailed information, these researchers define coding criteria that consider how detailed the information is, in both qualitative and quantitative terms. Therefore, when no information is available for a certain item, a score of 0 is assigned; when only qualitative information is available, presented in descriptive terms, 1 point is assigned; and when both qualitative and quantitative information is available (in monetary or non-monetary terms), 2 points are assigned.

The absolute individual score ranges from 0 to 54 points (27 items measured, each worth a maximum of 2 points). The index, which is a proxy for voluntary disclosure, is obtained by dividing of the absolute score of each company for each year by the maximum possible score. The closer the ratio is to 1, the better the company's voluntary disclosure is.

Along the same line presented by Francis et al. (2008), it is understood that a voluntary disclosure policy comprises a stable set of disclosure practices. Although voluntary disclosure also occurs in conference calls, websites, and newspapers, the documents cited are consulted because they are subject to a fairly uniform presentation framework, making it possible to compare companies and monitor the regularity of their disclosures.

3.2 Measuring Earnings Management

According to Dechow and Dichev (2002, p. 39-40), accruals are temporary adjustments that delay or anticipate the recognition of cash flows. Because not all financial decisions are directed at earnings management, researchers have separated total accruals into discretionary (opportunistic behavior) and non-discretionary (related to the level of business activity) accruals. The literature offers a variety of models for estimating DA, many of which are attempts to improve on previous models. For this study, we use the model by Dechow et al. (1995), known as the Modified Jones model. This model uses aggregate accruals to try to estimate a "normal" level of accruals and deviations from this level are considered evidence of earnings management. The advantages and disadvantages of this model have been discussed by Dechow, Ge, and Schrand (2010), DeFond (2010), Fields et al. (2001), Guay, Kothari, and Watts (1996), Lo (2008), Thomas and Zhang (2000), and Young (1999), among others, but no alternative approach offers a superior solution. According to Subramanyam (1996), the DA estimated by this model are priced by the market.

To estimate the DA, it is first necessary to calculate the total accruals obtained using the balance sheet approach. The total accruals of company i at time t is defined as follows:

$$TA_{i,t} = (\Delta CA_{i,t} - \Delta Cash_{i,t}) - (\Delta CL_{i,t} - \Delta CFL_{i,t}) - Depr_{i,t} / A_{i,t-1} \quad \boxed{1}$$

where $TA_{i,t}$ is the total accruals of company i at time t, $\Delta CA_{i,t}$ is the variation in the current assets of company i at the end of time t-1 to the end of time t, $\Delta Cash_{i,t}$ is the variation in the available cash of company i from the end of time t-1 to the end of time t, $\Delta CL_{i,t}$ is the variation in the current liabilities of company i from the end of time t-1 to the end of time t, $\Delta CLF_{i,t}$ is the variation in the short-term loans and financing of company i from the end of time t-1 to the end of time t, $Depr_{i,t}$ is the amount of depreciation, amortization, and depletion of company i during time t, and $A_{i,t-1}$ is the total assets of the company at the end of time t-1.

DA are estimated using pooled ordinary least squares (OLS) with the following equation:

$$TA_{i,t} = \alpha_1\left(\frac{1}{A_{i,t-1}}\right) + \alpha_2\left(\Delta REV_{i,t} - \Delta REC_{i,t}\right) + \alpha_3\left(PPE_{i,t}\right) + \varepsilon_{i,t} \quad \boxed{2}$$

where $\Delta REV_{i,t}$ is the variation in the net revenue of company i from time t-1 to time t, weighted by the total assets at the end of time t-1, $\Delta REC_{i,t}$ is the variation in the accounts receivable (net) of company i from time t-1 to time t, weighted by the total assets at the end of time t-1, $PPE_{i,t}$ is the balance of the fixed asset accounts (gross) of company i from time t-1 to time t, weighted by the total assets at the end of time t-1, and $\varepsilon_{i,t}$ is the error term of company i for time t.

All model variables are deflated by the total assets of the previous time period ($A_{i,t-1}$) to minimize the effect of company size and the problem of heteroscedasticity. Regarding the parameters of the modified Jones model, the fixed assets and the difference in variation between net revenue and accounts receivable are the main drivers of the process of recognizing accruals. Using the estimated coefficients α_1 and α_2 of each company-year (equation 2), the non-DA ($NDA_{i,t}$) are calculated as follows:

$$NDA_{i,t} = \hat{a}_1\left(\frac{1}{A_{i,t-1}}\right) + \hat{a}_2\left(\Delta REV_{i,t} - \Delta REC_{i,t}\right) + \hat{a}_3\left(PPE_{i,t}\right) \quad \boxed{3}$$

The absolute DA ($DA_{i,t}$) represent the difference between total accruals ($TA_{i,t}$) and non-DA ($NDA_{i,t}$) as follows:

$$DA_{i,t} = TA_{i,t} - NDA_{i,t} \quad \boxed{4}$$

In this sense, DA are the residuals of the regression. The farther the residual is from 0 (whether positive or negative), the greater the level of earnings management is. Table 2 shows the estimates of the parameters obtained by the Modified Jones model.

Table 2 *Coefficients estimated by the Modified Jones model (2005-2012)*

	Expected sign	Coefficient	Standard Error	t	p-value	VIF
Constant		0.0595	0.0261	2.2788	0.0231**	-

White's test						39.11***
Normality of residuals						125.55***
Observations						528

Note: *the dependent variable is total accruals (TA).*
coefficient $\alpha_1 = 1/A_{i,t-1}$; *coefficient* α_2 = *variation in the net revenue of company i from time t-1 to time t, weighted by the total assets at the end of time t-1, minus the variation in accounts receivable of company i from time t-1 to time t, weighted by the total assets at the end of time t-1; coefficient* α_3 = *balances of fixed assets accounts (gross) of company i at the end of time t, weighted by total assets at end of time t-1; VIF = variance inflation factor.*
***,** ***, ***: significant at the 10, 5, and 1 levels, respectively.*
Source: *Prepared by the authors.*

The variance inflation factor shows that the model does not have multicollinearity problems in the specification. The Durbin-Watson statistic shows that there is no serial autocorrelation. In turn, the model's residuals do not follow a normal distribution. Nevertheless, according to Wooldridge (2002, p. 167), the OLS estimators satisfy asymptotic normality; that is, they have an approximately normal distribution in sufficiently large sample sizes. White's test detects heteroscedasticity, which makes the OLS estimators inefficient.

The α_2 coefficient is negative and related to the difference in variation between net revenue and accounts receivable. Theoretically, the sign expected for this coefficient is difficult to predict because it is related to the increase in accruals, both for increasing and decreasing reported earnings. The α_3 coefficient represents fixed assets, which is responsible for expenses associated with depreciation, amortization, and depletion and, as expected, is positively correlated with these expenses.

3.3 Statistical Model

The research strategy is designed based on a simultaneous equations model. From the theoretical arguments outlined in the literature, it is assumed that corporate disclosure policy and the management of accounting data result from endogenous decisions. Therefore, the following two structural equations are defined to compose the system of simultaneous equations:

$$DA_{i,t} = \alpha_0 + \alpha_1 VDI_{i,t} + \alpha_2 ROA_{i,t-1} + \alpha_3 LEV_{i,t} + \alpha_4 IFRS_{i,t} + \alpha_5 SIZE_{i,t} + \varepsilon_{i,t} \quad (5)$$

$$VDI_{i,t} = \alpha_0 + \alpha_1 DA_{i,t} + \alpha_2 CON_{i,t} + \alpha_3 LIQ_{i,t} + \alpha_4 IFRS_{i,t} + \alpha_5 SIZE_{i,t} + \varepsilon_{i,t} \quad (6)$$

where $DA_{i,t}$ is the discretionary accruals of company *i* at time *t*, $VDI_{i,t}$ is the index of voluntary disclosure of company *i* at time *t*, $ROA_{i,t-1}$ is the ln of the profitability of corporate assets for company *i* from the end of time *t-1* to the end of time *t*, $LEV_{i,t}$ is the ln of the book leverage of company *i* at the end of time *t*, $LIQ_{i,t}$ is a dummy for the liquidity of the shares of company *i* at the end of time *t*, $IFRS_{i,t}$ is a dummy for the period of alignment with international financial reporting standards of company *i* at time *t*, taking the value of 1 for the 2009-2012 period and 0 otherwise, $SIZE_{i,t}$ is the size of the company, as measured by the ln of the total assets of company *i* at time *t*, $CON_{i,t}$ is the control rights, as measured by the percentage of common shares held by the main controlling shareholder or the sum of the percentages of common shares held by those who participate in the shareholders' agreement for company *i* at time *t*, and $\varepsilon_{i,t}$ is the error term for company *i* at time *t*.

The two-stage least squares (2SLS) method is used to estimate the system of simultaneous equations. The OLS method produces inconsistent estimators for models with endogenous explanatory variables. In turn, if no endogenous explanatory variables exist, or in the case of weak instruments, then the 2SLS method produces inefficient estimators, i.e., they lack the minimum variance.

3.4 Sample

This study employs the same sample of companies that is used in Consoni and Colauto (2016). The sampling procedure favors the random selection of companies that have maintained an active registration in the BM&FBOVESPA during the 2005-2012 period, excluding financial companies. By calculating the minimum size for finite populations, with a significance level of 5% and a 10% margin of error, Consoni and Colauto obtain a sample of 66 companies, representing 32% of the population considered.

These criteria lead to the formation of a balanced panel containing 568 observation-years. Companies in the electric power and the steel and metallurgy sectors predominate in the sample, totaling 30%. Over 55% of the sample companies belong to the traditional market and, on average, the concentration of control rights is 73%, as measured by the percentage of common shares held by the controlling shareholder or, in some specific cases, the sum of common shares held by participants in the shareholders' agreement.

In considering whether the sample is appropriate for the aims of this study and, consequently, the analysis of its results, the following factors are taken into consideration: (i) The sample has survival bias; that is, companies that closed or went public after 2005 are not included in the sample. Including only companies with active registrations makes it possible to indirectly control for the potential effects of economic and regulatory changes on the main variables of the study, particularly on voluntary disclosure. In addition, this study seeks to monitor the consistency of companies' voluntary disclosure policies. However, the survival bias makes it more difficult to generalize the results; (ii) To avoid impairing the measurement of some variables, such as the proxy for earnings management, companies in the finance and insurance sector are excluded from the sample because they have their own rules, chart of accounts, and specific property that are not comparable to other sectors; (iii) A sample of 66 company-years makes it possible to construct a disclosure index, given that, according to Core (2001), disclosure indices require intensive manual labor and are viable only for small samples.

4. RESULTS

4.1 Regression Analysis Using 2SLS

The results obtained by the 2SLS and the diagnostic statistics for the estimates are presented in Table 3.

DA = discretionary accruals; VDI = voluntary disclosure index.
, **, *: significant at the 10%, 5%, and 1% levels, respectively.*
Source: *Prepared by the authors.*

The Shea R^2 statistic from the first-stage regression indicates that the instruments are relevant in explaining the endogenous regressors. To ensure over identification, the lagged endogenous variables are used as instruments. The Sargan test of over identifying restrictions is used to assess the fit of the instruments. This test evaluates the statistical plausibility of the assumption that the instruments are exogenous. The result shows that the instruments are statistically relevant. To perform analyses with appropriate estimators, it is necessary to test simultaneity between DA and VDI, adopting the Wu-Hausman specification test. The test indicates that the residuals are not significant, as reported in Table 3; thus, it is impossible to reject the null hypothesis of exogeneity. In other words, DA and VDI show no simultaneous relationship in this model.

The estimation of models with endogenous explanatory variables by the OLS method produces inconsistent estimators. However, the 2SLS method for estimating models produces inefficient estimators that lack the minimum variance when no endogenous explanatory variables exist or in the case of weak instruments. Because there are no indications of simultaneity, it is more efficient to use the OLS method.

4.2 Regression Analysis of Panel Data

Panel data, specifically the fixed effects model, may be used to identify the sequential interrelationship between the DA and VDI variables. However, if only one of the relationships is significant, a unidirectional relationship will be observed between these variables. Therefore, the equations are estimated individually. First, the functional relationship between the dependent and independent variables is tested to observe the behavior of the VDI variable and of the control variables in relation to the DA and *vice versa*.

The Hausman test for the null hypothesis of the consistency of random effects estimators indicates that the fixed effects estimators are less efficient; thus, the random effects model is deemed more suitable. The results of the panel diagnostic tests and other results are shown in Table 4.

Table 4 *Random effects model with panel data*

DA = discretionary accruals; CON = stock concentration; IFRS = dummy for the period of alignment with international accounting standards; LEV = ln of the book leverage; LIQ = dummy for stock liquidity; ROA_{t-1} *= ln of the first asset profitability lag; SIZE = ln of total assets; VDI = voluntary disclosure index.*
, **, *: significant at the 10, 5, and 1% levels, respectively.*
Source: *Prepared by the authors.*

For the regression in which DA are the dependent variable, the only significant variable is LEV. This positive and significant relationship suggests that companies with high debt ratios tend to manage their earnings to show higher profit. Because it is a log-level function, all things being equal, a 10% increase in leverage has, on average, practically no effect on earnings management. This result shows that, although significant, the economic effect is very small. The other variables are not significant, nor do they show significant coefficients. These results contradict the theoretical assumption that these variables should be included in the model and, therefore, it is inferred that voluntary disclosure has no influence on variations in DA in the same time period. The analysis of the results for the regression in which voluntary disclosure (VDI) is the dependent variable shows that, with the exception of the ownership concentration variable (CON), the other control variables are significant at the 1% or 5% level. The relationship of these variables is consistent with that which was expected.

Based on the results presented, a relationship between earnings management and voluntary disclosure in the 2005-2012 period is not found by the simultaneity test; even the regression analysis with panel data finds no association between them. If a unidirectional relationship was found in the current period, then it may be inferred that a dependent relationship existed between the variables of interest; that is, the decision about whether to make voluntary disclosure would depend on the prior choice of accounting policy and *vice versa*.

To allow the analysis of the influence of the independent variables on the dependent variables over time, dummy variables are included to control this dimension. In this study, the dummies are presented for 2006 to 2012, given that 2005 is taken as the reference year. Only the year 2008 was found to be significant in both models, it was demonstrated that there is a difference between the periods before and after 2008. This difference may have occurred because many current accounting regulations went into effect that year as Brazil aligned with international accounting standards; 2008 was also the year of the subprime lending crisis.

Although it is found that the DA and VDI variables do not appear to be associated in the current period, this study seeks to determine whether the level of voluntary disclosure at *t-1* affects earnings management and whether earnings management at *t-1* affects voluntary disclosure. New tests are conducted to test the relationship between voluntary disclosure in the prior period and earnings management and *vice versa*. Tests to identify the most appropriate panel data approach are again performed. The first two tests reject the null hypothesis that the pooled OLS model is appropriate, validating the alternative hypothesis that fixed or random effects models are appropriate. The result of the Hausman test indicates the random effects model is the most appropriate. Overall, the results do not differ from those found when the variables were analyzed for the current period alone (Table 4).

This finding shows that the relationship between earnings management and voluntary disclosure is not significant. Thus, there is no evidence that greater voluntary disclosure is reflected in a lesser propensity to manage earnings in the methodological context of this study. This finding contradicts the underlying theoretical assumptions and differs from the empirical results presented by Iatridis and Kadorinis (2009), Jo and Kim (2007), and Lobo and Zhou (2001) in addition to the study of Brazil by Murcia and Wuerges (2011). These studies conclude that voluntary disclosure is one of the factors inhibiting the practice of earnings management. It is important to note that the different methods and analyses used in each of these studies make it difficult to draw direct comparisons with the results found in this study.

5. CONCLUSION

The theoretical assumptions of this study were that, when managers decide the level of voluntary disclosure, they may be inclined to practice earnings management to shape market actors' perceptions to suit their plans, perhaps even acting in their own self-interest.

This study is based on the idea that voluntary disclosure contributes to the reduction or elimination of information asymmetry and that lower information asymmetry makes it more difficult to engage in earnings management. Therefore, companies with a higher index of voluntary disclosure tend not to practice earnings management. It was hypothesized that there is a negative relationship between these variables.

In the inferential analysis performed, it is found that voluntary disclosure and earnings management do not appear to be simultaneously determined. Based on the procedures employed in this study, it is not possible to infer a significant relationship between the measures used. Accordingly, the results are inconclusive with regard to the ability of the voluntary disclosure variable to explain whether companies are likely to manage earnings. The lack of a relationship between earnings management and voluntary disclosure suggests that disclosure decisions are not a determining factor in companies' involvement in earnings management in Brazil.

Although it may seem that this result contrasts with the assumption that voluntary disclosure reduces information asymmetry and hence limits the opportunistic practice of earnings management, this study does not consider under which conditions and at what time full disclosure is likely to occur. A market that values additional information may help raise the level of voluntary disclosure and improve the quality of information disclosed. Therefore, it is conceivable that the influence of voluntary disclosure on the extent of earnings management depends on the complex mix of companies' characteristics and factors related to the institutional environment.

One possible explanation for the results obtained is the perception that, in Brazil, many companies may have no intention of making high-quality voluntary disclosures because their controlling shareholders are in a comfortable position, taking advantage of private benefits that flow from their preferential access to information. This situation reduces the importance of the potential market demand for information, stratifies information asymmetry, and does not prevent opportunistic earnings management.

The companies listed on the BM&FBOVESPA have gradually improved some aspects of corporate governance, but change has been very uneven. Brazilian companies are still marked by highly concentrated ownership and fragile corporate governance, with the concentration of control being made possible by the large number of non-voting (preferred) shares issued and the use of pyramidal structures (Silveira, Leal, Barros, & Carvalhal-da-Silva, 2009).

Due to the survival bias that guided the sampling process and measurement of the earnings management variable and the voluntary disclosure variable, it is noted that the reported results should be interpreted with caution. With regard to the estimation of DA, there are still doubts concerning the models' ability to measure earnings management, that is, to accurately distinguish between discretionary and non-discretionary components. The choice of model used reflects only the researcher's choice because the study was not intended to prove its effectiveness.

Research into aspects of companies' voluntary disclosure has difficulty obtaining an appropriate measure of disclosure. For various reasons, many researchers choose to develop their own measures. Although the metric's construction is grounded in previous studies and care is taken to identify the items whose disclosure has over time ceased to be voluntary, the process is not without subjectivity. Subjectivity can be present both in the selection of items and in the process by which they are coded.

It appears that several issues still need to be discussed in future studies. One should bear in mind that the literature on voluntary disclosure and earnings management is very dispersed, at times resembling a puzzle. This situation may be due to the differences in the conceptual understanding of each researcher, as well as their motivations. It is crucial to understand voluntary disclosure as a response to information asymmetry. As noted by Francis et al. (2008), the idea that voluntary disclosure is a determinant of earnings management ignores the fact that voluntary disclosure may also be based on poor information. This aspect makes it particularly difficult to identify the interaction between earnings management and voluntary disclosure.

Moreover, one of the great challenges of empirical research into earnings management and voluntary disclosure is the question of causality. Due to the hypothesis of the endogenous nature of causality, it is difficult to establish and identify the exact effect that one mechanism may have on the other. In this sense, the present study is only an attempt to investigate the relationship between them. The development or application of other methods can also make substantial contributions to this endeavor.

Insider trading and the post-earnings announcement drift

By

Christina Dargenidou, Ian Tonks, and Fanis Tsoligkas*

October 2017

Abstract:

We show that trades by corporate insiders after an earnings announcement determine in part the extent of the post-earnings announcement drift anomaly. Contrarian trades mitigate the under-reaction to earnings announcements, and confirmatory trades allow for price discovery with price movements continuing in the same direction of the earnings surprise. These results are consistent with insider trading being a mechanism that provides relevant information on transitory or permanent changes to the earnings process allowing the market to make appropriate inferences about the nature of the earnings surprise.

1 Introduction

This paper examines the consequences of trading by corporate insiders on the well-documented post-earnings announcement drift (PEAD) anomaly, whereby large positive unexpected earnings (UE) announcements are followed by an upwards drift in security returns, and large negative UE are followed by a downwards drift. The PEAD represents an under-reaction to earnings surprises, predominantly in those stocks with the largest surprises, for both positive (good news) and negative (bad news) announcements. Using a sample of 7,980 annual earnings announcements in the U.K. over the period 1995-2013, we first report evidence of the PEAD phenomenon: the spread in returns between the top and bottom quintiles formed on the basis of UE is a significant 3.4% six months after the earnings announcement. We go on to argue that corporate insider trading in the period after the earnings announcement affects the market's learning process of whether a structural change in the earnings series has occurred by providing additional information to the market about the interpretation of the earnings surprise. We show that information in contrarian directors' trades after an earnings announcement - director sales after good news or director buys after bad news - mitigate the PEAD. The market observes the trading behaviour of directors and infers that the earnings surprise reflects only a transitory change in earnings. Conditioning on these contrarian directors' trades, we find that the top to bottom quintile spread is reduced to an insignificant -1.4% six months later. In contrast, those companies with confirmatory director trades (in the same direction as the earnings surprise: director sales after bad news or director buys after good news) are deemed by the market to signal that there has been a permanent shift in earnings but the magnitude is difficult to determine. The post-earnings quintile spread in these companies that display confirmatory directors' trades increases to a highly significant 7.3%. This exacerbated PEAD represents price discovery as the market learns about the values of the new parameters in the earnings process. In the absence of any directors' trades, the market remains uncertain about the structural break. Our evidence on the market response to the joint signals of an earnings surprise and subsequent directors' trades suggests that the PEAD represents a learning response to the identification of permanent and transitory changes in the earnings process.

Seeking to explain the PEAD anomaly, Bernard and Thomas (1990) attribute it to the failure of stock prices to fully reflect the implications of time series properties of earnings for future earnings.[1] Taking further the hypothesis that PEAD is caused by investors' inefficient use of information to predict future earnings, subsequent research ascribe the anomaly to: unsophisticated

[1] A comprehensive literature review of the PEAD can be found in Richardson, Tuna and Wysocki (2010) and Kothari (2001). The PEAD is illustrated in Figure 1 by the upward drift in returns represented by the unconditional good news PEAD box following a positive earnings surprise. The downward drift in returns following a negative earnings surprise is illustrated by the position of the unconditional bad news PEAD box.

investors’ trades (Bartov, Radhakrishnan and Krinsky, 2000), the underestimation of the implications of inflation (Chordia and Shivakumar, 2005), accounting conservatism (Narayanamoorthy, 2006) as well as poor disclosure readability (Lee, 2012). Recent research by Milian (2015) documents that the PEAD anomaly persists, albeit concentrated over a shorter period of time. A possible explanation for the pervasiveness of PEAD may arise from cognitive biases preventing investors from fully reacting to the new information in the earnings surprise, including limited attention (Hirshleifer, Lim and Teoh, 2009), investors’ overconfidence in their private beliefs (Liang, 2003) and limits to arbitrage (Ng, Rusticus and Verdi, 2008). Alternatively, what appears to be a delayed reaction to the implications of current earnings for future earnings could be an implication of investors’ learning or ‘‘rational structural uncertainty’’ (e.g. Francis, Lafond, Olsson and Schipper, 2007). Learning models predict that investors’ under-react to information signals after a structural shift has occurred, because there is uncertainty as to whether a structural shift has in fact happened. Brav and Heaton (2002) note significant similarities in the underpinnings of behavioural and rational learning theories, and caution that it may be difficult to distinguish between them.

In a similar vein, we argue that trading by corporate insiders provides information that investors use to address the inference problem as to whether a structural shift in the earnings process has occurred. Investors who observe the direction of corporate insider trading are able to infer directors’ private information about the earnings surprise. We follow Seyhun (1998) and identify a set of contrarian insider trades, taking place after the earnings announcement but in the opposite direction to the sign of the earnings surprise. These trades provide a signal to the market that the earnings surprise denotes a transitory realization, and the market’s response reverses the initial reaction to the earnings announcements. The remaining set of insider trades occur in the same direction as the earnings surprise which we classify as confirmatory trades. These trades signal that informed insiders believe that the earnings surprise represents information about a permanent change in the earnings process. The market updates its beliefs about the permanent-transitory nature of earnings on the basis of this additional information and in the case of confirmatory directors’ trades, the initial under-reaction to the earnings surprise adjusts as prices continue to move in the same direction as the surprise, representing price discovery.[2]

Francis et al. (2007) predict that the under-reaction to earnings announcements is negatively associated with the level of the precision of the earnings signal, because investors’ learning is delayed when the earnings signal is less precise. We extend this argument and examine the effect of interacting the precision of the earnings signals with corporate insider trading. We demonstrate that in the presence of contrarian insider trading after the earnings announcement, there is no under-reaction to earnings announcements in firms with low earnings precision. The implication is that in these hard-to-value cases, contrarian directors’ trades allows the market to interpret the earnings surprise as a temporary event. In contrast, we find that in the presence of confirmatory trading the under-reaction is still significant. This suggests that confirmatory trades initiate a learning process to establish the extent of the permanent shift in the earning process even under circumstances where this is not likely to occur, i.e., under high earnings precision.

[2] Veenman (2012) also distinguishes between insider confirmatory buys after good news, and contrarian buys after bad news.

Our research contributes to the literature examining the implications of insider trading disclosure for the valuation of corporate earnings. To date, this research has indicated that the information contained in directors' trading allows the market to develop inferences about future earnings. For instance, Udpa (1996) shows that insider trading prior to an earnings announcement mitigates the market reaction to the subsequent earnings announcement. In a similar vein, Roulstone (2008) reports that insider purchases and sales result in lower market reaction during the earnings announcement. Beneish and Vargus (2002) find that the discretionary component of accruals in earnings is more persistent when accompanied by directors' purchases and less persistent when accompanied by sales. More recently, Choi, Faurel and Hillegeist (2017) show that the market uses pre-announcement insider trading information to anticipate and interpret the current earnings news leading to improved stock price efficiency during the post-earnings announcement period. In contrast to this stream of research, we are interested to find out how the market employs the information in directors' trading that occurs *after* the earnings announcement.

Kolasinski and Li (2010) examine insider trading after the earnings announcement. However, they focus on whether insiders exploit the initial under-reaction to an earnings announcement. Our study is mostly related to Veenman (2012) who investigates the short-term market reaction to the post-earnings announcement disclosure of insider purchases. Veenman (2012) finds that insiders' purchases enable the market to resolve the uncertainty associated with the valuation of past reported earnings. We differ from Veenman (2012) by investigating the implications of insider trading for the post-earnings announcement drift. This allows us to demonstrate that insider trading does not simply trigger a short-term market reaction but instead, initiates a learning process of uncertainty resolution with respect to whether a structural change in the earnings series has occurred.

The remainder of the paper is structured as follows: in Section 2 we discuss the regulation and practices with respect to insider trading around earning announcements in the UK. In Section 3 we develop our hypotheses concerning the impact of insider trading on the post-earnings announcement drift. In Section 4, we discuss the methodology that we employ to test our hypotheses, and in Section 5, we describe the data and the construction of our variables. In section 6 we report our findings, and finally in Section 7, we present the conclusions to the study.

2 Insider trading around earnings announcements: Regulation and practices in the UK

The regulatory framework and common practices in the UK allow us to determine the timing of transactions which are most likely to convey insiders' private information about the interpretation of the earnings surprise. The UK provides a unique setting for our investigation since the institutional arrangements allow first, directors to trade immediately after the earnings announcement and associated trading ban, and second, a speedy disclosure of transactions.

Insider trading on price sensitive information and in particular the trades by directors in the UK are regulated by The Companies Act 1985, The Criminal Justice Act (CJA) 1993, The Financial Services and Markets Act (FSMA) 2000, Listing Rules and Disclosure Rules administered by the

Financial Conduct Authority, who may impose penalties such as fines or imprisonment to insiders found guilty of trading on inside information. The London Stock Exchange Model Code (1977) (part of the Listing Rules), requires directors who trade in their own company's shares first, to seek clearance to trade from the Board ahead of the transaction and second, to report their trades to the company no later than the fourth day after the transaction occurred.[3] In turn, the company must notify the Stock Exchange no later than the following day, when the information about the trade is disseminated to the market. Although the duration of this process appears to be lengthy, in practice, the disclosure of insider trades in the UK is very timely. Fidrmuc, Goergen and Renneboog (2006) report that 85% of the directors' trades in the UK are announced to the market either on the same day they occur or on the following day. This is confirmed in our data, with 82.11% of the shares traded within the first 10 trading days after and including the earnings announcement day, being disclosed on the same or following day.

In addition, the Model Code prescribes a clearly-defined and well observed trading ban,[4] forbidding insiders from trading for two months prior to the earnings announcement. The purpose of this trading ban is to prevent insiders from exploiting any private information with respect to the forthcoming earnings announcement. However, an insider may trade after the end of the trading ban, with the trading restriction ending immediately after the earnings announcement has been made public. Our analysis will focus on these directors' transactions taking place shortly after the earning announcement.

3 Hypothesis development

In this section we develop our hypotheses concerning the impact of corporate insider trading on the post-earnings announcement drift – the market's under-reaction to earnings announcements. We argue that trading by corporate insiders allows the market to make improved inferences about changes in the underlying earning process and that such revisions can partly explain the PEAD. Bulkley and Tonks (1989), Timmermann (1996), and Veronesi (1999) have shown that since standard valuation models rely on estimates of the growth process for dividends and earnings as inputs, small revisions to these growth estimates can generate large changes in equity values which can explain the observed excess volatility of stock prices. Investors form expectations of future fundamentals such as earnings or dividends based in part on the time series properties of previous fundamentals. They update their beliefs about these estimates as new data on dividends and earnings become available. When a large surprise in earnings is announced, whether positive or negative, investors must decide whether this change represents a transitory or permanent variation in earnings. If the nature of the change in earnings is transitory, then the value of the company will only change by the contemporaneous change in the most recent earnings level. For instance, Freeman and Tse (1992) show that transitory earnings have small or no impact on prices. On the other hand, if a structural change has occurred in the earnings process, then the announced earnings represent the first

[3] Insiders in the UK are normally interpreted to be executive and non-executive directors of the company. Thus, we use the terms "insiders" and "directors" interchangeably to refer to corporate insiders.
[4] These listing rules apply to firms on the Main Market and on AIM. The trading ban in the UK has been shown to be well observed (e.g. Korczak, Korczak and Lasfer, 2010) with directors either abstaining from trading during this period, or trading with the permission of the company chairperson.

realisation from a new earnings process, and the value of the firm should change to reflect the new earnings process. From the perspective of a learnings model, investors face an identification problem from the most recent earnings figure, as to whether the unexpected value is an outlier from the previous earnings process, or is the first observation in a new earnings series. As well as explaining excess volatility puzzles, learning models in finance have been applied to explain asymmetric time-varying volatilities (David, 1997), the equity risk premium (Brennan and Xia, 2001), the value premium (Pástor and Veronesi, 2003), and term structure puzzles (Bulkley and Giordani, 2011). Lewellen and Shanken (2002) develop an equilibrium rational learning model where Bayesian-investors under-react to information signals after a structural shift has occurred, because there may be some uncertainty as to whether a structural shift has in fact happened. If there has been a structural shift, then investors face the difficult problem of valuing a new income stream with new parameters. Lewellen and Shanken (2002) suggest that many stock market anomalies can be explained by rational learning about parameter uncertainty but argue that this does not mean that there are exploitable arbitrage opportunities because "the strategy earns abnormal profits in a frequentist sense, but not from the Bayesian perspective of investors" (p. 1125). Brav and Heaton (2002) also note that it may be difficult to distinguish between rational learning and behavioural explanations for stock market anomalies.[5]

In an environment with parameter uncertainty investors will look around for further information that will allow them to make a better inference on the transitory or permanent shock to earnings. One such source of information is the trading behaviour of corporate insiders, who are allowed to trade after the earnings announcement in the UK following the relaxation of the two-month prior trading ban. Insider trading is a mechanism that enables private information held by corporate insiders to be incorporated into stock market prices (Manne, 1966). We argue that after an earnings announcement, large earnings surprises may reflect either an extreme value from existing distribution, representing a transitory component to earnings, or a value from new distribution, representing a structural change in the earnings process. Investors must assess whether a structural change has occurred.[6] Bayesian investors update beliefs from sample information generated by the relevant distribution, and directors' trades after the earnings announcement represent that sample information. We assume that directors with private information about the fundamental value of their firm, trade to maximise their wealth.[7] They will buy (sell) shares when the

[5] These learning models do not distinguish between learning and imitating. Acemoglu, Dahleh, Lobel and Ozdaglar (2011) incorporate social networks into a sequential learning model, and demonstrate even when there are an influential group of agents whom other agents copy, there will still be an asymptotic convergence to the efficient outcome (no herding) provided that the information signals received by individuals are unbounded.

[6] In Appendix 1 we provide a simple example of a shock to an earnings process generated by a uniform distribution, which reveals a structural change with an unknown upper support. Conjugate prior beliefs on this unknown parameter are represented by a Pareto distribution, meaning that investors who update from the likelihood function according to Bayesian rules will have posterior beliefs that are also Pareto. We show that such a learning mechanism generates a price process that replicates a PEAD.

[7] Bagnoli and Watts (2007) model managers' disclosure strategy around earnings announcements, and show that the optimal strategies are asymmetric around good and bad news, reflecting transitory and permanent components. However, an underlying assumption in Bagnoli and Watts (2007) is that the manager selects a voluntary disclosure strategy to maximize the market price of the firm. In our setting, we assume that managers trade to exploit their information advantage for their own benefit.

market price undervalues (overvalues) their estimate of the firm's fundamental value. This behaviour is consistent with the empirical evidence which demonstrates that information in directors' trading is associated with significant market reactions in both the short run (Fidrmuc et al., 2006) and long run (Lakonishok and Lee, 2001). Further, work by Seyhun (1998), and Hillier and Marshall (2002) has established trading patterns around the earnings announcement that illustrate insiders' informational advantages. Contrarian directors' trades in the post-earnings announcement period imply that corporate insiders know the earnings surprise is a transitory event, and that current prices are driven by an over-reaction to the earnings surprise. The market infers that earnings surprise reflects a transitory change in earnings, and there will be no PEAD. On the other hand, confirmatory directors' trades, in the post-announcement period reveal that insiders know the earnings surprise represents a permanent structural change. The market will correctly infer that there has been a permanent change in the earnings process, although the parameters of this new distribution will need to be estimated.

Seyhun (1998) notes that an insider who wants to purchase shares and anticipates a negative earnings surprise will hold back from trading until after the bad news has been announced in order to buy shares at a lower price. Conversely, an insider who wishes to sell and anticipates a positive earnings surprise will again postpone trading until after the public announcement, in order to sell at a higher price. These contrarian trading patterns are motivated by insiders' information that the earnings surprise represents a transitory event. Specifically, Seyhun (1998) argues that "Following their sales, insiders do not necessarily expect negative future performance. They only know that past expectation of good performance is completed and the stock price fully reflects insiders' expectations." (p 51). Following Seyhun (1998), we argue that the contrarian direction of these insider trades reveals that prices have over-reacted to the information in the earnings surprise, with the implication that such earnings surprises represent only a transitory change in earnings. The contrarian nature of these trades provides a contradictory signal to the earnings surprise, and causes market participants to revise their expectations in the opposite direction to the sign of the earnings surprise. The joint signal of an earnings surprise and a contrarian directors' trade, allows investors to infer that the earnings surprise does not reflect a permanent change in earnings, and we would not expect any further price movement in the direction of the earnings surprise; in fact, PEAD will be dissipated. Following these discussions, we set out our first hypothesis:

Hypothesis 1 (H1): Informed contrarian directors' trading after an earnings announcement conveys a signal on the transitory nature of the earnings surprise that attenuates the PEAD.

Figure 1 illustrates the pattern in returns that we predict following either of two joint signals: (positive earnings surprise and directors' sells) or (negative earnings surprise and directors' buys). In both cases we expect the initial stock price reaction to the earnings surprise to represent an over-reaction which is then mitigated by the contrarian trades, represented by the attenuated PEAD boxes.

FIGURE 1 ABOUT HERE

We now turn to the other type of insider trading around the earnings announcement: confirmatory insider trades. Confirmatory insider trades are those directors' trades that occur after the earnings announcement and in the same direction as the sign of the earning surprise, and are also illustrated in Figure 1. From these trades investors infer that there has been a permanent shift in the earnings process, since with confirmatory trades informed insiders are either buying shares after the good earnings news, or selling shares after the announcement of a bad earnings surprise. In both cases confirmatory directors' trading reveals a mis-valuation of the underlying firm fundamentals, and that the initial price reaction was an under-reaction to the earnings surprise. The direction of these confirmatory trades indicate that prices have still to fully reflect the information in the earnings surprise. This behaviour is consistent with the latest earnings surprise figure representing a permanent change to the earnings process. However, there are two issues in relation to the inferences that the market makes from confirmatory directors' trades.

First, the absolute upper limit on the permanent change in earnings is undefined whether for good news or bad news. Although the market may infer from these trades that there has been a permanent change in earnings, the parameters of this new earnings process are not yet known, and there is still much uncertainty about the ultimate equilibrium share price.[8] Although the joint signal of confirmatory trades and the earnings surprise indicates that a structural break has occurred, it is well-known that analysts typically under-estimate the extent of earning changes (e.g. Abarbanell and Bernard, 1992). Further, Ali, Klein and Rosenfeld (1992) show this under-estimation is more severe when earnings are deemed permanent. It is therefore unlikely that with a joint signal of an earnings surprise and a confirmatory insider trade prices will immediately jump to a new equilibrium level. It is more likely that there will be subsequent drift to the new equilibrium given that even professional investors (e.g. analysts) under-estimate the permanence of the structural change.

Second, insiders have reduced incentives to engage in confirmatory trading after the earnings announcement, given that the earnings surprise reveals in part the insiders' information. Directors would have greater incentives to trade prior to the earnings announcement to fully exploit their private information about the forthcoming earnings surprise. In the context of the UK's two month trading ban, an insider would purchase (sell) shares before the announcement of a positive (negative) earnings surprise, just prior to the imposition of the trading ban. However, pre-earnings announcement insider trading is rare as it exposes insiders to both litigation and reputation costs. Hillier and Marshall (2002) report that although insiders with private information about the upcoming earnings announcement may trade prior to the start of the trading ban period, the transparency of the trading disclosures and the legal consequences means that such trades are uncommon. Piotroski and Roulstone (2007) show that insiders refrain from pre-earnings announcement trades when the magnitude of the surprise is extreme. Also, there is evidence of a substantially higher incidence of directors' trading in the period following the earnings announcement, and this is consistent with insiders' reluctance to trade before the announcement and preference to delay their trades (Hillier and Marshall, 2002).

In summary, although the patterns associated with confirmatory insider trading are consistent with insiders exploiting their informational advantage over the interpretation of the earnings surprise, we anticipate the asymmetric incentives (compared with contrarian trades) may

[8] A similar issue arises in the case of insider trading around earnings restatements. Badertscher, Hribar and Jenkins (2011) argue that it is only possible to identify directional hypotheses about how stock prices respond to insider trading and accounting restatements, but not the rank order of the magnitude of the effects.

render a delayed stock market response to the earnings surprise. This discussion leads us to our second hypothesis:

Hypothesis 2 (H2): Informed confirmatory directors' trading after an earnings announcement conveys a noisy signal that a structural change in the earnings distribution has occurred, resulting in an exacerbated PEAD.

Figure 1 illustrates the predicted pattern in returns following confirmatory directors' trades. For both good and bad earnings surprises, the initial stock price reaction under-estimates the long-run fundamental price, and the subsequent stock price reaction is represented by the exacerbated PEAD boxes. The underlying conjecture in the development of hypotheses H1 and H2 is that the disclosure of informed directors' trading provides relevant information to the market which accelerates investors' learning with regards to the transitory-permanent nature of the earnings surprise and thus, either attenuates or exacerbates the reaction to the earnings announcement. We may seek further support for these arguments by examining these conjectures in relation to the characteristics in the earnings surprise related to the difficulty investors have in interpreting these signals. Francis et al. (2007) argues that a testable consequence of a rational learning model explanation of the PEAD is that we would expect the PEAD anomaly to be most prevalent in high information uncertainty firms whereby uncertainty is captured by the precision of earnings. They show that in these hard-to-value firms the under-reaction to earning announcements is exacerbated by the low precision in earnings signals since the investors' inference problem becomes more complex for these cases, and the speed at which investors incorporate the information in the earnings surprise is delayed. Veenman (2012) and Bhattacharya, Desai and Venkataraman (2013) extend these arguments and show that a low precision earnings signal amplifies the information asymmetry between insiders and outsiders, and increases the importance of insiders' private information for investors' assessments.

Hypothesis 3 then seeks to expand the evidence of the impact of contrarian and confirmatory trades conditional upon the influence of earnings precision:

Hypothesis 3:

(H3a): Contrarian insider trading attenuates the PEAD for low earnings precision (high information uncertainty) firm-announcements.

(H3b): Confirmatory insider trading exacerbates the PEAD for high earnings precision (low information uncertainty) firm-announcements.

The two parts to H3 seek to corroborate the learning mechanism underlying the impact of contrarian and confirmatory insider trading outlined in H1 and H2. In the case of contrarian trades, evidence of a mitigated PEAD under circumstances when it is most likely to occur, validates the suggested mechanism through which learning occurs. H3a predicts that in low precision firms, contrarian directors' trades will be effective at weakening the PEAD. We might anticipate a corollary of H2 with respect to confirmatory trades in high precision firms. We expect that in high earnings precision firms the PEAD will not be present, in which case if we find evidence of a PEAD following confirmatory directors' trades in such firms, this again will validate directors' trades as a learning mechanism. H3b predicts that in high precision firms, the presence of confirmatory insider trading will lead to a PEAD effect.

To summarise, our main hypotheses H1 and H2 are concerned with the role of informed contrarian and confirmatory insider trading in explaining the PEAD. Hypothesis H3 complements the first two hypotheses, since it aims to corroborate the role of insider trading in the context of low and high earnings precision firms, and thus validate that this learning mechanism is distinct from the learning that relies on fundamentals.

4 Research design

To investigate the effect of informed insider trading on the under-reaction to earnings announcements, we follow the event-study methodology to first identify the post-earnings announcement drift (e.g. Bartov et al., 2000) and then include variables that examine the impact of contrarian and confirmatory directors' trading on stock market returns. The timing of these events ensures that causality flows from the joint signal of the earnings surprise and directors' trades through to abnormal returns. Evidence of the under-reaction to earnings announcements is documented by a significant association between the earnings surprise and subsequent returns, as follows:

$$BHAR_{i,t} = \alpha_0 + \alpha_1 RUE_{i,t} + \alpha_2 Controls_{i,t} + \varepsilon_{i,t} \qquad (1)$$

where, $BHAR_{i,t}$ denotes market adjusted buy-and-hold abnormal returns using the FTSE all share marked index measured from 11 days after the earnings announcement to six months later (day +126), where a month is defined in terms of 21 trading days, and RUE_{it} is the rescaled quintile rank of the earnings surprise. Our main results refer to the PEAD over an approximate 6-month trading horizon. We concentrate on this time period since Bernard and Thomas (1989) report "a disproportionately large fraction of post-announcement drift is concentrated in the few days preceding and including the next quarter's earnings announcement" (p. 30). In the US where most firms report on a quarterly basis the timing of the PEAD is often measured over a 3-month horizon to capture the next earnings announcement date. In the UK where semi-annual reporting is much more common, Liu, Strong and Xu (2003) report the existence of the PEAD over a range of time horizons, but concentrate their abnormal return tests on the 6-month horizon. In order to assess the robustness of our results to the timing effects, we undertake additional tests for PEAD returns measured at 2-month (+11 to +52), 3-month (+11 to +73), 4-month (+11 to +94) and 5-month (+11 to +115) time horizons.

We first calculate unexpected earnings defined as the quintile rank of the earnings surprise, where the cut-off points are determined by the distribution of the earnings surprise in the previous year. We define the earnings surprise based on the difference between actual earnings and the latest analysts' earnings forecast (e.g. Ayers, Li and Yeung, 2011). We follow Mendenhall (2004) and define $RUE_{i,t}$ as a variable taking the value "-0.5" when an observation belongs to the bottom quintile rank of earnings surprise and "0.5" when an observation belongs to the top quintile rank of earnings surprise. For the intermediate quintiles, we set $RUE_{i,t}$ to be equal to zero. In this case, the difference between the extreme earnings surprise quintiles is equal to unity and therefore, α_1 represents the spread in average abnormal returns between observations in the highest and lowest unexpected earnings surprise quintiles. Figure 1 shows how this spread is measured. In the case of a positive earnings surprise the unconditional PEAD is measured by the vertical distance represented by the GN_PEAD box. Similarly, an unconditional bad news PEAD is measured by the BN_PEAD box. The spread measures the difference between these two boxes: spread = [GN_PEAD – BN_PEAD].

We control for the risk factors and variables that have been shown to be relevant for the UK stock market (e.g. Jiang, Soares and Stark, 2016). These include (i) size measured as the market value of the company at the fiscal year end, (ii) book-to-market which is the ratio of common shareholder's equity to the market value of the company at the day of fiscal year end, (iii) momentum which is measured as the buy and hold market adjusted return over the six months prior to the earnings announcement, (iv) the effect of R&D, captured by the ratio of R&D expense to the market value of the company, (v) leverage, measured as total debt divided by the market value of the company at the fiscal year end, (vi) the cash flow effect, captured by the ratio of operating cash flows to the firm's total assets, (vii) the natural logarithm of the share price at the begging of the accumulation period, and (viii) capital expenditures divided by the market value at the fiscal year end. In each case we control for these risk factors by means of the quintile rank of the corresponding variables (e.g. Hirshleifer, Myers, Myers and Teoh, 2008). In Appendix 2 we provide details on how these variables have been estimated.

Building on the evidence for the PEAD reported for the UK (e.g. Liu et al., 2003) and the US (e.g. Ayers et al., 2011), we predict a positive and statistically significant coefficient α_1 denoting an abnormal returns continuation along the sign of the earnings surprise $RUE_{i,t}$. In order to test Hypotheses H1 and H2, we adjust (1) by partitioning the association between the earnings surprise and subsequent returns in the presence of informed contrarian (*Ctrar*) and confirmatory (*Cfirm*) insider trading. Specifically, we modify (1) as follows:

$$BHAR_{i,t} = \beta_0+\beta_1 Ctrar\_RUE_{i,t}+ \beta_2 Cfirm\_RUE_{i,t} + \beta_3 NT\_RUE_{i,t} + \beta_4 Ctrar_{i,t} + \beta_5 Cfirm_{i,t} + \beta_6 Controls_{i,t} +\varepsilon_{i,t} \quad (2)$$

where, $Ctrar\_RUE_{i,t}$ equals to $RUE_{i,t}$ when directors engage in contrarian trading after the earnings announcement, and zero otherwise; $Cfirm\_RUE_{i,t}$ equals to $RUE_{i,t}$ when directors engage in confirmatory trading after the earnings announcement, and zero otherwise; $NT\_RUE_{i,t}$ equals to $RUE_{i,t}$ when directors abstain from trading after the earnings announcement, and zero otherwise. We also include the main effects of $Ctrar_{i,t}$ and $Cfirm_{i,t}$ in order to control for the possible effect of contrarian and confirmatory trading on subsequent abnormal returns.

Hypothesis H1 postulates that contrarian insider trading conveys useful information on the transitory nature of the earnings surprise that attenuates the under-reaction to earnings announcements. Hence, we expect the coefficient β_1 to be insignificantly different from zero ($\beta_1 =0$) indicating that the earnings surprise is not associated with a subsequent drift. H2 predicts that the presence of confirmatory insider trades will convey information about the permanent nature of the earnings surprise, which nevertheless, involves significant uncertainty and thus, there will be a continuation of the PEAD. Therefore, we expect the coefficient β_2 to be positive and significant ($\beta_2>0$). Additionally, the absence of any insider trading implies that the additional information needed to allow the market to interpret the permanent-transitory nature of the earnings surprise is not available, and we might expect β_3 to be positive in line with the overall evidence on PEAD. The case of PEAD in the absence of insider trading will be further investigated when testing H3. Furthermore, we seek to corroborate the distinct role of directors' trading in promoting efficient stock prices as set out in H1 and H2 by comparing these coefficients, and we anticipate: $\beta_2 > \beta_3 > \beta_1$. Referring back to Figure 1, the conditional good news PEAD after contrarian insider trading is given by the GN_{ct}_PEAD box, and the conditional bad news contrarian PEAD is given by the BN_{ct}_PEAD box. So, the contrarian spread is the difference between these two boxes: Contr. Spread = [GN_{ct}_PEAD – BN_{ct}_PEAD]. Similarly, for the confirmatory spread: Conf. Spread = [GN_{cf}_PEAD – BN_{cf}_PEAD].

In order to test Hypothesis H3, we need to obtain an estimate of the earnings signal precision. Following Francis et al. (2007) we measure the earnings signal precision by means of the magnitude of discretionary accruals.[9] To construct our measure of earnings precision, we rank firms annually based on the magnitude of their discretionary accruals. We assign an earnings precision variable (PREC) which takes the value of 1 if a firm belongs to the bottom tercile of this ranking, and 0 otherwise. Observations ranked in the bottom tercile of the unsigned discretionary accruals' distribution are considered to exhibit high earnings signal precision (PREC=1) while the remaining observations are considered to exhibit low levels of precision (PREC=0).

Equation (3) then enables us to test H3 by examining the association between the earnings surprise and subsequent returns, as described in (2), conditioning on the earnings signal precision (PREC).

$$\begin{aligned} BHAR_{i,t} = {} & \gamma_0 + \gamma_1 Ctrar\_RUE_{i,t} + \gamma_2 Cfirm\_RUE_{i,t} + \gamma_3 NT\_RUE_{i,t} \\ & + \gamma_4 Ctrar\_RUE_{i,t} * PREC_{i,t} + \gamma_5 Cfirm\_RUE_{i,t} * PREC_{i,t} + \gamma_6 NT\_RUE_{i,t} * PREC_{i,t} \\ & + \gamma_7 Ctrar_{i,t} + \gamma_8 Cfirm_{i,t} + \gamma_9 PREC_{i,t} + \gamma_{10} Controls_{i,t} + \varepsilon_{i,t} \end{aligned} \tag{3}$$

The coefficients of particular interest in (3) are the coefficients γ_1 and γ_5. These coefficients represent respectively: the influence of contrarian insider trading in low earnings precision firms (*PREC=0*) where the PEAD is most prevalent; and the role of confirmatory insider trading in high earnings precision firms (*PREC=1*), where it has been shown that the PEAD is largely absent. Consistent with the distinctive ability of contrarian insider trading to facilitate investors' learning under low earnings precision, H3a predicts that γ_1 would be insignificantly different from zero. H3b predicts that even for high precision firms investors will be sensitive to the confirmatory directors' trades, and therefore we anticipate $\gamma_5 > 0$. In the absence of insider trading, we anticipate a negative and significant coefficient γ_6. This is because in the absence of insider trading, the information acquisition process is largely based on the underlying fundamentals as suggested by Francis et al. (2007).

[9] The main tests in Francis et al. (2007) employ a model that relies on a long time series of data and is based on Dechow and Dichev (2002). However, they report similar results when using the proxy that we employ here (cf. page 427 of their paper).

5 Data and empirical proxies

5.1 Data

We collect data for all UK non-financial companies listed in both the MAIN and the AIM markets for the period between 1995 and 2013. This yields an initial sample of 19,804 observations. Requiring an intersection between Datastream and I/B/E/S Detail History files to collect the necessary data for estimating the earnings surprise variable, we lose 9,366 data points mainly due to missing earnings announcements.[10] We note that requiring this intersection between Datastream and I/B/E/S datasets introduces a selection bias against the inclusion of very small and illiquid companies without an analyst following. We define the earnings surprise as:

$$UE_{i,t}=(Actual\_EPS_{i,t}-Forecasted\_EPS_{i,t})/P_{i,t-1}$$

where, $Actual\_EPS_{i,t}$ is the actual earnings per share reported in I/B/E/S for year *t*; $Forecasted\_EPS_{i,t}$ is the single most recent forecast made by the timeliest analysts prior to the earnings announcement;[11] and $P_{i,t-1}$ is the stock price at the previous fiscal year end. We convert $UE_{i,t}$ into quintiles of earnings surprises based on the magnitude of the surprise. We acknowledge that not all companies announce earnings at the same time and the distribution of earnings surprises might not be known prior to the portfolio formation date. Therefore, we define the quintiles of the earnings surprises from the distribution of the preceding year's surprises. We further eliminate 2,044 observations due to missing market data from Datastream, and a further 7 observations are eliminated due to missing accounting data that are necessary for the calculation of discretionary accruals.[12] Trimming buy-and-hold abnormal returns as well as the variables involved in the estimation of the discretionary accruals at the 2st and 98th percentiles of their distributions reduces further the sample by 334 firm-year observations. These selection criteria yield a final sample of 7,980 firm-year observations from 1,373 different firms, of which 1,524 firm-year observations and 429 firms are AIM-listed. Table 1 summarises the sample selection procedure.

TABLE 1 ABOUT HERE

5.2 Abnormal returns

We measure the post earnings announcement returns as the buy-and-hold market adjusted returns beginning from the 11th day and ending six months later, relative to the earnings announcement. We calculate returns using daily prices and dividends from Datastream given the concerns in Ince and

[10] We require the annual final earnings announcements to be available in Datastream or I\B\E\S, and ignore any interim announcements. After eliminating earnings announcements announced more than 200 days after the fiscal year end, we supplement the earnings announcements in Datastream from I\B\E\S and choose the earliest given the concerns of I\B\E\S reliability (Hung, Li and Wang, 2014). Most UK companies also report interim earnings announcements after six months, but a small number report quarterly interim earnings announcements. We undertake a robustness check of our results and exclude the 75 firms that make quarterly announcements.

[11] Following Bartov, Givoly and Hayn (2002), we only consider the latest forecast preceding the earnings announcement by at least three days. Using the latest forecast is quite common (e.g. Bartov et al., 2002; Ayers et al., 2011) and is known to be more closely related to the market reaction at the earnings announcement (Brown and Kim, 1991). We further exclude forecasts preceding the earnings announcement by more than 200 days to prevent stale forecasts being included in the analysis.

[12] We eliminate firm year observations whose accounting reporting period is less than 340 and more than 380 days (similarly to García Lara, García Osma and Mora, 2005).

Porter (2006) with regard to returns estimated from the Return Index (RI) data-item. Following Lee (2011) we drop any day where more than 90% of the shares outstanding are not traded (i.e. have zero return on that day). Furthermore, in order to filter out suspicious stock returns, we follow Chui, Titman and Wei (2010) and set returns that are greater than 100% (-95%) equal to 100% (-95%). Finally, thin trading leading to missing returns may also compromise our statistical inferences, and therefore we calculate trade-to-trade returns (Maynes and Rumsey, 1993). Specifically, trade-to-trade returns are calculated from non-missing price days. For a stock with a missing price, the corresponding portfolio return is added to the next non-missing price day's portfolio return for a trade-to-trade abnormal return calculation.[13] In addition, to reduce the influence of our thin trading adjustment on abnormal returns, we follow Hung et al. (2014) and require firms to be traded for at least 70% of the trading days within our measurement period.

5.3 Insider trading

Information on directors' trading is from the Hemmington Scott Directors' Trading Dataset. In line with prior research in the UK (e.g. Fidrmuc et al., 2006), we define insider transactions as purchases or sales by both executive and non-executive directors, but we allow for a number of different definitions of the directors trading signal. A common definition is the net purchase ratio (e.g. Beneish and Vargus, 2002), and we employ this firm-specific measure of net insider trading, aggregating all directors' trading activity within a period, as follows:

$$NPR = [PURCHASES - SALES]/[PURCHASES+SALES] \qquad (4)$$

where *PURCHASES* is the value of shares purchased by directors and *SALES* is the value of shares sold in the period after the earnings announcement. A positive *NPR* could be the result of directors purchasing more shares or selling fewer shares and *vice versa* for a negative *NPR*. A positive *NPR* indicates net insider buying, whereas a negative *NPR* indicates net insider selling. *NPR* is estimated using only open market purchases and sales of common shares in line with Veenman (2012) . A possible criticism of the *NPR* in equation (4) is that it does not take into account the relative importance of directors' trades in terms of their personal wealth: a trade which represents only a small percentage of the shares already owned by the director is likely to be less informative than a trade with a substantial impact on the directors' wealth. We address this concern by estimating a "weighted-NPR", where the weights applied are estimated as the ratio of the respective trade-size to the shares owned by the director. In the case of a single director trading, this will have no effect on the definition of a buy or sell signal. However, when many directors trade, the weighted-NPR depends on weights attached to the respective trades. We also employ an alternative measure which identifies the direction of the insider trading signal based on the direction of the majority of directors' trading. We refer to this signal as "Net trades", and in this case a buy signal would be defined when more directors are buying shares than directors selling shares, and vice versa for a sell signal. Finally, we acknowledge that in the presence of conflicting transactions (e.g., some directors sell and some buy), the insider trading signal may be ambiguous. In contrast, when all directors trade in the same direction, the trading signal is likely to be strong and clear. Our

[13] An alternative approach is to calculate lumped returns which consist of trade-to-trade returns on non-missing price days and zero on missing price days with no adjustment to the portfolio return when returns are missing, given that this procedure does not allow for missing returns. Using lumped returns, instead of trade to trade, does not alter our conclusions.

final definition of a directors trading signal is based on "Consistent trades", when multiple directors in a given company all trade in the same direction.

We provide summary statistics on the sample of directors' trades both before and after the earnings announcement in Table 2. Each panel reports the value of directors' purchases and sales (which are fewer in number but larger in value), the daily net value of these trades across directors trading in the same firm, and the NPR calculated over the relevant period. We organise the presentation of this data across various windows of insider trading observation around the earnings announcement day (0): Panel A reports the insider trading statistics over the period of 72 days before the earnings announcement to 10 days after it (-72, +10); Panel B captures the period preceding the trading ban (-72, -42) and Panel C covers the trading ban period (-41, -1). In Panel D, we identify insider trading transactions that are disclosed within the first ten days after and including the earnings announcement, which also coincides with the end of the trading ban. Additionally, Panel D presents summary statistics for the four alternative proxies of the insider trading signal employed here: (NPR, weighted-NPR, Net trades and Consistent trades) corresponding to the top and bottom quintiles formed on the basis of the earnings surprise. Note that both NPR and weighted-NPR are scaled to lie between (-1, +1). Figure 2 summarises the information in Table 2 and shows the number of daily insider trading transactions across all firms in our data set around the time of an earnings announcement (day 0), from 72 days before the earnings announcement to 10 days after. The figure confirms the effectiveness of the trading ban starting from approximately 42 (trading) days before the earnings announcement.

TABLE 2 AND FIGURE 2 ABOUT HERE

Figure 2 indicates that the incidence of directors' trading in the period after the earnings announcement is dramatically higher than in the period before the earnings announcement, and motivates our choice of a 10-day post-announcement period to compute our directors trading measures. The figure confirms insiders' reluctance to trade before the announcement and preference to delay their trades as the former may expose them to litigation or reputation costs. In particular, the patterns of directors trading presented on Figure 2 demonstrate that they trade as early as the earnings announcement day and these trades are disclosed to the market in a timely fashion.

5.4 Discretionary accruals

We estimate discretionary accruals in a two-stage procedure. In the first stage we use the Modified Jones (1991) model to predict the level of "non-discretionary" accruals as a function of the growth in revenues and gross property, plant and equipment. Specifically, we run a regression of total accruals for firm *i*, year *t* and sector *j* (two- digit ICB industry classification[14]) on the change in revenues and gross property, plant and equipment where all variables are scaled by the beginning total assets for each year. The second stage predicts the non-discretionary component of accruals using the estimated coefficients from the first stage. Note that in second stage, the influence of the cash sales is also taken into account by introducing the change in receivables, similarly to Dechow, Sloan and

[14] The two digit ICB provides 15 industry classifications where the equivalent SIC leads to 66 industry classifications, excluding missing and financial observations. We require at least 6 observations for each industry-year sub-sample (similarly to García Lara et al., 2005).

Sweeney (1995).[15] The "non-discretionary" part of the accruals then represents an estimate of the expected level of accruals and the remaining component is presumed to include managements' discretion on accruals. Moreover, since performance might also be a determinant of the level of accruals, the estimated discretionary accruals here are also "performance adjusted" in the manner advocated by Kothari, Leone and Wasley (2005) by adding return on assets (ROA) as an additional explanatory variable in the estimation of "non-discretionary" accruals. Since firms do not announce their earnings on the same day or time of the year, the variables used to calculate discretionary accruals are not available for all firms in the same industry-year portfolio. Therefore, the entire distribution of discretionary accruals is typically unknown to the investors at the earnings announcement and, as a result, the hedge portfolio strategies that underlie our investigation cannot be implemented. Following Louis and Sun (2011), we address this issue by estimating the accrual model one year prior to the portfolio formation and then applying the estimated coefficients to the second stage of the estimation process and using the cut-off points from the year before (similar to the quintile ranks of the earnings surprise).

6 Analysis

6.1 Results

Table 3 presents the initial univariate evidence on the post earnings announcement buy-and-hold market adjusted abnormal returns over the six months period (+11, +125) after the earnings announcement. Panel A shows returns corresponding to the top and bottom quintiles of earnings surprises. The spread in returns between the top and bottom quintiles supports the presence of under-reaction to the earnings announcement. The average abnormal returns in the top quintile of earnings surprises are larger (+ 2.3%) than those in the bottom quintile (-1.1%), and this difference (+3.4%) is statistically significant, confirming the presence of the PEAD anomaly in the UK.

TABLE 3 ABOUT HERE

Panel B of Table 3 demonstrates the effect of conditioning these buy-and-hold abnormal returns on contrarian insider trading. In the presence of contrarian insider trading, the average buy and hold abnormal return over six months following the earnings announcement for the observations in the top quintile of the earnings surprise has a smaller magnitude than the corresponding figure for the observations in the bottom quintile. Moreover, the magnitude of the returns in both quintiles is low and not significantly different from zero. Confirming our first hypothesis H1, this finding suggests that in the presence of contrarian trades, the market interprets the earnings surprise as a transitory change in the earnings process and thus, does not capitalise its magnitude into share prices: there is no subsequent market reaction and the PEAD is mitigated. In contrast, the results in Panel C show that when there are confirmatory insider trades, the market infers that there has been a permanent change in the earnings process. Prices continue to move along the direction of the earnings surprise indicating that the market considers that the earnings surprise has information about a permanent change in the earnings process. The PEAD anomaly is particularly pronounced among this set of observations as the return spread between top and

[15] The change in receivables is included in order to control for managers' attempts to manipulate earnings through discretionary revenues

bottom earnings surprise quintiles is 7.3%. Further analysis indicates that this result is driven by the effect of insider purchases rather than sales. Being a costly and hence, credible signal of good prospects, confirmatory purchases represent a strong signal that insiders regard the earnings surprise as reflecting a permanent change in the earnings process. Panel D reports the univariate results for earnings announcements with no subsequent directors' trades. In this case the drift is similar to the pooled sample, but is smaller than in Panel C, highlighting the exacerbated response to confirmatory trades accelerates investor learning. Evidence of PEAD in the absence of directors' trading implies that directors' trading can only partly explain the PEAD.

Table 4 reports the multivariate implementation of model (1) and provides evidence of an under-reaction to earning announcements after controlling for risk factors relevant to the UK stock market. In addition, the regression employed here takes into account the panel structure of the data using firm- clustered standard errors and year fixed effects. Evidence on the PEAD anomaly is shown by the positive and significant coefficient of *RUE;* as explained in Section 4, the coefficient on *RUE* represents the spread in average abnormal returns between observations in the highest and lowest unexpected earnings surprise quintiles. The spread results reported in the first column of Table 4 provide significant evidence of PEAD (0.020; p-value<0.05) even after controlling for size, momentum, book to market and other risk effects.

TABLE 4 ABOUT HERE

The results from testing hypotheses H1 and H2 are reported in the last four columns of Table 4. Consistent with our univariate tests, we find no significant evidence of under-reaction to the earnings surprise in the presence of contrarian insider trading. Specifically, the coefficient on *Ctrar_RUE* denoting the spread in average abnormal returns in the presence of contrarian trading, is -0.039 and statistically insignificant when we define insider transactions based on the net purchase ratio. We report similar results when we use the alternative definitions of the directors' trading signal. These findings support our hypothesis H1 with respect to the role of contrarian trading in mitigating the PEAD. In contrast, confirmatory insider trading conveys information to the market that there has been a permanent change in the earnings process. This is denoted by the magnitude and significance of the *Cfirm_RUE* coefficient across all alterative definitions of the insider trading signal. (e.g. 0.087; p-value<0.01 when defining directors' trading signal based on NPR). In the absence of directors' trading there is still significant evidence of the PEAD as reflected by the value of the coefficient on *NT_RUE* across all definitions of directors' trading signal (e.g. 0.019; p-value<0.05 when defining directors' trading signal based on NPR). Share prices continue to move along the direction of the surprise, but the drift is less pronounced than in the case of confirmatory directors' trade. This would suggest that directors' trades cannot completely explain all of the PEAD, but there may well be other sources of information available to investors' post-earnings announcement enabling them to infer the permanent-transitory nature of the earnings surprise.

To further support our evidence with respect to the information conveyed by contrarian and confirmatory insider trading about the permanent-transitory nature of earnings surprise we test whether the coefficients are statistically significantly different from one another using Wald tests. Collectively, the results indicate that the coefficient of *Cfirm_RUE* is significantly higher than the coefficient of *NT_RUE* which in turn, is larger than the coefficient of *Ctrar_RUE.* This hierarchy highlights the distinctive effect of insider trading upon the PEAD and is in line with our predictions as illustrated in Figure 1. Overall, these findings confirm the important role for directors' contrarian trading in alleviating the PEAD anomaly while confirmatory insider trading explains, in part, the PEAD.

The proposition advanced in the development of hypotheses H1 and H2 is that the disclosure of informed insider trading provides relevant information to the market that accelerates investors' learning on the transitory-permanent nature of the earnings surprise. In Table 5, we provide further support to our hypotheses by examining the influence of earnings precision on the speed at which investors incorporate the news about the earnings surprise.

TABLE 5 ABOUT HERE

Francis et al. (2007) argue that low earnings precision delays investors' learning and hence, aggravates the under-reaction to earnings announcements. In line with this argument, we find that the PEAD is more pronounced and significant under circumstances of low earnings precision. In the first column of Table 5, we report that the coefficient of RUE_{it} is positive and significant (0.031; p-value <0.01), but the PEAD dissipates as earnings precision increases (denoted by the interaction between PREC and RUE: -0.035; p-value<0.10).

The remaining four columns in Table 5 present the results of testing the two parts of Hypothesis H3 for the four alternative proxies of insider trading signals. In H3 we predict that the insider trading signal initiates a learning process which is distinctive from the learning process underlying the earnings precision. That is, we expect that contrarian directors' trading has a distinct ability to unravel the earnings process even under circumstances where we expect that the PEAD should occur (H3a). The tests reported in Table 5 confirm this hypothesis by means of the small magnitude and insignificant coefficient of *Ctrar_RUE*, when the earnings precision is low. This result is in contrast to the coefficients of *Cfirm_RUE* and *NT_RUE* both of which are significant and large in magnitude. A comparison of the coefficients reported in the "*Low earnings precision*" panel supports this inference.

Analogous to H3a, hypothesis H3b predicts that confirmatory trades will initiate an exacerbated PEAD even under circumstances where the PEAD is not expected to occur. The results reported on Table 5 support this prediction. First, we find that the coefficient of *Cfirm_RUE* is large and significant. The coefficient of *Cfirm_RUE* captures the PEAD anomaly for those firms with low earnings precision (PREC=0) in the presence of confirmatory insider trading, and its estimated value is 0.065 with a p-value <0.10, in the case of the NPR signal. More importantly, the coefficient of the interaction between *Cfirm_RUE* and *PREC* is positive and insignificant denoting a persistent PEAD, even under circumstances of high earnings precision. Again, the results from a comparison of the coefficients reported in the "*High earnings precision*" panel re-affirm this inference: under high earnings precision, the PEAD is present only when directors trade in a confirmatory direction.

Finally, when directors are not trading, we find that the earnings precision effect dominates, with the absence of insider trading in low precision firms, denoted by *NT_RUE*, producing a coefficient that is positive and significant (0.036; p-value <0.05). High precision earnings mitigate the uncertainty as reflected by the significant negative coefficient of the interaction between *NT_RUE* and *PREC*. The contrast between the results in the absence of insider trading and the results discussed earlier serves to attest to the distinctive effect of insider trading on the PEAD.

6.2 Sensitivity tests

We conduct a series of sensitivity checks to confirm whether our findings are robust to alternative definitions of the key variables. These results are available in an On-line Appendix 3, but we summarise the main findings here. It might be argued that the apparent PEAD anomaly, identified in Table 3 and in the first column of Table 4, may be spurious if it is not economically important, even though it is statistically significant, since it might not be possible to design a trading strategy that implements the apparent anomaly.[16] We have therefore re-estimated the initial multivariate PEAD regressions (first column Table 4) on the significance of the spread between top and bottom quintile portfolios (formed from earnings surprises) using implementable returns following Soares and Stark (2009). We use a "June-strategy" and rank firms each year according to their unexpected earnings at the end of June. Subsequently, we measure returns from the beginning of July and for six months using daily returns as in our original tests. The spread on the RUE coefficient remains positive and significant, so the original PEAD is robust to implementable returns; and there is an anomaly to be explained.

In a second robustness test we assess the PEAD over alternative time horizons (2, 3, 4, and 5-months), and we find that the unconditional spread is always significantly positive, with values of 1.3% for the 2-month, 0.9% at the 3-month and 4-month horizons, 2.0% at the 5-month horizon, and increases to 3.4% (as reported in Table 3) at the 6-month horizon. In the presence of contrarian trades, at all horizons this spread is not significantly different from zero. In contrast, conditioned on confirmatory trades, the spread is significantly positive, and the median spread increases with the time horizon. The multivariate regression results for 2-month, 3-month 4-month and 5-month post-earnings announcement time horizons confirm that conditioning on contrarian trades, the PEAD spread evaporates, but is exacerbated in the presence of confirmatory trades. To further confirm that the effect of insider trading on the PEAD is distinct from the initial short term reaction to its disclosure (Veenman, 2012), we delay the starting date of return accumulation. Rather than starting on day (+11), we start the accumulation on day (+21) and we observe the PEAD over the subsequent 5-months period. The unconditional spread is now even wider (+2.4%) and our inference with respect to the effect of insider trading remains unchanged.

Third, we check the sensitivity of our results to the period over which we observe the insiders' signal. Instead of calculating the directors' trading signals over the 10-day period after the earnings announcement, in a third set of tests we calculate the four alternative signals over the period (0, +5) and (0, +17), starting the return accumulation over six months from day +6 and +18 respectively. We find that the unconditional PEAD spread, and the PEAD spread conditioned on confirmatory and contrarian trades are of the same order of magnitude as the reported results in Tables 3 and 4,

[16] As we discuss in the research design we determine the cut-off points of the quintile ranks of the earnings surprise and earnings precision by the distribution of the earnings surprise and discretionary accruals in the previous year in order to ensure that the portfolio strategies are implementable similar to Louis and Sun (2011).

although with the short (0, +5) directors' trading period, we lose some significance because the numbers of observations with directors' trading is smaller.

Fourth, we exclude 370 observations from 75 companies that report quarterly interim reports after the annual earnings announcements. Fifth, we exclude 439 firms that were listed on AIM, rather than the Main Market on the basis that trading in these firms is likely to be relatively illiquid. Finally, we partition our earning precision measures in terms of quintiles instead of terciles. In all cases the results are consistent with the main findings with respect to the effect of contrarian and confirmatory directors trading on the PEAD.

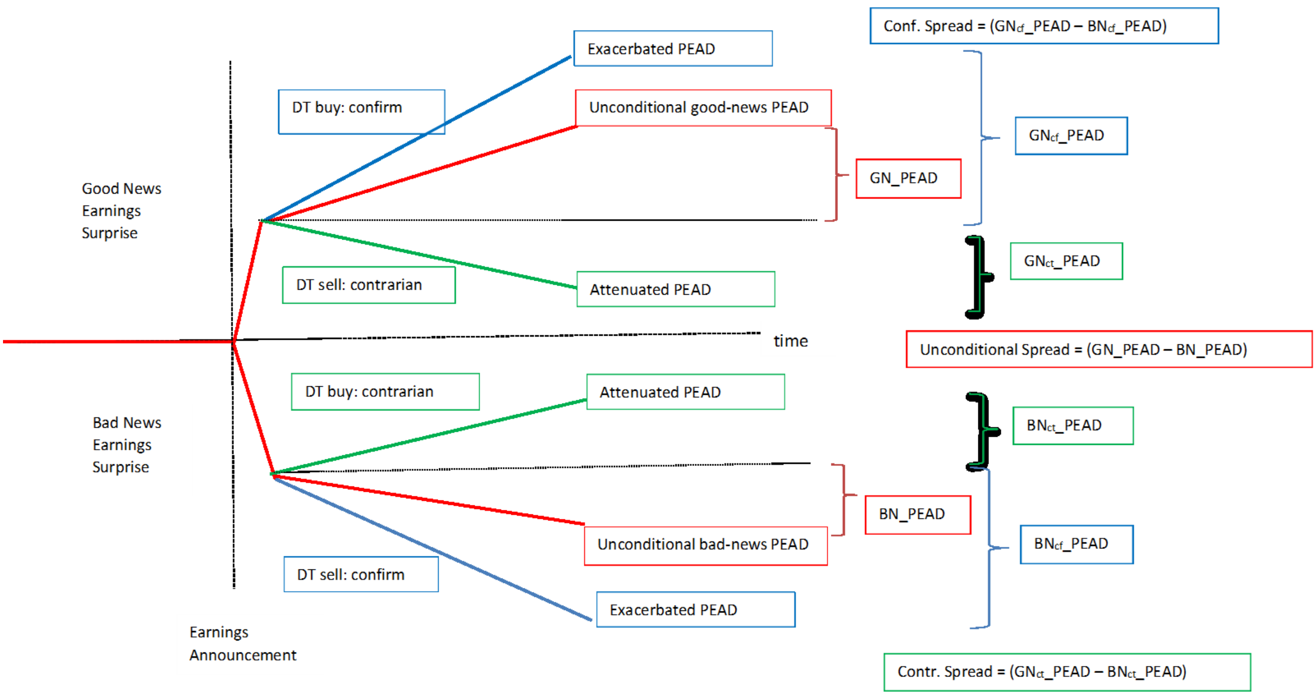
7 Conclusions

In this paper we have argued that the PEAD is a consequence of investors learning and updating their beliefs as to whether a structural change has occurred in the earnings process. When companies announce unexpectedly high or low earnings, investors must establish the implications of the earnings surprise for future earnings: does the earnings announcement represent a transitory change in profitability or a permanent change in earnings to a new average level? Directors trading immediately after the earnings announcement provide additional information on the transitory or permanent nature of the earnings surprise. Given directors' access to inside information we would expect them to be in an advantageous position to assess the valuation implications of an earnings surprise. If directors sell after good news, or buy after bad news – in other words trade in a contrarian direction to the earnings surprise - this suggests that the director believes that the earnings surprise reflects only a transitory change in the earnings process and therefore, it will not support a further change in the share price along the direction of the earnings surprise. We also examined directors buying after good news and selling after bad news, and such confirmatory trades suggest directors consider the earnings surprise to represent a permanent change in earnings. Nevertheless, we note that in the case of confirmatory trades, investors may have difficulty in assessing the new permanent levels of equilibrium share prices resulting in a stronger drift.

We find that conditioning stock price movements after an earnings announcement on contrarian and confirmatory directors' trades sheds light on the well-documented anomaly, the market under-reaction to earnings announcements, or PEAD. Recognising that the under-reaction represents a delayed response to the earnings surprise, we demonstrate that contrarian directors' trades mitigate the PEAD, and confirmatory trades allow for a continuation of the PEAD as prices to continue to move in the direction of the earnings surprise. Further analysis demonstrates that contrarian trades guide the market to establish that the earnings surprise does not consist a permanent shift in the earnings process even in hard-to-value firms with low earnings precision. On the contrary, confirmatory trades initiate a learning process to establish the shift in the earning process even under circumstances where this is not likely to occur, i.e., under high earnings precision. Taken together these results speak to the particular effect of insider trading on the long-term price discovery.

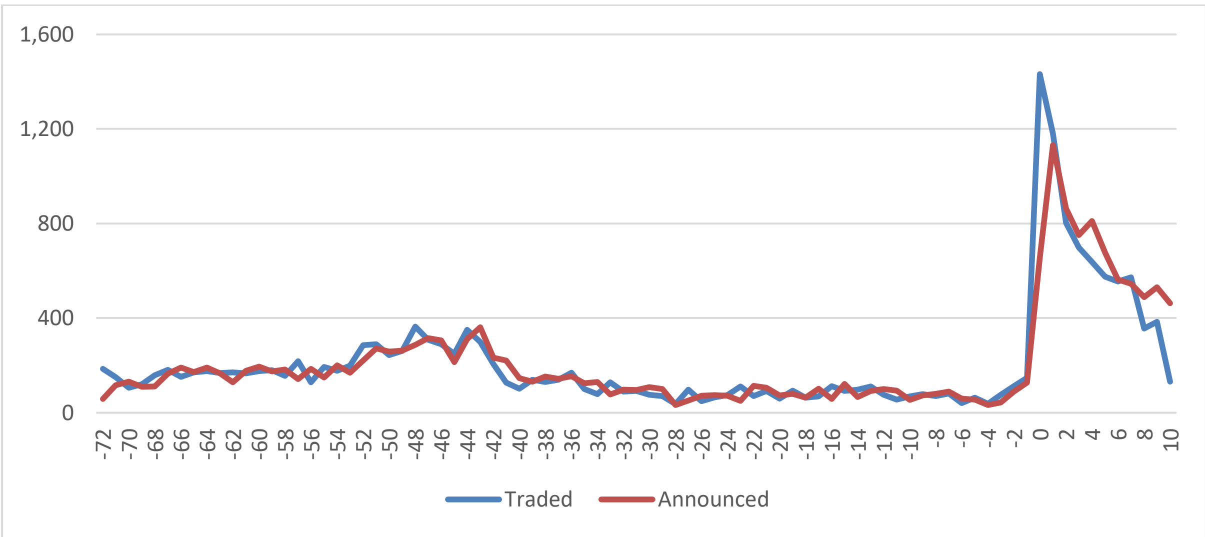
A caveat to these findings is that insider trading can only in part explain the PEAD. Although our study contributes to the understanding of the PEAD anomaly from a learning mechanism perspective, further research could identify other sources of information that investors use to update their beliefs on structural changes to the earnings process.

Figure 1: Predicted effects on stock prices of directors' trading after an earnings announcement



Notes: The figure shows predicted stock market responses after the earnings announcement and post-earnings announcement directors' trades, and the effect of conditioning on confirmatory and contrary directors' trades (DT).

Figure 2: Number of directors' trades per day around earnings announcements



Notes: The figure shows the total number of daily directors' trades up to 72 days before an earnings announcement and 10 days after. The trading ban is in place from day -42 to day 0. The blue line denotes days when the directors' trades occur, and the brown line denotes days when the directors' trades are reported to the market.

Table 1: Sample Selection process

19,804		**Initial sample of firm-year observations** The initial sample consists of all publicly listed companies in the UK between 1995 and 2013 with available accounting data. In identifying the firms that have been listed in the UK, we use Datastream's research lists of active (GRP1-6) and dead companies (DEADUK1-7). From these lists we eliminate duplicates, instruments which are not classified as equity, non-primary issues and financial firms (based on ICB industry classification).
(11,824)		Total firm-year observations excluded, of which:
	(9,366)	Missing earnings announcements. We require the earnings announcements to be available in Datastream or I\B\E\S. We use the earliest earnings announcement reported in Datastream or I\B\E\S after eliminating earnings announcements announced 200 days after the fiscal year end.
	(73)	Missing data needed to estimate unexpected earnings
	(2,044)	Missing returns data needed to estimate returns
	(7)	Missing accounting data needed to estimate earnings precision
	(334)	Outliers removed
7,980		**Final sample: [*firms =1,373*]**

Notes: The table provides descriptive statistics on the sample of directors' trades (by executive and non-executive board members) in their own company shares across 1,373 firms over the period 1995-2013 in the 92-day period (-72,+10) around the annual earnings announcement. Panel A documents directors' trading statistics for the full sample period; Panel B for the period (-72, -42) before the trading ban; Panel C for the period (-41, -1) during the trading ban; Panel D for the period (0, +10) after the earnings announcement which is made at the start of day 0. The first and second rows of each panel shows the distribution of the value of shares purchased and sold; the third row shows the distribution of the net daily shares traded across directors in the same firm (positive for buys, and negative for sales) by value of shares traded; and the fourth row shows the distribution of the NPR calculated at the firm level for the relevant sample period by value of transactions. NPR is defined as the net value of shares traded scaled by the value of shares traded, and hence lies between (-1, +1). The fifth and sixth rows of Panel D show the distribution of NPR for the bottom and top quintile portfolios formed by earnings surprise. The seventh and eighth rows of Panel D show the distribution of Weighted NPR for the UE5 and UE1 quintile portfolios, where weighted NPR accommodates the effect of directors' shareholding wealth. The ninth and tenth rows of Panel D show the distribution of Net trades for bottom and top quintile portfolios, where Net trades is defined as the (unscaled) difference between the number of buy and sell signals. The last two rows

Notes: Table reports univariate six-month buy-and-hold portfolio returns after earnings announcement for quintiles of high earnings surprises (UE 5) and low earnings surprises (UE 1), and spread portfolio between these two portfolios (UE 5 – UE 1). Panel A reports buy-and-hold returns (BHARs) for the full sample. Panel B reports BHARs for sample of contrarian insider trades, and Panel C reports BHARs for sample of confirmatory insider trades. Panel D reports BHARs for a sample of firm announcements after which there are no directors' trades. In all cases the directors' trading signal is based on the net purchases ratio, NPR.

Notes: The first column of the table reports the results from estimating equation (1) and the remaining four columns report the results from estimating (2) under alternative definitions of the directors' trading signal: the second column presents the results when directors trading signal is based on the net purchase ratio (NPR); the third column when directors trading signal based on the weighted net purchase ratio, where weights depend on directors' shareholding wealth (weighted NPR); the fourth column when directors trading signal defined by majority of the directors are trading in the same direction (Net trades); and last column when directors trading signal depends on multiple directors all trading in the same direction (Consistent trades). UE is quintile rank of earnings surprise where unexpected earnings is calculated as the difference between the I/B/E/S actual reported earnings and the single most recent forecast deflated by the stock price; RUE stands for rescaled unexpected earnings quintiles, and equals -0.5 if the firms belongs to the lowest quintile of UE, 0.5 if a firm belongs to top quintile of UE and zero otherwise; *Ctrar*_RUE equals to RUE in the presence of informed insider trading, and zero otherwise; *Cfirm*_RUE equals to RUE in the presence of non-informed insider trading, and zero otherwise; NT_RUE equals to RUE when directors abstain from trading. Risk controls included: Q5MM, quintile rank of momentum measured as the buy-and-hold market adjusted returns over the 6 months up to the earnings announcement; QBM, quintile rank of the book to market ratio; QMV, quintile rank of the market value of the company measured at the fiscal year end for each company; Q5LEV, quintile rank of leverage; Q5RD, quintile rank of the ratio of research and development to market value; Q5SP, quintile rank of the natural logarithm of the share price measured at start of the return accumulation period; Q5CFO, quintile rank of operating cash flows divided by total assets, and Q5CC, quintile rank of capital expenditures divided by market value. Dependent variable is buy-and-hold abnormal return in excess of market return. Terms in brackets are t-statistics, computed from standard errors clustered at the firm level, and where *, ** and *** denote significance at the 10%, 5% and 1% respectively.

Notes The first column of the table reports the results from estimating equation (3) before taking into account directors' trades; the remaining four columns report the results from estimating (3) including directors' trading variables. PREC takes value of 1 if a firm belongs to the bottom tercile of the magnitude of discretionary accruals, and 0 otherwise. The remaining variables and risk controls are explained in the footnote to Table 4. Terms in brackets are t-statistics, computed from standard errors clustered at the firm level, and where *, ** and *** denote significance at the 10%, 5% and 1% respectively.

Appendix 1: Illustration of learning and a delayed response to earnings information

We consider a simple example to illustrate how investors updating their beliefs about a shock to the earnings process, can explain the documented PEAD. The purpose of this example is to show that with a structural change and parameter uncertainty there will be a delayed response to an earnings announcement, as Bayesian investors update on other relevant pieces of information associated with the structural change. There will be a pattern in stock prices following the structural change.

Suppose earnings (e_t) are generated by a uniform distribution $U(.)$, with support $(0, W_0)$. The present value model, with an earnings announcement imminent, would price this earnings stream as $p_{t-1} = 0.5W_0(1 + \delta)$, where δ is the appropriate discount factor. Realised earnings are then announced, and prices jump to $p_t=e_t+0.5\delta W_0$. At some point after the announcement the price will go ex-dividend, and the stock price will revert to its long-run expected value $(=0.5\delta W_0)$.

Suppose the announced realised earnings are above the upper support of the original uniform distribution: $e_t > W_0$. This event represents a structural change: the earnings process is still generated by a uniform distribution $U(0, W)$, but the distribution of the earnings process has changed, with parameter uncertainty about the new upper limit W. We assume that investors update their beliefs about the unknown parameter W according to Bayesian rules. Following De Groot (1970) Section 9.7 Theorem 1, a conjugate prior for the likelihood function being a uniform distribution is the Pareto distribution with parameters (w_0, α), meaning that the posterior distribution for W after observing a single piece of sample information x_1 from the uniform distribution, is also Pareto with parameters (w_0', α') where $w_0' = max\ (w_0, x_1)$ and $\alpha' = \alpha+1$. In the Pareto distribution w_0 is the minimum possible value of W and α is a positive parameter that reflects the shape of the distribution, and reflects the range of possible values of W above the scale parameter w_0. Over time, as more sample information is accumulated, the scale parameter is updated in the posterior distribution to mimic any higher realised values, and over time the shape parameter in the posterior distribution gets larger and the range of upside values above the scale parameter is reduced.

Figure 1 illustrates the initial uniform distribution $U(0, W_0)$, and the post-structural change uniform distribution $U(0, W)$, with the prior beliefs represented by a Pareto distribution of the unknown parameter W. The mean and variance of the Pareto distribution is given by

$$E(W) = \frac{\alpha w_0}{\alpha - 1}\ and\ Var(W) = \frac{\alpha w_0^2}{(\alpha - 1)^2(\alpha - 2)}$$

Which represent the prior beliefs about W. Given the sample information x_1, posterior mean and variance is:

$$E(W|x_1) = \frac{(\alpha + 1){w_0}'}{\alpha}\ and\ Var(W|x_1) = \frac{(\alpha + 1)w_0'^2}{\alpha^2(\alpha - 1)}$$

A reasonable candidate for the prior value of w_0 is the realised earnings announcement e_t, and so α represents the strength in the beliefs that e_t is the upper support of the new distribution, or whether the upper support is even higher.

<u>Prices at date *t* (the earnings announcement):</u> Following the unexpected earnings $e_t > W_0$, prices will jump to $p_t = w_0\left(1 + 0.5\delta\frac{\alpha}{\alpha-1}\right)$ which is based on the prior for the Pareto distribution, and is unambiguously higher than in the case of no structural change. Subsequent movements in prices after the earnings announcement depends on any additional sample information provided by whether there is trading by informed insiders or not. The piece of sample information that investors observe is whether a director trades on the day after the earnings announcement, or does not trade. Directors know the true value of *W*, and hence know the true fundamental price $p_t^f = (w_0 + 0.5\delta W)$, which differs from the market price depending on whether $W \geq \frac{\alpha w_0}{\alpha-1}$ investors believe that directors will buy shares if the stock price is $p_t < p_t^f$, and not trade if $p_t = p_t^f$.

So if directors buy shares, investors infer that $W>w_0$ (since $\frac{\alpha}{\alpha-1} > 1$), which constitutes the piece of sample information, and $w_0' = max\ (w_0, I{:}\ x_1 > w_0)$ and $\alpha' = \alpha+1$. A simple price adjustment rule is that if investors observe $x_1>w_0$ they set $w_0'=w_0+1$.[17]

<u>Prices at date *t+1*:</u> In which case prices become: $p_{t+1}|\ (I{:}\,x_1 > w_0) = w_0 + 0.5\delta\frac{(\alpha+1)(w_0+1)}{\alpha} > p_t$ if $\alpha>\surd(w_0+1)$. So that following the directors' trade, prices may rise or fall depending on parameter values. For example, prices would rise if $\alpha=w_0=2$, or $\alpha=4$, $w_0=8$. In these cases, prices will rise after the market observes directors' confirmatory trading, and there will be PEAD.

On the other hand if directors do not trade on the day after the earnings announcement, investors infer that $W<w_0$, and $w_0' = max\ (w_0, I{:}\ x_1<w_0)$, $\alpha' = \alpha+1$, and prices unambiguously decline: $p_{t+1}|\ (I{:}\,x_1 < w_0) = w_0\left(1 + 0.5\delta\frac{(\alpha+1)}{\alpha}\right)$.

For some parameter values prices will fall in both cases, irrespective of the sample information because the learning effect induces an increase in the posterior precision of the unknown parameter W, (Veronesi, 1999). The price fall is always greater in the case of directors not trading. That is, the price following a directors' trade is always higher than the price with no directors' trade: $p_{t+1}|(\,I{:}\,x_1 > w_0) > p_{t+1}|(I{:}\,x_1 < w_0)$.

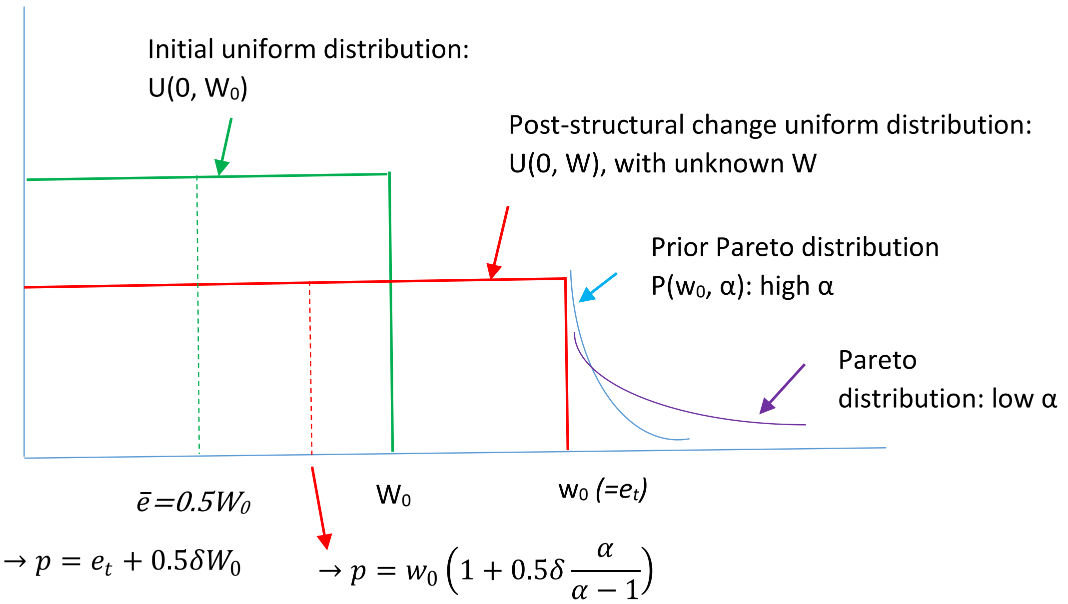
<u>Prices at date *t+2*:</u> Now we progress into the second day after the earnings announcement, and investors will again observe whether directors trade or not. Investors have new priors given by the posterior Pareto distribution from the previous time period with parameters (w_0', α'). Investors will again update their beliefs from the trading behaviour of directors in period t+2 (x_2). If there are no trades from directors, prices fall again to: $p_{t+2}|\ (I{:}\,x_2 < w_0) = w_0\left(1 + 0.5\delta\frac{(\alpha+2)}{(\alpha+1)}\right)$; but if directors trade, investors again infer that the fundamental price is above the current market price, and will update their beliefs accordingly, and prices become: $p_{t+2}|(I{:}\,x_2 > w_0) = w_0' + 0.5\delta\frac{(\alpha+2)(w_0+2)}{(\alpha+1)}$, with a sufficient condition for being greater than p_{t+1} is the same conditions as previously, so that

[17] There may be faster updating rules for prices depending upon the model that investors believe directors are following to trade strategically.

we observe a PEAD. This process will continue until market prices converge to fundamental prices, which is when directors cease trading.

This example illustrates how learning about a structural change in the context of a shock to earnings and subsequent directors' trading leads to a pattern of stock prices that with the benefit of hindsight may look predictable, but as Lewellen and Shanken (2002) observe, no Bayesian investor would be able to take advantage of this apparent predictable pattern in prices.

Figure A1: Initial and post-structural change uniform distributions for earnings process, along with prior Pareto distribution



The diagram illustrates the shift in the uniform distribution, and the Pareto prior for the unknown W. Note that the subsequent posterior distributions (which depend on the sample realisations) are not represented in this figure.

Appendix 2: Variable definitions

VARIABLE	DEFINITION	SOURCE
BHAR[a]	Buy-and-hold market adjusted abnormal return measured from +11 to +136 days relative to the earnings announcement calculated from trade to trade daily returns. For a stock not traded on a given day, the corresponding market return is added to the next non-missing price day's index return.	Datastream: Price (P), Dividend (DDE), Market return (FTALLSH)
UE	Quintile rank of unexpected earnings. Unexpected earnings are defined as the difference between actual EPS and forecasted EPS scaled by lag price. Quintilecut-off points of the earnings surprise are based on the distribution of the preceding year's surprises.	IBES: forecasted EPS IBES: actual EPS Datastream: Prices (P)
RUE	Rescaled quintile rank of unexpected earnings, which takes the value "-0.5" when an observation belongs to the bottom quintile rank of earnings surprise and "0.5" when an observation belongs to the top quintile rank of earnings surprise. RUE is equal to zero for the intermediate quintiles.	IBES: forecasted EPS IBES: actual EPS Datastream: Prices (P)
Q5MM	Quintile rank of momentum measured as the buy and hold market adjusted returns over the 6 months up to the earnings announcement.	Datastream: Price (P), Dividend (DDE), Market return (FTALLSH)
Q5BM	Quintile rank of firm book-to-market.	Worldscope: Common equity: (WC03501), Market Capitalisation (WC08001)
Q5MV	Quintile rank of firm size measured as the market value of the company measured at the fiscal year end.	Worldscope: Market Capitalisation (WC08001)
Q5LEV	Quintile rank of leverage measured as total debt divided by the market value of the company measured at the fiscal year end.	Worldscope: Total Debt: (WC03255), Market Capitalisation (WC08001)
Q5RD	Quintile rank of the ratio of research and development expenses to the market value of the company measured at the fiscal year end.	Worldscope: R&D expense: (WC01201), Market Capitalisation: (WC08001)
Q5SP	Quintile rank of the natural logarithm of the share price measured at the start of the return accumulation period	Datastream: Price (P),
Q5CFO	Quintile rank of operating cash flows divided by total assets.	Worldscoppe: Total Funds From Operations (WC04201), Other Funds From Operations (WC04831), Total assets (WC02999)
Q5CC	Quintile rank of capital expenditures divided by the market value	Worldscope: Capital Expenditure (WC04601), Market Capitalisation (WC08001)
Ctrar	Dummy variable which equals 1 if the directors' trading signal indicates trading in the opposite direction to the earnings surprise and zero otherwise	Hemscott: Directors trades:
Cfirm	Dummy variable which equals 1 if the directors' trading signal indicates trading in the same direction of the earnings surprise and zero otherwise.	Hemscott: Directors trades:
Ctrar_RUE	Equals to RUE when directors' trading signal indicates trading in the opposite direction of the earnings surprise (when Ctrar equals to 1) and zero otherwise.	IBES: forecasted EPS IBES: actual EPS Datastream: Prices (P)
Cfirm_RUE	Equals to RUE when directors' trading signal indicates trading in	IBES: forecasted EPS

	the same direction of the earnings surprise (when Cfirm equals to 1) and zero otherwise.	IBES: actual EPS Datastream: Prices (P)
NT_RUE	Equals to RUE when the directors' trading signal indicates no directors' trading, and zero otherwise.	IBES: forecasted EPS IBES: actual EPS Datastream: Prices (P)
PREC	Earnings precision variable equals to 1 if a firm's earnings are precise and zero otherwise. We define earnings precision based on the magnitude of total discretionary accruals. Firms belonging in the bottom tercile rank of the magnitude of total discretionary accruals have low levels of discretionary accruals and are deemed to report more precise earnings. The cut-off points of the tercile ranks are determined by the distribution of the magnitude of discretionary accruals at the year before. Discretionary accruals are estimated based on the modified Jones (1991) model adjusted for performance.	Worldscope: Income Before Extra Items: WC04001 Total Funds From Operations (WC04201), Other Funds From Operations (WC04831), Sales (WC01001), Total assets (WC02999), Receivables (WC02051), Gross Property, Plant and Equipment (WC02301)

[a] variable trimmed at 2% at the top and bottom of its distribution

Abstract: Within the extensive literature investigating the impacts of corporate disclosure in supporting the sustainable growth of an organization, few studies have included in the analysis the materiality issue referred to the information being disclosed. This article aims to address this gap, exploring the effect produced on capital markets by the publication of a recent corporate reporting tool, Integrated Report (IR). The features of this tool are that it aims to represent the multidimensional impact of the organization's activity and assumes materiality as a guiding principle of the report drafting. Adopting the event study methodology associated with a statistical significance test for categorical data, our results verify that an organization's release of IR is able to produce a statistically significant impact on the related share prices. Moreover, the term "integrated" assigned to the reports plays a significant role in the impact on capital markets. Our findings have beneficial implications for both researchers and practitioners, adding new evidence for the IR usefulness as a corporate disclosure tool and the effect of an organization's decision to disclose material information.

Keywords: corporate disclosure; materiality; integrated report; event study; share price

1. Introduction

Over time, the importance of communicating the most relevant information about a business and the organization's activities to the market has led to the development of specific codes of corporate disclosure (within Company Laws, Accounting rules, or Securities Laws) aimed at regulating the level and content of the mandatory communication by each organization. The main aim of these regulations is to reduce the information asymmetry between managers and stakeholders to contain the related risk to trade (as investor, client, supplier, and so on) within the organization [1].

However, more and more organizations are deciding to go beyond these regulations, freely opting to disclose further (mostly non-financial) information on their business in the form of "voluntary disclosure" [2]. Such a decision is specifically included in the increasing attention to corporate social responsibility (CSR) spurred by the widespread conviction that CSR may "pay off" for organizations as well as for their stakeholders and society and supporting the organizations' achievement of strategic benefits oriented towards value creation [3].

Indeed, following the stakeholder approach to strategic management initially promoted by Freeman [4], corporate disclosure is certainly a CSR action as it may substantially support the legitimacy management necessary to build "sustainable growth for business in a responsible manner" [5] (p. 17), [6,7].

The two aforementioned typologies of corporate disclosure (mandatory and voluntary) are mutually complementary and influence each other. The reason for this is that the former may restrain or boost the latter depending on the quantity of compulsory information that organizations are already being asked, whereas quality or credibility of the latter may affect the former, thus encouraging greater or lesser market regulation [8–10]. Subsequently, the issue of corporate disclosure requires a consideration of not only (or not so much) the amount of (mandatory and voluntary) data disclosed, but also the materiality of the corporate communication, which is to be assessed while checking if the information provided is actually useful for the different stakeholders and their behaviors towards the organization.

To date, the considerable literature on the topic has mainly focused on the role of corporate disclosure for capital markets, assuming that managers have to take relevant disclosure decisions even in an efficient capital market due to their superior knowledge of the organization in comparison to outside investors, e.g., [11–17]. Indeed, previous studies have mainly investigated the following: on the one hand, the reasons underlying the organization's propensity for the (voluntary) communication of more information about its activities, and on the other, the impact of corporate disclosure on the organization's performance in the short, medium, and long term.

The literature on the topic is very extensive and is mostly focused on the impact of corporate disclosure on specific variables of the capital markets such as stock performance, cost of capital, or analyst coverage [18], mainly adopting the disclosure index or the event study approach [19]. Unfortunately, some of these studies include measurement errors that affect the interpretation of results, hence requiring further investigation on the topic [20]. Moreover, few studies have included in their analysis the concept of materiality and the necessity of relating the impact on the capital markets to the disclosure of material information [21,22].

To address this research gap in the literature, the aim of this article is to specifically analyze the impact produced on the capital markets by the publication of a recent tool of corporate disclosure, characterized by the essential purpose of providing a holistic representation of the organization's performance, and explicitly adopting materiality as its guiding principle. We refer to the "Integrated Report" and the framework released by the International Integrated Reporting Council (IIRC) [23]. Specifically, the article aims to:

- first, verify, through the event study methodology, if the publication of the Integrated Report, containing material information on the organization, is able to support the overall scope of corporate disclosure, thus definitely producing a statistically significant effect on the share price of that organization;
- second, investigate, by means of the adoption of a statistical significance test for categorical data, the association of the share price impact with the naming of the report; specifically, the aim is to verify if (and eventually to what extent) the name "integrated" (instead of "sustainability" or "annual") for a report and its specific association with the principle of materiality play a significant role in the impact registered on the share price of the organization.

The article is structured as follows. The next two sections introduce a brief literature review on corporate disclosure and its combination with the materiality principle as premises for the development of the research hypotheses of the study. The next section presents the method adopted for the analysis and the results achieved. The last section discusses the results referring to the research hypotheses, including some conclusive considerations.

2. Corporate Disclosure and Capital Markets: A Brief Literature Review

In recent years, organizations have increasingly improved their disclosure processes for two reasons. The first is due to the critical role played by corporate disclosure for the effectiveness of business exchanges and activities in a capital market, while the second focuses on the sustainable growth of an organization [5,7,24]. Corporate disclosure may include financial statements, management discussions, footnotes, as well as press releases, internet sites, and every other type of business report useful to provide data and information about the organization's activities to the market [20]. Over time, scholars have suggested a number of corporate reporting models, which is partly a consequence of changes in the international markets and the related requirement for continuous business innovation, including the disclosure processes implemented by the organizations [25].

To understand the reasons underlying the development of corporate disclosure, previous studies have analyzed a wide range of variables to identify which factors may influence the level of corporate communication to the market—e.g., [26,27]. A necessary premise of this research is the information asymmetry between managers and shareholders that was introduced by the separation of roles (decision-makers on one side, capital providers on the other) and relies on the traditional agency approach to the relationship between ownership and control [28]. Under agency theory, managers need to resort to corporate disclosure in order to affect the organization's access to capital as required by the capital market users, including both sophisticated subjects (such as brokers or investment funds) and non-sophisticated ones (i.e., capital providers without specialized knowledge) [24].

Specifically, previous studies have searched for the factors affecting the level of corporate disclosure, while underlining the relevance of variables such as the organization's size and typology, the information asymmetry risk of the market (influencing the potential assumption of opportunistic behaviors), the professional degree of the intermediary agencies (affecting the credibility of the information disclosed), the board composition (also in terms of the presence of women), or the traditional attitude of the management (whose hostility toward the costs of voluntary disclosure may be mainly reduced by strong economic incentives)—e.g., [29–34].

Moreover, focusing on the managers' decision on this issue, other studies have identified some forces which can intensify the corporate disclosure level for capital market reasons [20]. These forces entail the necessity of reducing the information asymmetry between managers and outside investors in order to improve the conditions for the following:

- capital market transactions, by reducing the cost of capital—e.g., [35–37];
- corporate control, by affecting the managers' turnover—e.g., [38,39];
- stock-based compensation plans, by correcting potential undervaluation—e.g., [40];
- development of litigation hypotheses, in turn impacting on the disclosure behaviors—e.g., [41,42];
- managers' recognition, spreading their talent—e.g., [43];
- competition in product markets, which is the only hypothesis assuming the absence of conflict of interest between management and ownership—see [13,44].

With respect to these motivations, other studies have associated the evidence of some positive effects with the development (especially in terms of voluntary decision) of corporate disclosure, essentially as a consequence of the mitigation of the cited investors' information asymmetry and the possibility of using private information in trading [11]. These effects essentially refer to three typologies of positive impact on capital markets: the stock liquidity, the cost of capital, and the information intermediation [20]. These studies have tested that voluntary disclosure can:

- increase the stock liquidity, thus improving investors' trust about the (affected) "fair price" of stock transactions—e.g., [45,46];
- reduce the cost of capital, limiting the information risk—e.g., [47–51];
- develop information intermediation, reducing the cost of attaining data for financial analysts—e.g., [52,53].

However, other studies have highlighted that corporate disclosure may also have negative impacts on the capital markets, primarily because revealing substantial data to competitors may harm the competitive position of the organization—e.g., [13,54–56]. This eventuality may induce managers to reduce the (voluntary) information disclosed, thus foregoing the advantages derived from corporate disclosure previously noted. This is in consideration of the perceived risk of losing the competitive position possessed against the organization's existing or potential competitors. The "nature" of the information to disclose (i.e., if there is good or bad news about the organization's performance) may certainly influence such a managers' decision, as tested by previous studies focused on their tendency to withhold bad news—e.g., [41,57,58].

In addition, it is worth remembering that corporate disclosure also entails supporting some specific costs, derived by the same disclosure process in terms of technological and human resources involved in the data collection, processing, and auditing, that might lead to the managerial decision to limit the flow of information to the market [24] (p. 1409). Assuming the costs related to the mandatory disclosure are unavoidable, the managerial decision on the degree of voluntary disclosure requires a specific cost-profit analysis (which is rather difficult to implement and is subjective) and is essentially aimed at checking that the marginal cost of additional information does not exceed the marginal profit resulting from the addition of information [59]. With this aim in mind, Holland [19] (p. 30) suggested that "management would publicly disclose up to (or towards) the point where the perceived reduction in the agency costs of equity capital equalled the increased costs of public disclosure to markets and the public domain".

Such an analysis is undeniably rather difficult to implement and is subjective, and requires the adoption of practical rules aimed at detecting and calculating the positive and negative effects of corporate disclosure. Some scholars have specifically explained the organizations' decision to extend the disclosure level beyond the mandatory requirements with considerations related to the concept of materiality [21,22], as better specified in the next section.

3. Disclosing Material Information: The Hypotheses Development

"Materiality is a vital concept, one of the cornerstones of accountancy" [60] (p. 116). From the 1960s and the development of capital markets, this axiom has been reiterated in the accounting and auditing literature, highlighting the relevance of what should be one of the main guides for accountants and auditors, despite the difficulty in understanding its actual meaning. Many scholars have tried to provide a definition of the concept of materiality but its meaning is still quite intuitive [22]. All of the definitions provided essentially point to the relationship between materiality and the decision-making processes in organizations, underlining the necessary "decision usefulness" of material data [61,62].

In these terms, an item is "material" if it is suitable to condition the behavior of an informed investor (or, generally, of a reasonable person), adding to his/her total information more than it detracts by complicating a report with the further detail provided. The materiality level of an item is measured by its potentiality to change the decision-maker's expectations, beyond its absolute dimension [22]. Moreover, according to Black et al. [63] (p. 144), the materiality principle arises as "a practical guide which helps the accountant decide to what extent to follow accounting principles" and it is related to the "relative importance" of data that can influence the decisions of the reader of a specific organization's report and only under particular circumstances. This implies the necessary involvement of the managers' judgment, essentially aimed at identifying what the report users need to know about the organization's activities in order to make reasonable decisions [64]. Many variables may influence this judgment, including both financial and non-financial issues, as well as both quantitative and qualitative factors, such as some characteristics (experience included) of the organization or its industry, the general economic context, the managers' ability and wishes, and so on [65–67].

Assuming the multi-dimensionality of corporate disclosure decisions, involving not only the amount but also the timing and nature of the information that is to be provided, an effective study on corporate disclosure consequently needs to consider the materiality principle as a key reference for the selection and the analysis of the data being disclosed. Unfortunately, few studies in the literature have included the impact of materiality in their analysis of corporate disclosure [21,22], justifying the development of further studies characterized by the inclusion of such a relevant variable.

Materiality is now a key reporting principle, not only for the financial impact of the organization's activities, but also for their social and environmental effects, in the interests of all of the organization's stakeholders [68]. Indeed, the materiality principle already appears in some corporate reporting models provided by scholars and/or professional accounting bodies to answer the aforementioned need of corporate disclosure beyond compulsory requirements. These models include the Global Reporting Initiative (GRI), according to which the materiality principle lies in the commitment of the report to "cover aspects that: Reflect the organization's significant economic, environmental and social impacts; or Substantively influence the assessments and decisions of stakeholders" [69] (p. 17), and the AA1000 standard, which defines as material any "issue that will influence the decisions, actions and performance of an organization or its stakeholders" [70] (p. 12).

Within this context, our study focuses on a more recent (and thus less analyzed) model of corporate disclosure, i.e., Integrated Report (hereafter IR), aimed at providing a holistic representation of the organization's activities and the related financial, social, and environmental performance achieved. Despite the wide variety of information provided and the interests involved, a crucial aim of this report is the organization's access to capital, since, according to its framework, "The primary purpose of an integrated report is to explain to providers of financial capital how an organization creates value over time" [23] (p. 8). The IR proposition builds on the explicit demand for a reporting approach integrating financial and sustainability information suggested by scholars and practitioners on the expectation of improving the decision-making processes for providers of financial capital [71–73]. Nevertheless, there is not enough evidence on whether integrated reports are concretely more useful than traditional annual reports in supporting investors' decisions [74–76].

In these terms, an analysis on the impact of IR on market valuation may certainly provide new evidence on the IR usefulness for investors [77] and, more broadly, on the effect of corporate disclosure on the organizations' access to capital, as required by the measurement errors affecting results of previous studies [20].

Specifically, the first research hypothesis of this study concerns the capacity of IR, as a corporate disclosure tool, to influence the organization's access to capital, producing, at the time of its publication, a significant impact on the share price of the organization. The analysis is coherent with the aforementioned necessity of integrating the disclosure issue with the materiality principle, as materiality represents one of the seven guiding principle suggested by the IIRC to prepare and present effectively an integrated report [23] (p. 17). Indeed, in line with the primary purpose of the IR framework, the report has to include all material information assuming that "a matter is material if it is of such relevance and importance that it could substantively influence the assessments of providers of financial capital with regard to the organization's ability to create value over the short, medium and long term" [78] (p. 2). We thus formulate the first research hypothesis of this study as follows.

Hypothesis 1 (H1). *The IR publication, disclosing material information of an organization, significantly affects the share price of that organization.*

The article also aims to further investigate the impact of IR on the capital markets focusing on its name, in order to check if (and eventually to what extent) it may be statistically associated with the effect produced by the report publication on the organizations' share prices. Such a research question may be connected with the literature debate developed in the last years on the comparison of IR with other corporate disclosure tools (mainly the "annual report" and the "sustainability report") in order to identify which one is the most effective model of corporate reporting. Specifically, this debate argues that sustainability reporting, even if aimed at mitigating the limitations of annual reporting (analyzing the organization's performance beyond its financial aspect), is usually presented as a distinct document and turns out to be incomplete in demonstrating the connection between sustainability and financial information [79–81]. According to its supporters, e.g., [82–84], IR on the other hand provides the specific benefit of highlighting any relationship among different organizational data as a consequence of the "integrated thinking" approach adopted and its overall aim of providing a holistic representation of the organization's performance [85,86].

Although related to distinct models of corporate reporting, the "annual report" and the "sustainability report" surprisingly represent the name of some integrated reports included in the database of the IR Pilot Program. This was probably due to two different reasons. First, some organizations participating in the program were probably interested in exploiting the greater notoriety that the other two models of corporate reporting certainly had in comparison with IR at the time of the report publication. Second, these reports, initially identified as "annual" or "sustainability" (reports) by the same organizations releasing them, could have been subsequently recognized by the IIRC as "integrated" as they were consistent with the content elements and the guiding principles of the IR framework.

Irrespective of the reason, it is the authors' opinion that this peculiarity about the IR name deserves further investigation aimed at testing its potential association with the impact produced in the capital markets by the report publication. Specifically, the second research hypothesis of the article builds on the assumption that the name "integrated" for the reports, drafted according to the IIRC framework, automatically stimulates providers of financial capital to recognize the existence and application of all of the guiding principles underlying those reports, with the principle of materiality being at the core of the entire process. In these terms, the adoption of the name "integrated" (instead of "sustainability" or "annual") for the report may contribute to producing some impact on the capital markets, as stated by our second research hypothesis:

Hypothesis 2 (H2). *The naming of the report as "integrated" and the related association with the principle of materiality play a statistically significant role in the impact produced by this disclosure tool on the organizations' share prices.*

4. Method and Results

4.1. Sample Selection

To identify which organizations to include in the analysis, we focused on the "Integrated Reporting Examples database" [87], which "contains examples of emerging practice in Integrated Reporting". The Examples database is structured in order to classify organizations not only by name, but also with reference to a variety of other features, such as their localization, or the fiscal year of the IR drafting. Moreover, the database allows the selection of reports according to the content elements and guiding principles applied to the report drafting, as identified by the IIRC Framework. Among these criteria of selection and according to the research hypotheses of this study, we adopted "materiality" as a filter to identify the integrated reports to be included in our analysis.

The criteria of selection returned 47 reports (drafted for the fiscal years from 2011 to 2015) that refer to organizations from any localization in the world.

We excluded six of the organizations that were not quoted on the capital markets, another one that was no longer active on the date of the analysis (since it had been acquired by a different company), and two others because it was not possible to identify the exact publication date of their IR.

The final sample therefore consisted of 38 reports.

According to the industry classification provided by the IIRC, the three industries most represented in our sample were: Financial services, Consumer goods, and Basic Materials. From a geographical point of view, almost 50% of the organizations involved in the analysis were from Europe.

Dates of publication were identified directly in the reports, or by searching the organizations' web sites, or by contacting the organizations and asking for this information.

To address our first research hypothesis, we decided to adopt the event study analysis, and we extracted all financial data relevant for the analysis from the Thomson Reuters DATASTREAM database.

To address our second research hypothesis, we adopted a statistical significance test for categorical data applied to the reports' names.

Below we provide more information on the event study analysis performed.

4.2. Event Study Analysis

Event study analysis [88–90] is a statistical technique aimed at determining if an event affects the returns of specific securities in a time period called an event window. Initially, event studies were very simple from a statistical perspective [91]. Later, the quality of event studies increasingly improved and their frequency of use increased in accounting, finance, management and other fields. From a practical viewpoint, event studies compare the returns that would have been expected if the analyzed event would not have taken place (normal returns) and the actual returns including one or more securities. The differences between actual returns and normal returns are called abnormal returns and represent the core element of event study analyses. If the distributional properties of abnormal returns are known (it depends on which techniques were used to estimate the normal returns), it is possible to assess if they are statistically significantly different from 0, which would mean that the event does affect the security price.

When performing an event study, the date of the event analyzed has to be accurately defined. The event window, which typically includes the event, consists of the day(s) on which the analysis is performed. Different test period lengths were used in event studies. For example, event windows from −4 to 4 trading days (where 0 is the publication date, −4 stands for the fourth day before the event and 4 is the fourth day after it) or from −5 to 5 trading days were used in some research articles focusing on the impact of corporate disclosure and other CSR actions—e.g., [92,93]. In this study, 33 event windows were considered. In particular, all the event windows from 1 to 9 days, containing the day of the event, the previous or the subsequent ones, were analyzed. Figure 1 shows all the event windows considered in this study.

EW(−1)				−1					
EW(0)					0				
EW(1)						1			
EW(−2;−1)			−2	−1					
EW(−1;0)				−1	0

EW(−2;4)			−2	−1	0	1	2	3	4
EW(−4;3)	−4	−3	−2	−1	0	1	2	3	
EW(−3;4)		−3	−2	−1	0	1	2	3	4
EW(−4;4)	−4	−3	−2	−1	0	1	2	3	4

Figure 1. Event windows analyzed.

Event windows may also include some days before the event analyzed in order to consider certain effects produced by previews or leaks (information leakage period). The maximum leakage period used in this study is 4 trading days. When considering a single organization, actual returns have to be compared with expected ones calculated using statistical or economic models. For organization i, event date τ and the conditioning information X_τ, the abnormal return, which is the difference between actual returns and estimated (normal) ones, is:

$$AR_{i\tau} = R_{i\tau} - E(R_{i\tau}|X_\tau) \quad (1)$$

With reference to the present study, daily expected returns were calculated using a simple linear regression model which assumes that the return on a generic *i*-th security at time t (R_{it}, explained variable) depends on the return on the market portfolio at the same time (R_{mt}, explanatory variable), i.e., the market model:

$$R_{it} = \alpha_i + \beta_i R_{mt} + \varepsilon_{it} \quad (2)$$

From the statistical model in Equation (2), the regression line can be written and the coefficients $\hat{\alpha}_i$ and $\hat{\beta}_i$ can be estimated, using historical data for R_{it} and R_{mt}:

$$\hat{R}_{it} = \hat{\alpha}_i + \hat{\beta}_i R_{mt} \quad (3)$$

From which:

$$AR_{i\tau} = R_{i\tau} - E(R_{i\tau}|X_\tau) = R_{i\tau} - \hat{\alpha}_i - \hat{\beta}_i R_{mt} \quad (4)$$

The time series data used in the market model refer to the so-called estimation window. From an econometrical point of view, the number of trading days which the estimation window (L_1) consists of is fundamental. In fact, abnormal returns are forecast errors, presenting the following distributional parameters:

$$AR_{i\tau} \sim N\left(0, {\sigma_{\varepsilon_i}}^2 + \frac{1}{L_1}\left(1 + \frac{(R_{m\tau} - \hat{\mu}_m)^2}{{\hat{\sigma}_m}^2}\right)\right) \quad (5)$$

The variance of abnormal returns is higher than the variance of the market model regression errors (${\sigma_{\varepsilon_i}}^2$) because abnormal returns are technically forecast errors. However, this difference becomes shorter and shorter when the estimation period increases—indeed, $\frac{1}{L_1}\left(1 + \frac{(R_{m\tau} - \hat{\mu}_m)^2}{{\hat{\sigma}_m}^2}\right)$ decreases bit by bit—and can be ignored if the number of observations used in the market model (L_1) is large enough. In this study, we chose an estimation period of 200 trading days, starting 216 trading days before the date of the analyzed event and ending the seventeenth trading day before it.

Once having calculated the abnormal returns for all the organizations and the event windows analyzed, they can be aggregated through the time generating the Cumulative Abnormal Returns (CAR), which indicate the financial returns for all organizations in all the event windows selected. Since Cumulative Abnormal Returns are random variables consisting of the sum of as many abnormal returns as the days composing the event window analyzed, their distributional parameters (as L_1 is large enough) are the following:

$$CAR_i(\tau_1, \tau_2) \sim N\left(0, (\tau_2 - \tau_1 + 1){\sigma_{\varepsilon_i}}^2\right) \quad (6)$$

Finally, in order to generalize the results obtained for the single organization, the Average Cumulative Abnormal Return ($\overline{CAR}$) can be calculated.

$$\overline{CAR}(\tau_1, \tau_2) = \frac{1}{N}\sum_{i=1}^{N} CAR_i(\tau_1, \tau_2) \quad (7)$$

Its distributional parameters, asymptotic with respect to L_1 and N (the number of events analyzed), are the following:

$$\overline{CAR}(\tau_1, \tau_2) \sim N\left(0, \frac{1}{N^2}\sum_{i=1}^{N} {\sigma_i}^2(\tau_1, \tau_2)\right) \quad (8)$$

The distributional parameters for *ARs*, *CARs* and ($\overline{CAR}$) allow us to test the evidence in relation to the null hypothesis that the given event does not have an impact on the behaviour of the security returns.

4.3. Empirical Evidence

This study considered the publication dates of the 38 integrated reports included in our sample.

Cumulative Abnormal Returns and Average Cumulative Abnormal Returns were calculated for all the 33 event windows analyzed and were tested in contrast to the null hypothesis that the report disclosure does not affect the behavior of the security returns. A total of 13 out of the 33 event windows analyzed show, on average, a statistically significant impact of the report publication on the returns of disclosing organizations. Thus, it is possible to reject the null hypothesis that the average cumulative abnormal returns are zero. The results are shown in Table 1. ($|s\overline{CAR}|$ are the absolute values of the scaled Average Cumulative Abnormal Returns for all the event windows analyzed).

Table 1. Absolute values of the scaled Average Cumulative Abnormal Returns.

Event Window	$s\overline{CAR}$
EW(−1;0)	2.009261862 *
EW(−2;0)	2.091188742 *
EW(−3;0)	2.081430737 *
EW(−2;2)	1.746811573
EW(−1;3)	1.781481845
EW(−3;2)	1.815400844
EW(−2;3)	1.944908851
EW(−1;4)	1.797592212
EW(−3;3)	2.005045063 *
EW(−2;4)	1.959255745
EW(−4;3)	1.696990416
EW(−3;4)	2.023923379 *
EW(−4;4)	1.739827633

Significance codes: 0.05 ‘*’, 0.1 ‘.’

With reference to the cumulative abnormal returns, 16 out of 38 disclosures analyzed highlight a statistically significant impact (at both 5% and 10% level) of the report publication on the returns of the disclosing organization on—at least—one event window. Out of the 16 significant reports, 75% were published after 2013. Reports whose disclosure significantly affects the return were released by organizations listed in Europe (37.5%), Africa (37.5%), America (12.5%), and Asia (12.5%). With reference to the economic sectors, considering the industry classification provided by the IIRC, 50% of the reports are released by organizations producing services, whereas the remaining 50% is equally distributed among organizations producing consumer goods and industrials.

Notably, 69% of the documents included in this study are named as “integrated reports” (whereas the others are either “annual reports” or “sustainability reports”). In detail, the analysis of the name was useful to address our second research hypothesis, according to which the naming of the report as IR plays a statistically significant role in the impact produced by this disclosure tool on the organization’s share price.

To this end, we performed a statistical hypothesis test aimed at determining whether there was a significant difference between the expected frequencies and the observed frequencies in one or more categories of the qualitative variables: significance (with reference to the values of the average abnormal returns) and the name of the reports. The results are shown in Table 2.

Table 2. Association between the CAR significance and the name of the reports disclosed.

		Name			
		AR	**IR**	**SR**	**Total**
Significance	NO	10	8	4	22
	YES	5	11	0	16
	Total	15	19	4	38

Pearson’s Chi-squared test: $X^2 = 5.3258$, $df = 1$, $p\text{-}value = 0.06975$; Fisher’s Exact Test for Count Data: $p\text{-}value = 0.08253$.

Table 2 highlights that there is quite a strong association between the variables' *significance* (which can assume the modalities "yes" or "no", depending on the fact that the CAR of the specific firm analyzed is statistically significantly different from 0 or not) and *name* of the disclosed report (annual report "AR", integrated report "IR" and sustainability report "SR"). Eleven out of nineteen Integrated Reports (58%) refer to firms whose disclosure affected their share price in a statistically significant way. On the other hand, annual reports and sustainability reports seem to influence the assessment of financial capital providers less substantively; in fact, only 33% and 0%, of respectively annual reports and sustainability reports, presented a CAR statistically significantly different from 0. The results of the tests performed seem to confirm these considerations: both the Pearson's Chi-squared test and the Fisher's Exact Test are statistically significant at 10%.

5. Discussion and Conclusions

The results we obtained in our event study analysis show that IR publications produced, on average, significant effects on disclosing share prices. As previously highlighted, the event windows confirming a statistically significant effect in the average CAR are specifically those including the days from −1, −2 and −3 to 0 and from −3 to 3 and 4 (where 0 is the publication date).

Our results provide support for Hypothesis 1, indicating that the organizations' decision to publish IR has a statistically significant effect on share prices. Indeed, consistent with this hypothesis, a significant number of analyzed organizations experienced share price shocks when their IR was published. Therefore, it is possible to claim that shareholders responded to the organizations' decision to adopt this disclosure tool.

Beyond the general aim of any IR (i.e., the holistic representation of an organization and its performance), our findings are probably related to the specific informative usefulness of the reports analyzed. Indeed, according to the criteria adopted to select the documents to be included in the analysis, all these reports efficiently apply the materiality principle as defined by the IR framework [78]. As indirectly stated by the same IIRC (through the association of the reports analyzed with the database filter referring to the guiding principle of materiality), all these documents include data and information which can influence the stakeholders' actions, and they communicate all material information affecting the decisions of the organization's financial capital providers. The analysis of the average CAR confirms this IR potential, hence demonstrating that the organizations releasing the report tended to modify their perception as investment in the capital markets [23].

This result has beneficial implications for both researchers and practitioners.

For the former category, our findings add new evidence to previous research on corporate disclosure, confirming that an organization's decision to improve its level of communication and transparency towards the market (in this case, releasing an IR) affects the shareholders' expectations about that organization's performance—see [20]. Moreover, this study contributes to validating the "vital" function of materiality in the corporate disclosure process [60], since the impact registered on the organizations' share prices assumes that the IR analyzed includes all material information on the process of value creation implemented [21,22].

With reference to practitioners, our results suggest that managers should make their disclosure decisions by trying to anticipate how the corporate reporting might be able to influence shareholders' behaviors and hence share prices. Specifically, this study adds new evidence on IR usefulness in acting on the information asymmetry between managers and outside investors, in line with the agency approach [28,84]. In these terms, our findings may also support the managers' judgement in interpreting the materiality principle [64,65], in association with the studies investigating the managers' communication strategy in relationship with the nature (i.e., good or bad news) of the information to be disclosed [41,58].

In reference to our Hypothesis 2, this study verified that, among the reports included in the statistical significance test for categorical data, the ones named "integrated" (instead of "sustainability" or "annual") report, were associated with a greater impact on the share prices. This result is consistent with our assumption according to which the name adopted for the reports may influence the investors' perception and behavior. Indeed, all of the organizations relying on the IIRC framework for drafting their integrated reports should adopt materiality as one of the guiding principles of the entire reporting process. However, the choice of the name "integrated" for these reports favors their association with the disclosure of the organization's information that may influence the assessments and decisions of providers of financial capital [78].

Regarding the extent of the impact association with the naming of the report, it is noteworthy remembering that the *p*-value registered for our analysis was statistically significant at the 0.1 level, but not significant at the 0.05 level. This was likely due to the size of the sample, including the 38 reports corresponding to the selection criteria adopted. Nevertheless, our result certainly represents a first interesting finding about the potential of the name "integrated" to be associated with the materiality of the information disclosed in the report.

As discussed for Hypothesis 1, the aforementioned results may also be commented on in terms of helpful implications and contributions for both researchers and practitioners, mostly referred to the specific disclosure tool analyzed here (i.e., IR).

For researchers, our findings support the greater appreciation that IR has recently received in the literature as an example of an effective corporate disclosure tool [82,83]. For practitioners, our result might be useful to support managers' decisions about how to "present" IR to the capital markets, assuming that if it is quickly recognizable as an integrated report (adopting this name for the document), its publication may have greater effects on the organization's share price.

Regarding the limits and further developments of this study, it is worth remembering that the concept of performance disclosed in an integrated report has a multidimensional quality, because it includes a variety of information about the social and environmental impacts of the organization's activities, plus the more traditional financial data. Indeed, the investors' decisions go beyond expected profits, and include the requirement of broader analyses related to the organization's environmental and social goals. Unfortunately, at this stage our analysis is not able to reveal which specific aspect of the organization's performance was mostly responsible for the share price shock registered in association with the IR publication. This is certainly a limit of this study that might be addressed by collecting further data on the investors' behaviors and investigating more deeply the reasons underlying their allocation decisions, as already planned by the authors for the future development of the research.

Moreover, with reference to our second research hypothesis, we planned to develop a few qualitative case studies in order to explore and understand in more detail the motivations and decisions (including the report name) that informed those organizations in drafting their integrated report.

Author Contributions: Although this article is the result of a joint collaboration, Maria Cleofe Giorgino is to be considered the author of the sections "Introduction", "Corporate disclosure and capital markets: a brief literature review", and "Disclosing material information: the hypotheses development"; Enrico Supino is to be considered the author of the sections "Event study analysis" and "Empirical evidence", and Federico Barnabè is to be considered the author of the sections "Sample selection", and "Discussion and conclusion".

Conflicts of Interest: The authors declare no conflict of interest.

Determinants of corporate financial performance relating to board characteristics of corporate governance in Indian manufacturing industry

An empirical study

Received 22 July 2016
Revised 21 November 2016

Abstract

Purpose – The purpose of this paper is to examine if certain board characteristics have an impact on the financial performance of manufacturing firms in India.

Design/methodology/approach – The study draws on data from 275 firms listed in NSE during from 2011 to 2015, using a multiple regression model. The present study examines the effect of board characteristics such as board size, CEO duality, independence and board activity devoted to the effectiveness of firms performance regarding market and accounting based financial performance measures.

Findings – The finding supports an inverse association between the extent of board characteristics and the firms' performance indicators. The study also finds a statistically significant negative relationship between board size and Tobins *Q*, ROA and ROE. The evidence also shows that the board independence and meeting frequency moderate the relationship between return on equity and return on assets by enhancing these measures among corporate governance mechanisms.

Research limitations/implications – The present study does not include all possible board characteristics, i.e., large shareholders dominance on the board and promoter's and institutional shareholding, to support firm's performance. Further research might include the ownership structure of the board to improve firm's performance.

Originality/value – The study focuses on the corporate governance issues such as size, duality, independence and activity of the boards and their influence on firm performance. The subject analyzes the possible impact of board characteristics and firm-related features that have received much attention from academic research, which has largely focused on studying the publications of corporate governance in India and Asian context.

Keywords Corporate governance, CEO duality, Board characteristics, Firms performance, Tobins *Q*

Paper type Research paper

Introduction

Corporate governance has become a popular discussion topic in developed and developing countries. Corporate governance comprises several elements of the structure of the government, which includes capital, labor, market and organization along with their regulatory mechanisms. The literature widely held view to contain the interests of shareholders has led to increasing worldwide attention. Today corporate governance has become a worldwide issue, and the

development of corporate governance practices has become a prominent issue in all countries in the world. Corporate governance is a system of structures and processes to direct and control the functions of an organization by setting up rules, procedures and formats for managing decisions within an organization. It specifies the distribution of rights and responsibilities among company's stakeholders (including shareowners, directors and managers) and articulates the rules and procedures for making decisions on corporate affairs. It thus provides the structure for defining, implementing and monitoring a company's goals and objectives and ensuring accountability to appropriate stakeholders. Hence, the corporate governance issue widely debated in the developed market economies needs to be discussed in a different vein in the Indian context. India, for example, did not share the set of factors responsible for the Asian crisis, which were largely macroeconomic and related to bank failure due to unprecedented and unchecked growth (Jaiswal and Banerjee, 2010). Similarly, structural characteristics in the Indian corporate sector are quite different from that of USA and UK leading to a different set of corporate governance issues here.

Corporate governance norms in India have evolved well over the year's post-economic liberalization, with SEBI constituting a number of committees to suggest codes of conduct for good governance of corporate organizations. This was followed by the listing agreement under Clause 49 and by the voluntary guidelines of corporate governance in 2009 laid out by the Ministry of Corporate Affairs. These norms are inherently related to the legal and institutional environment in the country. The legal framework for corporate regulations by the Ministry of Corporate Affairs and vital formulation of the Companies Act 1956 and the new companies Act 2013, also with fairly functional stock exchanges and their detailed listing requirements and corporate must be ensured that globally accepted standards. India is one of the major emerging economies in the world, and the importance in the global economy has increased in recent years as the aspects of global commerce are expected to grow in the future. The Indian approach to corporate governance, accounting and auditing, however, differs in many ways from the US model (and the Chinese model). India, as well as many other developing countries, often has the form but not the substance of governance when it comes to matters of law. Strict enforcement of laws and speedy punishment of the violators are as much a part of the rule of law as the written law itself (Narayanasamy *et al.*, 2012). After Satyam scam, lot has been said and done in India related to board mechanisms. After Clause 49 implementation, it was mandatory to comply with its recommendations. The Clause 49 listing agreement of independent director for listed companies was deferred for nine months till December 31, 2005. Finally, it was implemented from January 1, 2006. In response, many companies have done shuffling at the board level. The question arises whether these changes pertaining to internal governance structures are related to firm performance measures. In the Indian context, the term corporate governance is defined more in terms of agency problem. Managers and researchers see a corporate governance problem as a conflict between management and shareholders. The limited data available so far has confirmed that among corporates, only those companies who are going global follow strict international accounting standards and policies. Presently, Indian business system is moving toward the Anglo-American model of corporate governance. The Anglo-American model gives importance to the shareholders over other stakeholders. Here, the usefulness of this model to current Indian system can always be questioned (Gugnani, 2013).

Literature review

The effect of corporate governance on firm performance is the focus of extensive analysis in majority of the previous studies (Choi *et al.*, 2007; Donaldson and Davis, 1991; Jensen, 1993). It is indispensable to realize the corporate governance in the Indian context, a detailed critique of relevant literature explained with deliberate corporate governance practices and firm performance.

Gompers *et al.* (2003) developed a governance index from a sample of 1,500 large firms using the governance rules and investment strategy. They also found that the firm with strong shareholder's rights has higher fund value and higher growth. Black (2001) found that the governance practices are strongly related to price-earnings ratio, and similar results were found by Klapper and Love (2004). Shleifer and Vishny (1997) view corporate governance as a set of mechanisms which ensure that potential providers of external capital receive a fair return on their investment, because the ownership of firms is separated from their control. It also increases the firms' responsiveness to the need of the society and results in improving long-term performance (Gregory and Simms, 1999).

CEO duality is an important issue in corporate governance because the status of the CEO and chairperson may have an influence on firm performance. There are arguments in favor of CEO duality, meaning CEO duality has a positive impact on firm performance, and the result is consistent in favor of the stewardship theory. Likewise, there are arguments against CEO duality, asserting that it has a negative impact on firm performance and these support the agency theory (Huining, 2014). The monitoring role of the board and its effectiveness on the behalf of shareholders depend upon its size and composition while carrying out the functional areas of the corporate governance (John and Senbet, 1998). The board characteristics like size, independence and meetings have an impact on current or prior performance, and a weak association was found between the two in the case of Indian firms (Arora and Sharma, 2015). Another study by Brick and Chidambaran (2010) also stated the intensity of board activity as an important dimension of oversight function performed by the board. Furthermore, it had used number of "director-days" to proxy for the level of board monitoring activity. Some studies were used the board composition and board size to represent the board's monitoring ability; it is the outside directors who have the ability to provide more effective than internal monitoring, more specifically, appointment of the independent directors leads to effective monitoring (Mak and Li, 2001; Choi *et al.*, 2007; Agarwal and Knoeber, 1996). The board index which consist of composition and meetings has been found to have a negative and significant association on firm performance of selected IT companies in India (Palaniappan and Rao, 2015). Kathuria and Dash (1999) observed that size of the board increased with the size of the corporation. Using a sample of top Indian Bombay Stock Exchange (BSE)-listed companies, Jackling and Johl (2009) had also showed significant positive correlation between firm size and size of the board (Kumar and Singh, 2013). The average board size was significantly different between small and large firms. However, in contrast, Lange and Sahu (2008) in their study on Nifty-listed Indian companies found an insignificant (but negative) effect of firm size (measure for scale) on board size. Substantiating the same, Linck *et al.* (2008) found that small firms had the smallest boards, with greatest proportion of insiders. In addition to the frequency, board meeting attendance also acts as a proxy for supervising quality of the board (Lin *et al.*, 2013). The measures of board attendance have been determined the participation of directors in meetings, also called board diligence that have been tested in supplement to the governance measures which was conducted on the firms listed on the NSE in India (Ghosh, 2007).

As far as the relationship between board characteristics and firm-specific characteristics is concerned, the past literature has established that large firms need more number of directors due to the complexity involved in their operations (Boone *et al.*, 2007; Chen and Al-Najjar, 2012; Coles *et al.*, 2008; Monem, 2013). However, in those studies, the percentage of non-executive directors (NEDs) on the board and firm performance was found to be statistically insignificant. Connell and Cramer (2010) also noticed a significant difference between the average board size of small and large firms listed on Irish stock markets.

Indeed, previous studies in several other countries also found a negative relationship between board size and firm performance. A positive relationship between the variables of corporate governance and firm's performance was found in Sri Lankan companies (Velnampy and Pratheepkanth, 2012). According to the studies of Black *et al.* (2006), Drobetz *et al.* (2004), Ong *et al.* (2003) and Gedajlovic and Shapiro (2002), there was a positive significant relationship between corporate governance practices and firm performance in various countries; in contrast, based on the studies of Gugler *et al.* (2001), Hovey *et al.* (2003) and Alba *et al.* (1998), there was no significant relationship between corporate governance and firm performance. The primary contribution of the study is that it examines the determinants of firm performance on board characteristics for which existing literature is limited, especially in the Indian context. This study further contributes to the literature by providing a comprehensive analysis of the relationship between board characteristics and firm performance. The empirical analysis focuses on a large number of companies (around 275 firms) covering 18 important industries from the manufacturing sector in India; moreover, instead of considering just a single measure of firm performance, the study considers three alternate measures of performance covering both accounting (ROA and ROE) and market-based (Tobin's *Q*) measures. Finally, this study also proposes another governance measure, board meeting, which is also related to firm performance (Table I).

Conceptual model and research hypothesis

Based on the previous section, extensive literature shows that corporate board characteristics affect firms' financial performance.

In this sense, the current research makes the contributions of empirically testing the effect of board characteristics on firm's performance. In line with the extant literature, the current study hypothesizes directional relationships between the measures of corporate governance on firm's performance. Figure 1 summarized the relational paths among

Sl. no.	Statement	Previous studies
1	The larger boards tend to have a negative influence on firm performance, judged in terms of either accounting- or market-based measures of performance. CEO duality has a significant effect on the firm performance	Ghosh (2006), Kathuria and Dash (1999), Lipton and Lorsch (1992)
2	Clause 49 along with other recommendations has emphasized the role of independent directors over executive directors for better governance structure. So board composition is a natural variable of interest in relation to firm's performance	Kumar and Singh (2012), Gugnani (2013)
3	A greater proportion of outside directors on boards was associated with improved firm performance	Jackling and Johl (2009), Fama (1980)
4	The study measure the independence of a board as percentage of independent directors on a board and is expected to have a positive relationship with firm performance	Hermalin and Weisbach (1991), Bhagat and Black (2002)
5	A positive relation between CEO duality and performance of a firm. Knowledge of the fact that the influence of CEO duality on firm performance can be a great benefit	Sanda *et al.* (2005), Huining (2014)
6	The board index, which consist of composition and meetings, has been found to have a negative and significant association on firm performance	Palaniappan and Rao (2015), Shivdasani (2004)
7	A positive significant relationship between corporate governance practices and firm performance was found in various countries	Ong *et al.* (2003), Gedajlovic and Shapiro (2002). Velnampy and Pratheepkanth (2012)

Table I.
Summary of literature review

governance-related board characteristics and the firm's performance regarding both accounting- and market-based measures. The following subsections discuss in depth the hypotheses related to each selected board characteristics.

Board size

The corporate governance literature is highly contradictory on board size being linked with corporate performance. The number of directors on board is an important variable, though literature does not have a consensus on the influence of board size toward increasing in firm's performance. Some studies describe a positive association between firm performance and board size due to lag in decision making owing to lack of harmony. Valenti *et al.* (2011) pointed out that when there is some dispute regarding the effect of board size on performance in general (Alexander *et al.*, 1993; Yermack, 1996), the evidence suggests that larger boards are preferable than smaller boards (Dalton *et al.*, 1999). This consistency results were in-line with a study by Coles *et al.* (2008) which states the board size should increase with the optimal board size to achieve higher financial performance. In the previous literature, both smaller boards and larger boards have been favored on different grounds. For instance, larger boards have been favored on the grounds of greater monitoring and effective decision making. According to Shivdasani (2004), board composition of a firm is affected by the fall in financial performance because companies react to performance downturns by adding outside directors to the board for corrective actions and effective decision making. Bradbury *et al.* (2006) report no association. Board size is known to be correlated with observable and unobservable firm characteristics that potentially correlated with firm financial performance (Bennedsen *et al.*, 2007). This endogenous effect is in-line with significant relationship of a firm's financial performance and board size (Black *et al.*, 2003). Therefore, the study hypothesizes the subsequent based on inconclusive evidence of the association without predicting its direction:

H1. There is no significant association between board size and firm's performance.

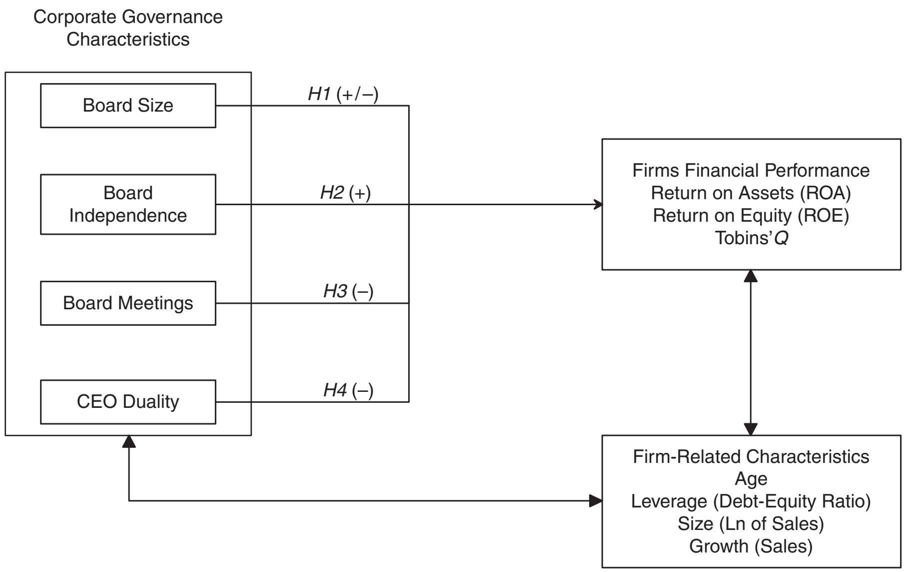

Figure 1.
Proposed conceptual model

Board independence

The number of independent director on the board is often used as proxy for good governance. The role of board of directors as effective monitoring mechanism for management is dependent upon them being non-executive and independent. Furthermore, the inclusion of independent directors on corporate boards is an effective mechanism to reduce the potential divergence between management and shareholders. Fama (1980) argued that more NEDs on the board act as professional referees and work for value maximization of shareholders. The independent directors are invited onto the board for oversight on behalf of shareholders (Baysinger and Butler, 1985). Rosenstein and Wyatt (1990) also suggested that higher proportion of independent directors is positively associated with excess returns. Similarly, Mak and Kusnadi (2005) revealed that a higher fraction of independent directors on the board is linked to greater firm value. Outsider-dominated on the boards in terms of percentage of independent directors which will enhance the reputation of the firm, as the firm is viewed as follows good corporate governance, improving the reliability of its financial disclosures. These shortcomings can be taken care of by choosing efficient board members. Bhagat and Black (2002) in their studies found that there is no significant relationship between number of independent directors and performance of a firm. These conflicting results on the association between board independence and firm's performance, with studies by Beasley (1996), Klein (2002) and Davidson *et al.* (2005), find significant negative association between the two. On the other hand, Park and Shin (2004), Peasnall *et al.* (2005) and Bradbury *et al.* (2006) fail to report any association between earnings management and independence of the board. Board independence is measured by the number of non-executive independent directors working on the board. The study measure the independence of a board as percentage of independent directors on a board and is expected to have a positive relationship with firm performance. Thus, the study examines the following hypothesis:

H2. There is a positive and significant association between firm's performance and board independence.

Board meetings

Next, the study estimated the impact of firm performance on board meetings, which is measured by the frequency of meetings annually. According to Vafeas (1999), board meeting is an important board attribute, but the relationship between firm performance and board meetings is not clearly established. There are several costs associated with board meetings such as managerial time, travel expenses and directors' remuneration. If a firm is not performing well, it might be possible that it may reduce the number of board meetings to avoid the costs associated with them. Jensen (1993) also pointed out that the meeting time might not be utilized for a significant dialogue among directors. Hence, the company might try to save upon the meeting costs by reducing the number of board meets. On the contrary, the firms have poor performance may try to conduct more meetings to discuss crucial issues like the reasons for their poor performance and setting strategies for improvement in performance. When directors meet frequently, they are more prone to discuss the concerned issues and monitor the management effectively, thereby performing their duties with better coordination (Lipton and Lorsch, 1992). If a firm is reasonably efficient in setting the frequency of its board meetings, it will also likely to attain high efficiency in agency costs. Thus, the impact of firm performance on board meetings is a valid research question, which should be examined empirically by following hypothesis:

H3. There is a significant negative association between attendance of directors in board meetings and firm's performance.

CEO duality

The literature argues that the status of CEO has direct impact on governance of firms. CEO position should be independent of the chairperson of the board to enable balance and check on misuse of power by the same. Agency theory supports the same to avoid conflict of interest for the board chairman to formulate the strategies and be responsible for implementing the same. This in turn would check firms' performance through better monitoring. Jensen (1993) argued that lack of independent leadership creates a difficulty for boards to respond to any failure. Fama and Jensen (1983) also argued that concentration of decision making makes it difficult for the board in independent decision making, and it affects the performance of a firm. Contrary to this view, Rechner and Dalton (1991) argued for role CEO duality as it would provide better incentives by linking CEO pay which will affect the firms' performance. Klein (2002) shows that role duality leads to unchecked powers and finds significant positive association with firm performance. Sanda *et al.* (2005) found a positive relation between CEO duality and performance of a firm, while Dalton *et al.* (1998) could found no significant relationship between CEO duality and firm performance. A number of studies report no significant relationship. Berg and Smith (1978) and Brickley *et al.* (1997) stated that it increases the conflict of interest, and the agency cost increases when CEO and the board chair is the same person. However, in another study, Rechner and Dalton (1991) argued that it is good if the board chair and the CEO is the same person as it reduces the bureaucracy in decision making. The study used CEO duality as a dummy variable and used a score of 1 when a person holds both position and 0 otherwise. This proposes that firms segregating the role of the chairperson of the CEO positively and significantly contributes to the firm's performance:

H4. There is a significant negative association between CEO duality and firms' performance.

Methodology

With the aim of analyzing the proposed model to explore the effect of board characteristics on firms performance and to empirically test the proposed hypothesis, the study conducted a content analysis among Indian manufacturing firms during 2011-2015 using firms' annual reports. Indian has become one of the most attractive destinations for investments in the manufacturing sector because of strong integrations of governance and control mechanism. The Government of India has taken several initiatives to promote a healthy environment for growth of manufacturing sector in the country (Media Reports, 2016). The data were collected with consist of detailed governance-related and financial performance information and indicators about the most actively traded and listed companies on the BSE of India during 2011-2015.

Sample selection and data collection

The data for empirical analysis are extracted from PROWESS (Release 4.0), a research database widely used in India, and from the corporate governance and annual reports of companies. The firms in our sample are chosen from important firms in the manufacturing sector. Banking and finance sector and government companies are completely excluded for the purpose of analysis because these firms have different type of structure and governance (Faccio and Lasfer, 2000). The firm classification of these 18 sectors is given in Table II. The total number of manufacturing firms listed under BSE in these sectors are 3,230 firms. The firms with missing data are excluded from the sample, which left with the final sample size of 275 firms. This study covers the time period of 2011-2015.

Table II.
Sample companies for various sectors

S. no.	Sectors	No. of samples

Variables construction
For the estimation purposes, the study use both accounting-based (ROA and ROE) and market-based (TQ) performance measures with respect to board characteristics such as size, independence, board meetings and CEO duality as the dependent variables in the analysis (Gompers *et al.*, 2003). The calculation of these variables has been shown in detail in Table III.

Empirical research results
In the analysis of the relationship between board characteristics and firm performance, the below regression equation will be used to test the main hypothesizes. To test the hypotheses, this study adopts the following empirical model:

$$\mathrm{ROA} = a + b_1\mathrm{BS} + b_2\mathrm{BI} + b_3\mathrm{BM} + b_4\mathrm{CEODUAL} + b_5\mathrm{AGE} + b_6\mathrm{LEV} + b_7\mathrm{SIZE} + b_8\mathrm{GROWTH} + e$$

$$\mathrm{ROE} = a + b_1\mathrm{BS} + b_2\mathrm{BI} + b_3\mathrm{BM} + b_4\mathrm{CEODUAL} + b_5\mathrm{AGE} + b_6\mathrm{LEV} + b_7\mathrm{SIZE} + b_8\mathrm{GROWTH} + e$$

$$\mathrm{TQ} = a + b_1\mathrm{BS} + b_2\mathrm{BI} + b_3\mathrm{BM} + b_4\mathrm{CEODUAL} + b_5\mathrm{AGE} + b_6\mathrm{LEV} + b_7\mathrm{SIZE} + b_8\mathrm{GROWTH} + e$$

where ROA, ROE and TQ are firm performance indicators of a company and b_1, b_2, b_3, b_4, b_5, b_6, b_7 and b_8 are the parameters for the explanatory variables. a is the constant number of the formula and e is the standard error.

This section presents the analysis and discussion of the empirical results.

Assumption of normality test
The normality assumption assumes that the errors of prediction are normally distributed. The Jarque-Berra statistics was used to check the null hypothesis that the sample is drawn

S. no.	Variables	Full form	Description	Expected outcome
Panel A: corporate governance measures				
1	BS	Board size	Number of directors serving on the board	Positive/Negative
2	BI	Board independence	Number of non-executive independent directors on the board	Positive
3	BM	Board meetings	Number of annual meetings	Negative
4	CEODUAL	Duality	A binary variable which equals 1 if a chairperson of the board is also the CEO of the firm and "zero" otherwise	Negative
Panel B: firm performance variables				
	ROA	Return on assets	PBDIT/Total assets	–
	ROE	Return on equity	PBDIT/Paid-up equity capital + reserves funds	–
	TQ	Adjusted Tobin's *Q*	Total assets + market capitalization – book value of equity – deferred tax liability)/total assets	–
Panel C: control variables				
	Age	Firm age	No. of years of a firm since its incorporation	Positive
	Lev	Leverage	Borrowings/Total assets	Negative
	Size	Natural log of sales	Sales is deflated using WPI, then natural log is taken and related to accounting performance of the firm	Negative
	Growth		Growth rate in net sales over that of the previous year	Positive

Table III. Constructs, items and description of variables

from a normally distributed population (Park, 2002). The Jarque-Bera statistics has an asymptotic χ^2 distribution with two degrees of freedom and was used to test the null hypothesis that the data follow a normal distribution. The Jarque-Bea statistic would not be significant, and *p*-value should be greater than 5 percent if the residuals are normally distributed (Brooks, 2008). The results in Table IV report a *p*-value of 0.4166, higher than 0.5, suggesting that normality assumption holds.

Assumption of homoscedasticity test

To test for homoscedasticity, the Breush-Pagan test and the White test were used, and the results reported in Table V indicate that the null hypothesis cannot be rejected since the *p*-values of both tests are considerably greater than 0.05. The results conclude that there is homoscedasticity, so no further corrections for the sample are required.

Assumption of autocorrelation test

Owing to the presence of auto correlation in the residuals, statistical inferences can be misleading. Since the Durbin-Watson test is only applicable to test autocorrelation in time

Test value	10.8771
(Prob. $> \chi^2$) *p*-value	0.4166

Table IV. Jarque-Berra test for normality

Breusch-Pagan test – H_0: *constant variance*		White test – H_0: *homoscedasticity*	
Test value	0.691	Test value	17.521
p-value	0.4016	*p*-value	0.3809

Table V. Breusch-pagan test for homoscedasticity series, this study also uses Wooldridge (2002) test appropriate in panel-data models where a significant test statistic indicates the presence of serial correlation. The p-value of the test is greater than 5 percent as shown in Table VI, suggesting the presence of no autocorrelation of errors. Drukker (2003) and Maladjian and Khoury (2014) used simulation results to show that the test has good size and power proprieties in reasonably sized samples.

Assumption for the multicollinearity test

Multicollinearity is the undesirable situation where the correlations among the independent variables are strong. Hence, if multicollinearity problem exists among the independent variables, then the regression results will not provide correct results. Lewis-Beck and Michael in their book *Applied Regression: An Introduction* have stated that if the correlation among the independent variables is greater than or equal to 0.80, then multicollinearity problem is assumed to exist. The same logic has been applied in this paper to define high correlation among the independent variables to give rise to multicollinearity problem. The multicollinearity problem is checked through correlation matrix. Correlation matrix is developed through SPSS between "firms' performance" and other independent variables. It is observed from Table VII (correlation matrix) that none of the independent variables have correlation greater than 0.8, hence we can safely deduce that multicollinearity does not exist among the independent variables.

From Table VII, Pearson correlation for selected explanatory variables shows that the Pearson correlation coefficient between board size and ROA is −0.733, ROE is −0.764 and Tobin Q is −0.752, which is found to be significant at 0.05 level. This indicates that board size and firm performance measures have a strong negative and significant association among the manufacturing firms in India. The results are consistent with Alexander *et al.* (1993) and Yermack (1996). The factor of board independence has been found to have a weak negative association among the firms' performance factors of ROA (−0.110), ROE (−0.101) and Tobins Q (−0.034), and the results are statistically insignificant and consistent with Lipton and Lorsch (1992). It is evident that board meeting has been found to have a moderate negative and significant relationship with firms' performance indicators such as ROA (−0.491), ROE (−0.551) and Tobins Q (−0.638), and the results are found to be significant at 0.05 level. The factor of CEO duality has been found to have a weak positive relationship among the firms' performance factors of ROA (0.061), ROE (0.086) and Tobins Q (0.183), and the results are statistically insignificant except for Tobins Q (at 0.05 level). This indicates that market-based performance (TQ) is increased if the positions of the CEO and chairperson are combined. The age of the firm and ROA have a positive and significant relationship at 0.481, and the result is significant at the 0.01 level. The size of the firm and Tobins Q has been found to be positively associated and significant at 0.01 level. The growth of the firm and ROE have a positive and significant association, and the results are statistically significant at 0.01 level. The remaining factors have insignificant association with the firms' performance factors.

Furthermore, the existence of multicollinearity is tested by calculating the variance inflation factor (VIF), where a VIF coefficient greater than ten indicates the presence of multicollinearity (Chetterjee and Price, 1977). Moreover, the mean of all VIFs is considerably larger than 1. The VIFs for individual variables were also very low, supporting the

previous conclusion that the explanatory variables included in the model are not substantially correlated with each other. The results of VIF among all the cases are shown in Table VIII.

Test to check whether the data are stationary or time series

Before going on with the subject, has to find out if the data have time series influence or are stationary. Durbin-Watson test has been conducted using SPSS to check the nature of the data. Computation of Durbin-Watson test was done taking the dependent variables (ROA, ROE and Tobins *Q*) and all the independent variables together. The result observed from Table IV reflects that Durbin-Watson test results are 1.946, 1.772 and 1.689 for ROA, ROE and Tobins *Q*, respectively, which fall within the acceptable range of 1.50-2.00 and satisfy the assumption of independence of errors. The Durbin-Watson test result is out of the range of −1.5 to +1.5, which proves that the data are time series one and are stationary. Moreover, by checking the Durbin-Watson table, it is observed that $d_u < d < 4-d_u$ (d_u is derived from the table and d is the Durbin-Watson test result). The results become closer to 2, which is in acceptable range, which proves that the data are not a time series one and are stationary. Thus, there is no autocorrelation between the dependent and independent variables. It is concluded from the above analysis that the data do not have time series influence and are stationary. Hence, we can utilize regression for the present study.

Regression results

The correlation analysis indicates that there exists a negative relationship between board characteristics such as board size, board independence and board meetings with firms' performance indicators of ROA, ROE and Tobins *Q*. So as to further analyze these relationships and to test the hypothesis, the OLS regression was run, and to be find out the predictors of firms' performance factors as dependent variables and board characteristics as independent variables, controlling for other variables was also done.

Tables IX and X sum up the results of regression analysis. It can be seen from Table IX that in model 1, board variables with ROA is fitted the regression equation and explains 44.6 percent variance in firms performance as shown by R square. The *F* ratio is 10.653 and is highly significant at less than 1 percent level. The R^2 value of model 2 is 0.438, which means that 43.8 percent of the dependent variable (ROE) is explained by independent variables. The R^2 value of model 3 is 0.570, which means that 57.0 percent of the dependent variable (ROE) is explained by independent variables. It can be observed from it that *F* statistics of the respective models are 10.653, 10.183 and 19.170, respectively, and the results are highly significant at 0.000. Hence, as the *p*-value is less 0.05, there can be a linear relationship between the dependent variables (ROA, ROE and Tobins *Q*) and selected independent variables.

The regression results as shown in Table X indicate that there is a statistically significant correlation between firms' performance and board effectiveness. It is also observed from the regression analysis (Model 1) in Table X that "leverage" has a *p*-value of 0.960 and the corresponding *t*-value of 0.150. It signifies that this particular variable is not important in

Table X. Regression result

the model. Similarly, "growth of the firm" (p-value of 0.768 and the corresponding t-value of −0.295) and "size of the firm" (p-value of 0.166 and the corresponding t-value of 1.389) have p-value more than 0.05 and t-values within the range of −2 to +2. These variables also seem not to be important enough in the model, so they need to be removed. While it is also observed that "board size," having a p-value of 0.046 and a t-value of −2.082; "board independence," having a p-value of 0.021 and a t-value of 3.115; "board meetings" having a p-value of 0.047 and a t-value of −2.369; "CEO duality," having a p-value of 0.049 and a t-value of −2.058; and "age," having a p-value of 0.000 and a t-value of 8.680, are highly significant variables in determining the firms performance (ROA) of manufacturing firms in India.

It is also observed from the regression analysis (Model 2) in Table X that "leverage" has a p-value of 0.413 and the corresponding t-value of −0.819. It signifies that this particular variable is not important in the model. Similarly, "board meetings" (p-value of 0.529 and the corresponding t-value of 0.631) and "age" (p-value of 0.299 and the corresponding t-value of −1.104) have p-values more than 0.05 and t-values within the range of −2 to +2. These variables also seem not to be important enough in the model, so they need to be removed. While it is also observed that "board size," having a p-value of 0.010 and a t-value of −2.791; "board independence," having a p-value of 0.000 and a t-value of −4.580; "CEO duality," having a p-value of 0.003 and a t-value of 4.164; "size," having a p-value of 0.018 and a t-value of 2.385; and "growth," having a p-value of 0.000 and a t-value of 8.383 are significant variables in determining the firms' performance (ROE) of manufacturing firms in India.

It is also observed from the regression analysis (Model 3) in Table X that "leverage" has a *p*-value of 0.054 and the corresponding *t*-value of –1.935. It signifies that this particular variable is not important in the model. Similarly, "age" (*p*-value of 0.547 and the corresponding *t*-value of −0.603) and "growth" (*p*-value of 0.332 and the corresponding *t*-value of 0.972) have *p*-values more than 0.05 and *t*-values within the range of −2 to +2. These variables also seem not to be important enough in the model, so they need to be removed. While it is also observed that "board size," having a *p*-value of 0.045 and a *t*-value of −2.833; "board independence," having a *p*-value of 0.031 and a *t*-value of −3.763; "board meetings," having a *p*-value of 0.003 and a *t*-value of −3.505; "CEO duality," having a *p*-value of 0.035 and a *t*-value of 2.859; and "size," having a *p*-value of 0.000 and a *t*-value of 11.629, are significant variables in determining firms' performance (Tobin's *Q*) of manufacturing firms in India. This positive sign is a consistent signal of stewardship theory which explain CEO duality positively influences firm performance (Huining, 2014) (Table XI).

Discussion, conclusion and implications

This study has investigated the influence the board characteristics of corporate governance measures has on the financial performance of Indian manufacturing industries. A sample of 275 industries across 18 different sectors was cross-sectionally analyzed with the help of OLS regression method. From the study, it can be said that "leverage," "age," "growth" and "board meetings" seem not to be statistically important and they do not influence the profitability of the manufacturing firms in India, whereas "board size, board independence, CEO duality and size of the firm" are important variables for determining the manufacturing firms' performance (ROA, ROE and Tobins *Q*) in India. It can be inferred from the results derived above that board characteristics and firms' performance of manufacturing firms in India. Theoretically, the effectiveness of board of directors, a central governance mechanism, is expected to be positively related to corporate governance quality. The study explored this relationship empirically with the use of board size, board independence and board meeting and found contradictory results regarding firms' performance parameters. These results were consistent and similar to previous studies (Arora and Sharma, 2015; Palaniappan and Rao, 2015; Sarpal and Singh, 2013). The study found that board size of a firm has emerged as an important determinant of firm's performance but the interesting part is that it is negatively related with firm performance (Gugnani, 2013). The results indicate that among the various factors affecting the corporate governance, board characteristics are strongly and negatively related to firms' performance

Table XI. Summary of hypothesis testing results

Sl. no.	Hypothesis	Proposed Sign	Hypothesis test result ROA	ROE	Tobins *Q*	Tools
H1	There is no significant association between board size and firm performance	±	Negative and significant	Negative and significant	Negative and significant	Regression
H2	There is a positive and significant association between firm's performance and board independence	+	Positive and significant	Negative and significant	Negative and significant	Regression
H3	There is a significant and negative association between attendance of directors in board meetings and firm performance	–	Negative and significant	Positive and insignificant	Negative and significant	Regression
H4	There is a significant negative association between CEO duality and firm performance	–	Negative and significant	Positive and significant	Positive and significant	Regression

measured with both accounting and market-based performance indicators. This result is as expected and supports the hypothesis that the optimum size of the board leads to the improvement of firm's performance. The use of ROA and ROE as proxies for financial performance has its own limitations. The results suggest that the marketing-based measures of financial performance (Tobin' *Q*, P/E and P/B) were not able to establish any relationship with corporate governance. It shows that the stock market performance of a firm is not related with it corporate governance measures and indicators (Gugnani, 2013).

The results of the study do indicate that the influence that board characteristics of corporate governance has on firm performance is significant. Hence, this study recommends that corporate entities should promote corporate governance measures effectively to send a positive signal to potential investors. In addition, the regulatory agencies including government should promote and socialize corporate governance regulatory measures and its relationships to firm performance across industries. So when policy makers of a nation within the Indian context decide that manufacturing firms should have the attention of board characteristics on the basis of an improvement in firm performance. The contribution of this study has been to find that board characteristic does have an influence on manufacturing firms' performance in India. The outcome of the study has been learned about the relevance and in line with regards to other developing countries, the board characteristics have strongly influenced in the performance of the firms. Despite these benefits, much can still be said about the ongoing debate between the agency theory and stewardship theory.

Limitations and further research

As with all empirical studies, the current research has several limitations, and overcoming these can be a guide for future research. First, the data are based on board characteristics; therefore, the research is exempt from the board composition, that is, the presence of women director on the board, board meeting attendance of especially by independent directors concern, Annual General Meeting and number of meetings conducted by the firms with beyond the required statutory level. Future research could combine measures of presence of women directors, meeting of independent directors and AGM attendance, which have some effect on firms' performance. Second, the current research explores the effect of some board elements such as audit committee and other committees on overall firm's performance. Further research could extend the model to include additional dimensions of the audit committee-based measures in order to better understand the firms' financial performance. Third, the current study does not include all possible board characteristics such as large shareholders' dominance on the board, promoter's shareholding and institutional shareholding to support their firm's performance. Further research might include the ownership structure on board to improve the firm's performance. Finally, this research is limited to Indian manufacturing firms. Future research should consider different countries, inter-differences with medium- and large-scale firms and private and public undertaking firms. There are certain limitations of this study because it focuses on internal governance mechanisms, ignoring external factors, which can have a more significant impact on corporate financial performance.

A B S T R A C T

The purpose of this study is to describe the development of market based accounting research (MBAR) published in Indonesia for 10 years. This study attempts to explain the topics of MBAR, research method used, the variables, between-variable relationship formed, and the units analysis used in MBAR. This research uses qualitative-descriptive method to create descriptive models of MBAR articles published in accounting journals that have been accredited with minimum grade of B. The analysis of 109 MBAR articles of five accounting journals shows that 10 MBAR themes are still potential. Among three methods in MBAR, the multivariate association study is dominant. Some papers use intervening and moderating model to explore the relationship between accounting data and capital market reaction. The results for each theme are described in a research map that shows the relationship between variables (constructs) of MBAR from three units of analysis. This paper finds some implications to MBAR research agenda in the future, especially for meta-analysis research and triangulation research, due to many inconsistencies of the MBAR findings in Indonesia. In addition, accounting standard research topic is still promising in the moment of accounting standards transition.

1. Introduction

Lev and Ohlson (1982) and Meek and Thomas (2004) express the notion of capital market based accounting research (MBAR) to find the relationship between published accounting information with the consequences of the use of such information that is reflected in the characteristics of securities traded in capital markets. MBAR is considered as a popular topic because various MBAR papers presented at the *Simposium Nasional Akuntansi* or SNA (Indonesian Accounting Symposium) as well as published in Accounting Review journal. Table 1 presents the number of MBAR articles presented in SNA and Accounting Review.

MBAR generally tests the decision of accounting information (see Scott, 2006, 122-148). In Indonesia, accounting research that aims to map the development MBAR is not too popular. Mapping research is descriptive research that transfers data into more meaningful format, indicates areas that need further study, provides a basis for discussions that produce a common understanding about a problem, and produce a model that represents a descriptive structure of MBAR development (Abdel-Khalik and Ajinkya,1979, 21-23; Kothari, 1990, 2-3; Meyer and Rigsby, 2001).

This study aims to describe the development of MBAR in Indonesia for a decade. To achieve these objectives, the study seeks to generate graphical models that represent (1) the description of the themes examined by MBAR; (2) the description of the variables involved in MBAR; (3) the description of the research methods used; and (4) the description of the relationship between variables formed. The study reviews the development of MBAR in Indonesia and identifies research topics that need further investigation.

This research contributes to the development of MBAR in Indonesia by providing pedagogically valuable document as defined by Kothari (2001) which helps MBAR researchers to avoid reinventing the wheel. Descriptive research is very important to evaluate the development of a particular topic, highlight the theory, and criticize the empirical findings (for example see Brown et al., 1987; Brown et al., 2007; Cho and Jung, 1991; Healy and Palepu, 2001; Heck and Bremser, 1986; Simon, 2007). These research is useful for meta-analysis study that synthesize the results of relevant research to produce a conclusion about a body of research (Cooper, 2010, 6-7).

Table 1. MBAR Paper in SNA (National Accounting Symposium) & Accounting Review (AR)

Year	SNA			AR		
	MBAR paper	Total paper	%	MBAR paper	Total paper	%
2000	15	41	37%	3	68%	16%
2001	18	52	35%	6	58%	21%
2002	10	53	19%	8	43%	17%
2003	18	91	20%	14	45%	34%

2005	9	69	13%	13	54%	28%
2 006	12	84	14%	12	46%	28%
2007	3	80	4%	9	25%	20%
2008	9	78	12%	10	41%	19%
2009	9	64	14%	14	39%	20%
Total	130	722	18%	100	46%	23%

2. Literature Review

The development of MBAR since the 1970s to the 1990s is well described by Lev and Ohlson (1982), Kothari (2001), Beaver (1982, 1996, 2002), and Dumontier and Raffournier (2002). There are 10 topics of MBAR found in previous studies. Accounting information content, discretionary behavior, market efficiency, and value relevance have been reviewed by more than one study. Table 2 presents the list of these themes.

Table 2. The Division of MBAR Theme by Previous Researchers

No	Theme	Researcher
1.	The consequences of Accounting Standards	Lev & Ohlson (1982)
2.	The consequences of Performance Measure Alternatives	Kothari (2001)
3.	The consequences of Accounting Disclosure	Dumontier & Raffournier (2002)
4.	Accounting Value Information Content	Lev & Ohlson (1982); Dumontier & Raffournier (2002); Kothari (2001)
5.	Analyst Behavior	Beaver (2002)
6.	Discretionary Behavior	Lev & Ohlson (1982); Kothari (2001); Beaver (2002)
7.	Valuation and Fundamental Analysis	Kothari (2001)
8.	Market Efficiency	Lev & Ohlson (1982); Kothari (2001); Beaver (2002)
9.	Value Relevance	Kothari (2001); Beaver (2002)
10.	Earning Response Coefficient/ ERC	Kothari (2001)

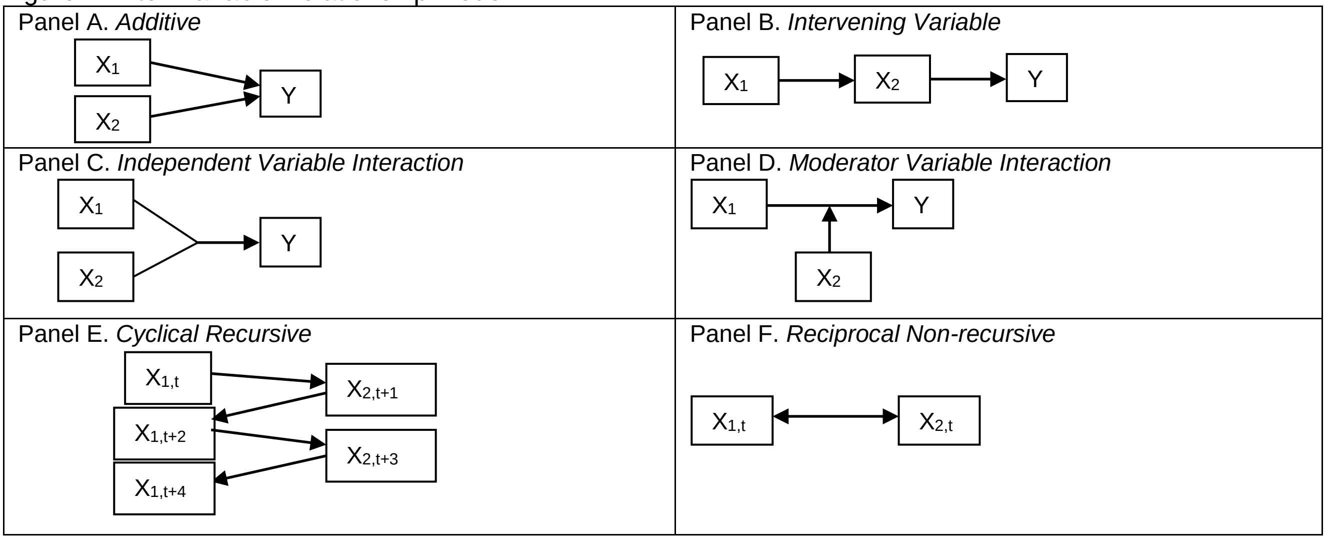
To test the 'relationship' between the accounting information published and the value of shares in the capital market, MBAR uses 2 methods i.e. event studies and association studies (Kothari, 2001). Through the event study, researchers will be able to conclude whether an event brings new information to market participants (Kothari, 2001) in timely basis. Specifically, if the returns before the event are different from the returns after or if the return in an event windows different with its average, the event has information content to investors (Tandelilin, 2010, 572-576). Event study is also used to test the efficiency of capital market (Hartono, 2008, 529-534).

On the other hand, association study provides evidence about the role of accounting data as a summary of events affecting the value of companies during the reporting period (Brown et al., 1999; Dumontier and Raffaournier, 2002). Association study does not conclude a causal relationship between accounting data and value stocks because accounting reports are not the only source of information (Kothari 2001). The strength of association between accounting information and price/return ordinary shares can be measured by R^2 (Brown et al., 1999; Dumontier and Raffaournier, 2002). Low association ($R^2 \approx 0$) means stock prices cannot be estimated using accounting data. High association ($R^2 \approx 1$) means that accounting data could be the estimator of stock price. These two methods will be used in descriptive modeling research framework (Figure 4) to describe the development of MBAR method in Indonesia.

According to definition of MBAR expressed by Lev and Ohlson (1982) and Meek and Thomas (2004), MBAR dependent variable should reflects investor reaction such as stock return and trading volume of shares (Deegan, 2000, 360; Beaver, 1968; Karpoff, 1986; Jang and Ro, 1989). Brown (1994, 27) states that the dependent variable of MBAR must reflect market behavior. In addition to returns and volume, there are some proxies of market behavior such as frequency of trading, bid-ask spread, or market depth. The independent variables of MBAR are any accounting information (events) that could change market expectations and reactions. MBAR does not search the relevance of any information other than accounting. The use of moderating and intervening variable in MBAR is not common. There were no published MBAR papers in JRAI (jurnal riset akuntansi Indonesia/ the Indonesian journal of accounting research) from 2000 to 2009 that stated using moderating and intervening variable in their title.

Luft and Shields (2003) have presented 6 models of inter-variable relationship that can be used by MBAR and represented descriptive structure of inter-variable relationship. These models are presented in figure 1.

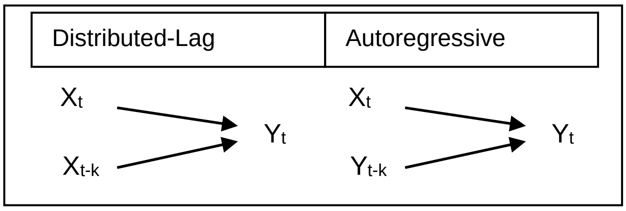
Figure 1. Inter-Variable Relationship Model



Source: Luft and Shields (2003)

There are 2 models that may be added since MBAR often use time series data i.e. distributed lag model and *autoregressive* model (Gujarati and Porter, 2009, 617). The two models are used because the independent variables have time lag in influencing the dependent variables.

Figure 2. Distributed-Lag and Autoregressive Model



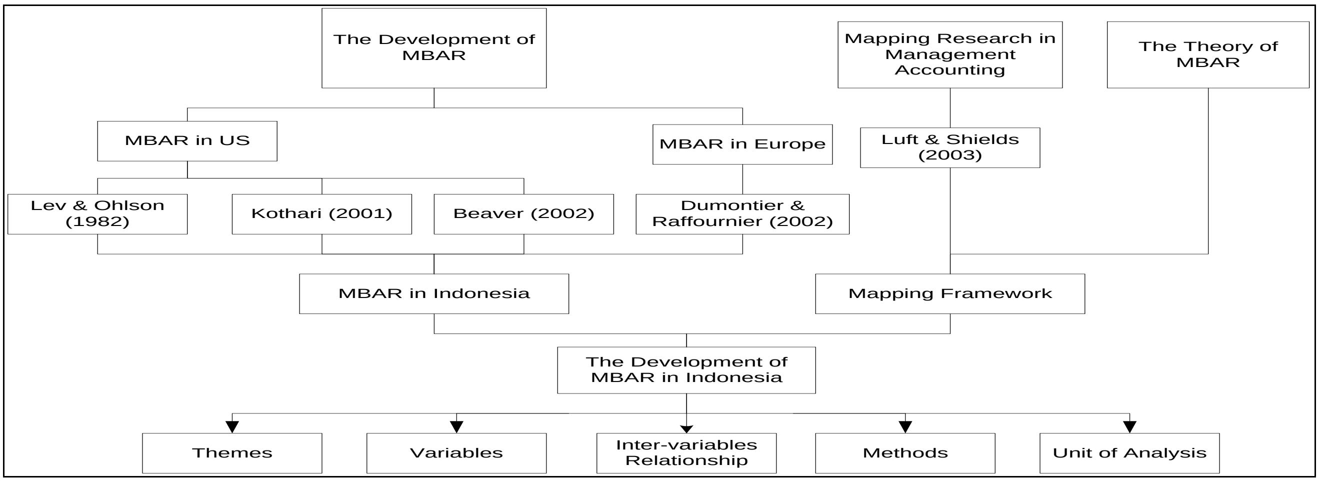
Source: Gujarati (2009: 617)

Luft and Shields (2003) divide the unit of analysis of accounting research into four categories. They are individual, organization subunit, organization, and beyond organization. MBAR usually uses organization as the unit of analysis. However, some of MBAR analyze market condition or macro-economic factors that is beyond organization.

One excellent review in accounting research is Luft and Shields (2003). Luft and Shields (2003) provide a guidance in reviewing the development of accounting research; include (1) identifying the themes and variables, (2) identifying the inter-variables relationship, (3) identifying the unit of analysis, and (4) establishing the mapping guidance. This paper borrows Luft and Shields' conceptual framework to mapping the development of MBAR in Indonesia. Moreover, this paper also develops its framework based on Lev and Ohlson (1982), Kothari (2001), Beaver (2002), and Dumontier and Raffournier (2002).

The framework of this research is shown in figure 3. This framework shows the gap of MBAR review in Indonesia. In mapping MBAR, this research uses Luft and Shields's framework that equipped with MBAR normative theory. The focuses of this research are to identify (i) MBAR themes, (ii) MBAR variables, (iii) relationship between variables, (iv) methods utilized, and (v) MBAR unit of analysis.

Figure 3. Research Framework



3. Research Methods

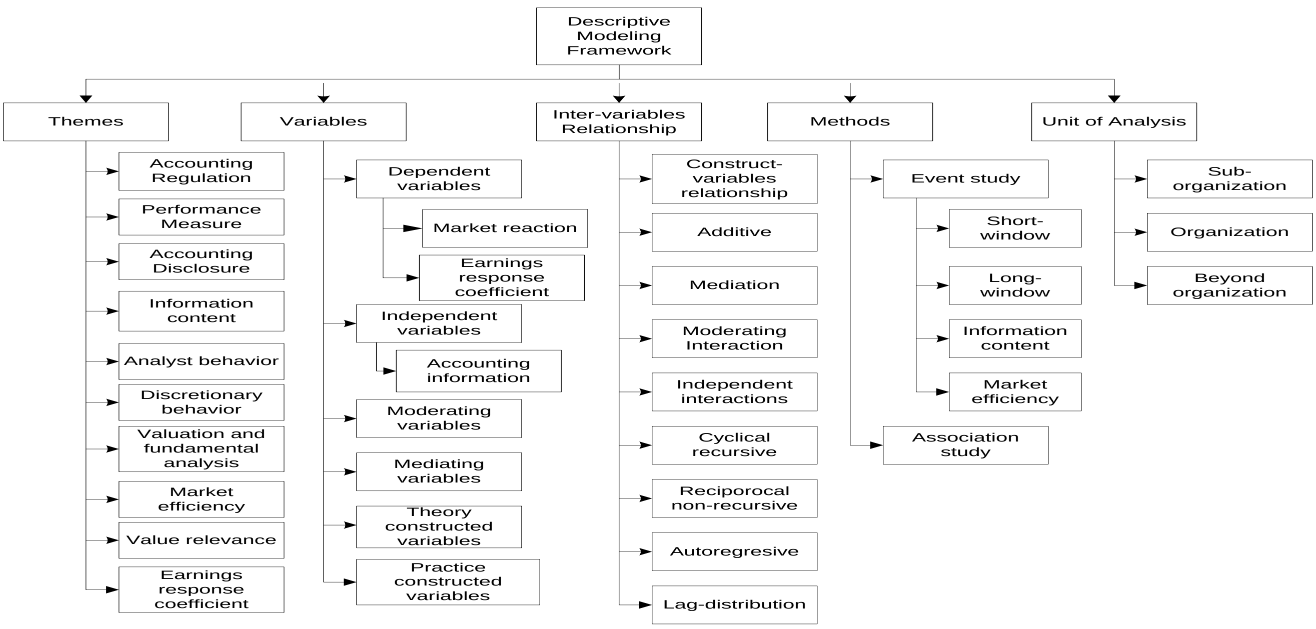
The framework developed in the literature review is used to describe the MBAR characteristics and offers ideas about future MBAR opportunities (the importance of research framework discussed in Sekaran, 2003, 122; Indriantoro and Supomo, 2002, 88). This study reviews MBAR articles published in Indonesia from 2000 until 2009. This research assumes that 10 years observations will be able to capture the development states of MBAR.

The subject of this research is MBAR papers that published in accredited accounting journals in Indonesia that satisfy two criteria. First, the journals should have B accreditation grade until 2010. This is important to control the quality of the MBAR articles. Second, the journals should publish accounting research articles only. A journal that publishes broad topics such as economics, management, and accounting might disproportionate the accounting topics.

This study uses Creswell's (2007, 150-155) recommendation to analyze qualitative data. The steps of analyzing the MBAR articles are (1) developing database; (2) sorting the data; (3) analyzing descriptive statistics, to find market share of MBAR, journal share, and the profile of research model; (4) analyzing the content of MBAR publications, to identify the themes of MBAR, the variables researched, the relationship between variables, the methods utilized, the unit analysis used, the summary, limitation, and future research chance; and (5) describing the data using text, table, or chart.

This research uses descriptive framework of Luft and Shields (2003) to describe the development of MBAR. This research will describe the development of MBAR in the sense of its topics, variables, inter-relationship of variables, methods, and the unit of analysis. This framework is used to discuss the findings of this paper (See figure 4.)

Figure 4. Descriptive Modeling Framework



4. Results and Discussion

This study finds 5 out of 22 accounting journals that satisfy the criteria. The journals are Jurnal Riset Akuntansi Indonesia (JRAI) published by Indonesian Institute of Accountant and the office in Universitas Gadjah Mada, Jogjakarta; Jurnal Akuntansi dan Keuangan Indonesia (JAKI) published by Universitas Indonesia, Jakarta; Jurnal Akuntansi (JA) published by Universitas Tarumanegara (UNTAR), Jakarta; Akuntabilitas (AK) published by Universitas Pancasila, Jakarta; and Jurnal Akuntansi dan Auditing Indonesia (JAAI) published by Universitas Islam Indonesia (UII), Jogjakarta. The list of these journals is shown in table 3.

Table 3. List of Accounting Journals

Panel A: Indonesia Accounting Journals

No	Name	ISSN	Description
1	Jurnal Akuntansi Dan Auditing Indonesia (JAAI)	1410-2420	Match the criteria

Others	72	31	112	73	69	357
Total	180	68	165	124	116	653

*FACM: financial accounting and capital market, a broader topic than MBAR.

4.1. Descriptive statistics of MBAR publication

Market share of MBAR is the percentage of MBAR articles that are published in a particular accounting journal (Hesford et al., 2007). MBAR is published in JRAI for 27.3% and 21.8% in JAKI. These two journals are leading in MBAR publication. Table 5 shows the trend of market share and journal share of MBAR.

Table 5. Market Share and Journal Share of MBAR

Panel A Market Share of MBAR
Market Share = (∑MBAR articles in journal *i*) ÷ (Total article of journal *i*)

Year	JRAI	JAKI	JA	AK	JAAI
2000	35.7%	–	NA	–	10.0%
2001	15.0%	–	NA	0.0%	10.0%
2002	19.0%	–	6.3%	0.0%	0.0%
2003	42.1%	–	NA	16.7%	9.1%
2004	45.0%	0.0%	0.0%	25.0%	25.0%
2005	38.9%	30.8%	10.7%	18.2%	16.7%
2006	16.7%	25.0%	16.0%	15.8%	16.7%
2007	16.7%	25.0%	16.0%	15.0%	25.0%
2008	17.6%	33.3%	11.1%	12.5%	0.0%
2009	26.7%	16.7%	13.3%	0.0%	0.0%
Average	27.3%	21.8%	10.5%	11.5%	11.2%

Panel B Journal Share of MBAR
Journal Share = (∑MBAR articles in *i* journal) ÷ (Total MBAR article in all journal)

Year	JRAI	JAKI	JA	AK	JAAI
2000	83.3%	–	NA	–	16.7%
2001	75.0%	–	NA	0.0%	25.0%
2002	80.0%	–	20.0%	0.0%	0.0%
2003	72.7%	–	NA	18.2%	9.1%
2004	60.0%	0.0%	0.0%	20.0%	20.0%
2005	38.9%	22.2%	16.7%	11.1%	11.1%
2006	20.0%	20.0%	26.7%	20.0%	13.3%
2007	18.8%	18.8%	25.0%	18.8%	18.8%
2008	25.0%	33.3%	25.0%	16.7%	0.0%
2009	44.4%	11.1%	44.4%	0.0%	0.0%
Average	51.8%	17.6%	22.5%	11.6%	11.4%

Journal share describes the total MBAR articles that published in a certain journal compare to all MBAR articles in all journals (Hesford et al., 2007). On average, JRAI contributes 51,8% of published MBAR articles in a decade. Though first published in 2004, JAKI provides 17.6% of MBAR articles.

Value relevance study gets the biggest portion (43.12%) of MBAR topics. Information content study had 15.60% portion from 109 MBAR articles and all journals have publication in this theme.

Table 6. The Themes of MBAR in Indonesia

Themes	The Amount of Articles						
	JRAI	JAKI	JA	AK	JAAI	Total	Portion
Analyst Behavior	–	–	–	–	–	0	0.00%
Valuation and Fundamental Analysis	1	–	–	–	–	1	0.92%
The consequences of Accounting Standards	2	–	–	–	–	2	1.83%
Market Efficiency	2	–	–	–	1	3	2.75%
The consequences of Performance Measure Alternatives	–	1	2	1	–	4	3.67%
The consequences of Accounting Disclosure	–	5	3	–	–	8	7.34%
Discretionary Behavior	8	2	–	2	1	13	11.93%
Earnings Response Coefficient	10	–	1	2	1	14	12.84%
Accounting Value Information Content	6	2	2	4	3	17	15.60%
Value Relevance	20	5	11	6	5	47	43.12%
Total	49	15	19	15	11	109	

ERC and discretionary behavior take the third and fourth position. The less researched themes are accounting disclosure consequences, consequences of performance measure, market efficiency, and accounting regulation consequences. The theme that never been researched in Indonesia is the market reaction toward analyst's forecasts because analyst forecast reports are not publicly available in Indonesia capital market.

4.2. Method and Inter-variable relationship

The result indicates that an article may use more than one research model and method. According to table 7, additive model is the most frequently used by researcher (panel A) and therefore, unidirectional and linear model become the most popular model (panel B). Moreover, MBAR that employs additive model and unidirectional (whether linear or not) is classified as association research (panel C). The result also shows that nonlinear relationship between accounting data with market reaction is unpopular (4 from 109 papers). The second popular model is construct-variable (panel A) that is used by event study and difference study (panel C). The third and fourth popular models are moderator variable interaction (panel A) and intervening model.

Table 7. MBAR Model and Method

Description	Frequency					
	JRAI	JAKI	JA	AK	JAAI	Total
Panel A: Research Model						
Additive (Add)	25	12	15	10	5	67
Intervening Variable (IV)	–	–	1	–	–	1
Independent Variable Interaction (IVI)	1	–	–	–	–	1
Moderator Variable Interaction (MVI)	11	3	2	–	1	17
Cyclical Recursive	–	–	–	–	–	–
Reciprocal Non-recursive	–	–	–	–	–	–
Distributed-Lag	–	–	–	–	–	–
Autoregressive	–	–	–	–	–	–
Construct-Variable relationship	17	3	3	5	5	33
Panel B: Classification of Model						
Unidirectional	37	15	18	10	6	86
Bidirectional	–	–	–	–	–	–
Linear	35	15	18	10	4	82
Curvilinear (Nonlinear)	2	–	–	–	2	4
Ordinal (*monotonic*)	12	3	2	–	1	18
Dis-ordinal (*non-monotonic*)	–	–	–	–	–	–
Construct-Variable relationship	17	3	3	5	5	33
Panel C: Research Method						
Association Study	37	14	18	10	6	85
Event Study	12	3	3	5	4	27
Difference Study	5	1	1	2	1	10

The theme of MBAR used in various research models are ERC and the discretionary behavior. On the other hand, market efficiency testing and information content study use only event study or difference study and the use of association study by these themes generally for additional analysis only. The other themes use various research methods. An article in valuation and fundamental analysis uses additive model with associative method. Such model and method are also used by performance measure alternative research. Research in consequences of accounting disclosure generally employs additive model (associative method) or construct-variable relationship (difference study). The last theme, consequences of accounting regulation, generally uses additive model, moderator interaction, and construct-variable relationship.

Table 8. The Using of Research Model and MBAR Themes

Research Model / MBAR Themes	Additive	Intervening variable	Independent var. Interaction	Moderating var. interaction	Construct-vari. relationship	Unidirectional	Linear	Nonlinear	*Monotonic*	Construct-vari. relationship	Association study	Event study	Difference study
Analyst Behavior	–	–	–	–	–	–	–	–	–	–	–	–	–
Valuation and Fundamental Analysis	1	–	–	–	–	1	1	–	–	–	1	–	–
The consequences of Accounting Standards	2	–	–	3	1	2	2	–	–	1	2	1	–

4.3. The development of MBAR

The next analysis emphasizes on qualitative aspect of MBAR development by drawing it into a research map. The map describes the variables researched, inter-variable relationship, and the unit of analysis. The map and its legend are presented in the appendix.

4.3.1. Analyst behavior

An analyst behavior research describes market consequences of analysts forecast publication. However, this research topic is not found because analyst forecast reports are not available for public. Therefore, regulatory body in Indonesia should consider that analyst forecast is to become one of the public information sources to make investment decision.

4.3.2. Valuation and fundamental analysis

Kothari (2001) describes that valuation and fundamental analysis aims to find out a company's valuation model that can reliably predict market value of shares. For a decade in Indonesia, only Wirama (2009) who studied the ability of Feltham and Ohlson (1995) valuation model in predicting market value of shares. However, many valuation models have not been researched yet such as dividend-discounting model or balance sheet model. *(See appendix 2)*

4.3.3. Accounting regulation consequences

Lev and Ohlson (1982) have described the development of research in consequences of accounting regulation in term of market reaction. There are 2 articles on this theme i.e. Alim and Hartini (2001) and Lestari and Baridwan (2008). They investigate the consequences of tax regulation changing and accounting policy difference, respectively. In Indonesia from 2000 to 2009, the global adoption IFRS has not been researched yet although it brings economic consequences (see for example Daske et al., 2008; Jeanjean and Stolowy, 2008). *(See appendix 3)*

4.3.4. Market efficiency

Three articles showed that Indonesia has a semi-strong capital market because it only reacts to existing information in capital market (Setiawan and Subekti, 2005; Marfuah, 2006). In term of decision-making, many investors react improperly to the growth of a company. Researchers conclude that Indonesian investors are more focus on potential cash information rather than financial statement indicators. However, the three researchers used the same model to test the efficiency market by using dividend announcement. Thus, many publications other than dividend have not been researched. *(See appendix 4)*

4.3.5. Performance measure alternative

Research in performance measure alternatives aims to identify the relationship between the uses of certain performance measured by the value of shares. The main conclusion of research in Indonesia is that EVA is still relevant to be used to predict the firm's value of shares although the result was not consistent. Other performance measures such as for banking, insurance, or mining that has special features remain to be potential research area. *(See appendix 5)*

4.3.6. Accounting disclosure consequences

Accounting disclosure consequences describes the relationship between accounting disclosure with the value of shares. Generally, the relationship between them in Indonesia was not conclusive. Besides accounting disclosure, many specific disclosures such as corporate governance or corporate social responsibility might influence investor decision making but have not been consistently proven. *(See appendix 6)*

4.3.7. Discretionary behavior

This theme focuses on the market reaction to discretionary behavior of management. In Indonesia, this research starts from the testing of differences in market reaction to financial statement containing earnings management. However, the results showed that earnings management inconsistently influenced market reaction. Researchers usually speculate on the reason of this inconsistency without giving more evidence. Therefore, motivation of earnings management, namely opportunistic and efficiency, needs to be elaborated in the future by using more sophisticated method.

The next step of discretionary research is to observe earnings management in the IPO session since there is a suspicion opportunistic behavior to get high initial price during the offering. Researchers found that listed companies did earnings management during the IPO although there was no consistent evidence of the ability of earnings management in influencing share price after IPO in the secondary market. *(See appendix 7)*

4.3.8. Earnings response coefficient (ERC)

ERC research in Indonesia is growing along the observation period. Kothari (2001) said that ERC researchers could only compare the significance of ERC with the response coefficient of other variables such as cash flow response coefficient. However, ERC in Indonesia runs more than Kothari (2001) expectation.

The explanatory variable of ERC is increasing such as foreign currency gain/loss, negative income, earnings surprise, auditor, and cash flow. Researchers usually use these variables as the moderator between unexpected earnings (UE) and cumulative abnormal return (CAR). In other words, these variables are used to test the responsiveness of CAR when there is an UE and other moderator variables. *(See appendix 8)*

4.3.9. Accounting information content

Accounting information content (AIC) can be called as announcement type research (Lev and Ohlson, 1982) because it seeks to find out the market reaction to the accounting publication/event using event study or difference study. The result shows that 17 articles of AIC use various publications such as earnings announcement, dividend, bonus share, bonds rating, right issue, and stock split. Earnings and dividend are still interesting for the market players although corporate action publication leads inconsistent reaction from market players.

AIC research remains interesting topic in the future because many questions have not been answered. Inter-industry information transfer could be potential topic to be further investigated since there was only one article discussed it about. Moreover, AIC research is facing a problem of the independency of price reaction with volume reaction although they come from the same market player. The date of earnings announcement in Indonesia still becomes classical problem because there is no such announcement in Indonesia unless for the companies that listed in cross-border stock exchange. Generally, researchers use the former of the date of financial statements submitting to the stock exchange, submitting it to SEC, or announcing it in mass media as the proxy of announcement date. Only some of MBAR researchers pay more attention to the direction of capital market reaction. Most of them focus on the existence of market reaction without considering the direction of the reaction. *(See appendix 9)*

4.3.10. Value relevance study

Value relevance study investigates the correlation of accounting data with stock price or its liquidity (Holthausen and Watts, 2001). Generally, the result of value relevance study indicates whether accounting value can predict stock price or not.

The consistency of prediction power of accounting value remains a questionable fact. Nonlinear model of relationship between accounting data and stock prices could not explain such inconsistency (Soepratikno and Hartono, 2005; Rahmawati, 2005, 2006; Sumarni and Rahmawati, 2007). Therefore, meta analysis is needed to indicate the best predictor of stock prices.

Although value relevance study is the most popular topic in MBAR, it has some weaknesses. Although the articles of value relevance study were published in accredited accounting journal, they used too small sample in utilizing parametric statistics. Other articles were not published in complete and standardized format. Moreover, an article was published twice in two different journals. This indicates the weaknesses of journal management and its review process. A common mistake of value relevance researchers is that they did not report the value relevance study, rather they found the best predictor of stock price and did not examine the causal relationship of accounting data and stock prices. *(See appendix 10)*

5. Conclusion

This research aims to describe the development of MBAR in Indonesia. The description is drawn on a research map that contains the theme of MBAR, variables, inter-variable relationship, methods, and unit of analysis MBAR. There are nine maps which represent the development of MBAR and contain 18 dependent variables, 154 independent variables, 19 moderating variables, 1 mediating variable, 34 constructs, 5 research models representing 3 research methods, and 3 unit of analysis. The analysis indicates that many MBAR areas are interesting to be investigated in the future. MBAR will be a more important research since the convergence process of international accounting standard is ongoing in 2012. Moreover, meta analysis is needed to synthesize the inconsistency results of MBAR.

However, this study contains some weaknesses. This paper only observes 10 years development while many previous researches make a review for at least 20 years. Due to the data limitation, this paper could review only a decade of Indonesia accounting research publication that historically starts in the late 90's. Since this study use descriptive approach for broad research area, the analysis is broad but not deep. Therefore, future research should deeply elaborate each theme mapped in this research.

APPENDICES

Appendix 1

Map Notation

The map notation used in this research is adopted from Luft and Shields (2003).

I. Association study

1. Additive, linear, and unidirectional:

Positive: 

Negative: 
Not Specific: 

Not Related 

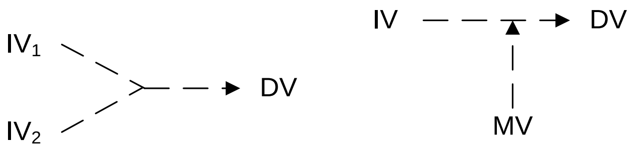
2. Intervening model, for example:

3. Interaction Model,

a. Ordinal (monotonic) model with general sign:

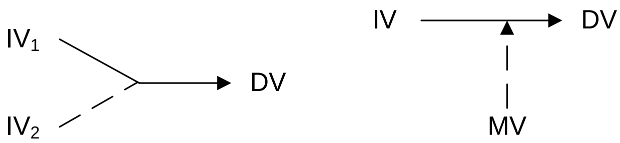
i. IV_2 or MV strengthen positive relationship of IV_1 – DV

ii. IV_2 or MV strengthen negative relationship of IV_1 – DV

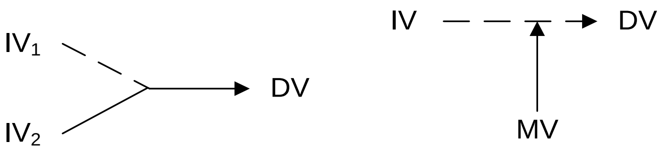


b. Ordinal Model with mixed-sign:

i. IV_2 or MV negatively influence the positive relationship of IV_1 – DV



ii. IV_2 or MV positively influence the negative relationship IV_1 – DV



4. Nonlinear unidirectional relationship:

a. U relation: 

b. Inverted U relation: 

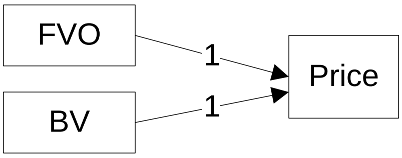
II. Construct-Variable relationship

1. Construct: informative event, sample divider factor (immeasurable) 
2. Variable (measurable) 
3. The relationship between construct and variable

Positive: 
Negative: 
Unspecific: 
Not related: 
Appendix 2 Fundamental Analysis and Valuation

Unit of analysis: Beyond organization
–

Unit of analysis: organization



Unit of analysis: Organization subunit
–

Dependent variable:
1. *Price*: Market capitalization

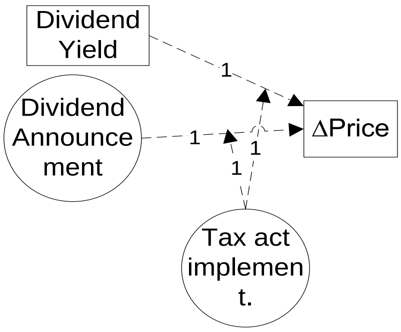
Independent variable:
1. BV: Companies book value
2. NMO: Ohlson (1995) model value

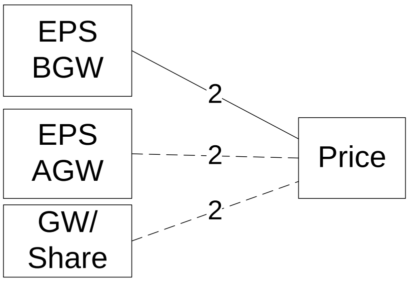
Source:
1. Wirama (2009)

Appendix 3 Accounting regulation consequences

Unit of analysis: Beyond organization
–

Unit of analysis: organization





Unit of analysis: Organization subunit
–

Constructs:
1. Tax act implementation: The category of difference test to divide sample into before-and-after tax act amendment
2. Dividend announcement: An event of announcing dividend

Dependent variables:
1. Price: Stock price
2. ΔPrice: Stock price changes

Independent variables:
1. EPSAGW: EPS after goodwill amortization
2. EPSBGW: EPS before goodwill amortization
3. GW/Share: Goodwill amortization per share

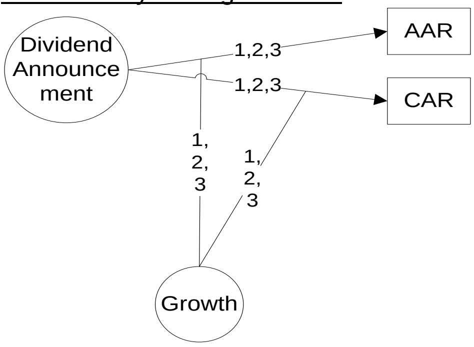
Sources:
1. Alim and Hartini (2001)
2. Lestari and Baridwan (2008)

Appendix 4 Market Efficiency

Unit of analysis: Beyond organization

–

Unit of analysis: organization



Unit of analysis: Organization subunit

–

Constructs:

1. Dividend Announcement: An event of announcing dividend
2. Growth: A category to divide sample into two groups i.e. growing and not growing, measured by market value equity/book value equity or capital expenditure/book value of asset)

Dependent variables:

1. AAR: Average abnormal return (market model)
2. CAR: Cumulative abnormal return (market model)

Sources:

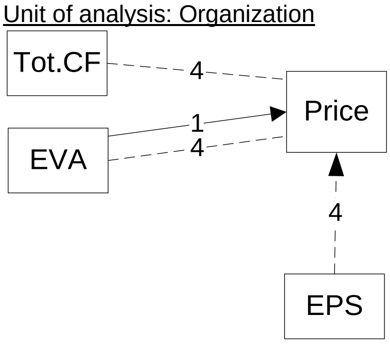
1. Setiawan and Hartono (2003)
2. Setiawan and Subekti (2005)
3. Marfuah (2006).

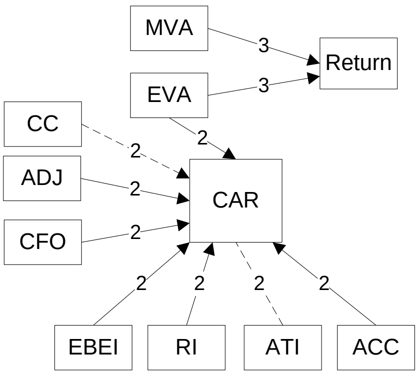
Appendix 5 Performance Measure Consequences

Unit of analysis: Beyond organization

–

Unit of analysis: Organization





Unit of analysis: Organization subunit

–

Dependent variables:

1. CAR: Cumulative abnormal return
2. Price: Stock price
3. Return: Stock return

Independent variables:

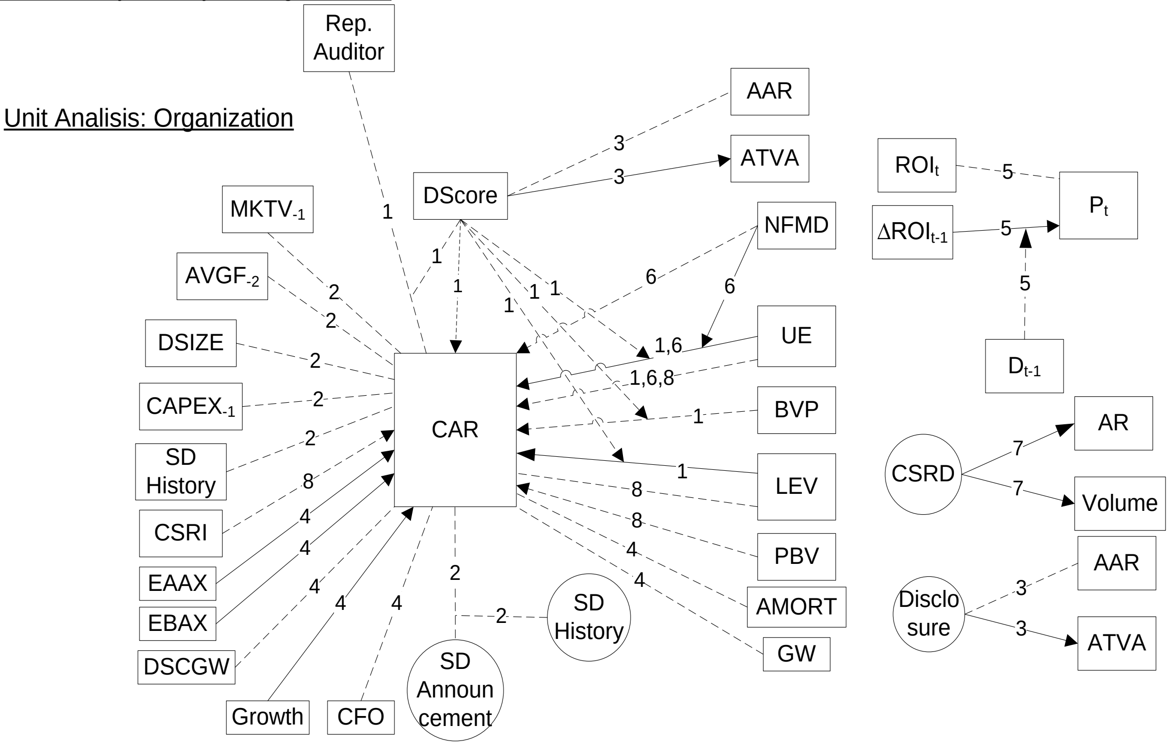
1. ACC: Accrual
2. ADJ: Accounting adjustment
3. ATI: After tax interest
4. CC: Capital charge
5. Tot.CF: Cash flow
6. CFO: Operating cash flow
7. EBEI: Earnings before extraordinary item
8. EPS: Earnings per share
9. EVA: Economic value added
10. MVA: Market value added
11. RI: Residual income

Sources:

1. Ekadjaja (2006)
2. Hidayat (2006)
3. Madiah, Sugiarto, and Siagian (2006)
4. Sriwahyuni (2007)

Appendix 6 Accounting Disclosure Consequences

Unit of analysis: Beyond organization



Unit of analysis: Organization subunit

–

Constructs:

1. CSRD: Corporate social responsibility disclosure index, sample divider
2. Disclosure: Announcement of financial statement
3. SD Announce: Stock dividend announcement
4. SD History Stock dividend history, sample divider

Dependent variables:

1. AAR: Average Abnormal return
2. AR: Abnormal return
3. ATVA: Average trading volume activity
4. CAR: Cumulative abnormal return (size adjusted model)
5. Price: Stock price
6. TVA: Stock trading volume

Independent variables:

1. ΔROI_{t-1} : ROI Changes
2. AMORT: The ratio of goodwill amortization expense and income after amortization
3. $AVGF_{-2}$: Two years operating cash flow average
4. BVP: Book value per share
5. $CAPEX_{-1}$: Capital expenditure
6. CFO: Operating cash flow
7. CSRD: Corporate social responsibility disclosure
8. CSRI: Corporate social responsibility index
9. DSCGW: Goodwill disclosure rate
10. DSIZE: Dummy for firm size

11. EAAX: Earning after goodwill amortization and extraordinary item
12. EBAX: Earning before goodwill amortization and extraordinary item
13. Growth: Company growth
14. GW: Goodwill portion of asset
15. LEV: Leverage
16. $MKTV_{-1}$: Market value of equity
17. NFMD: Nonfinancial measure disclosure
18. PBV: Price-to-equity book value
19. Rep. Auditor: Auditor reputation
20. ROI_t : Return on investment
21. SD History: Stock dividend history
22. UE: Unexpected earning

Moderating variables:
1. D_{t-1} : Disclosure index for period t-1
2. Dscore: Disclosure index

Sources:
1. Adhariani (2005)
2. Aloysius (2005)
3. Junaedi (2005)

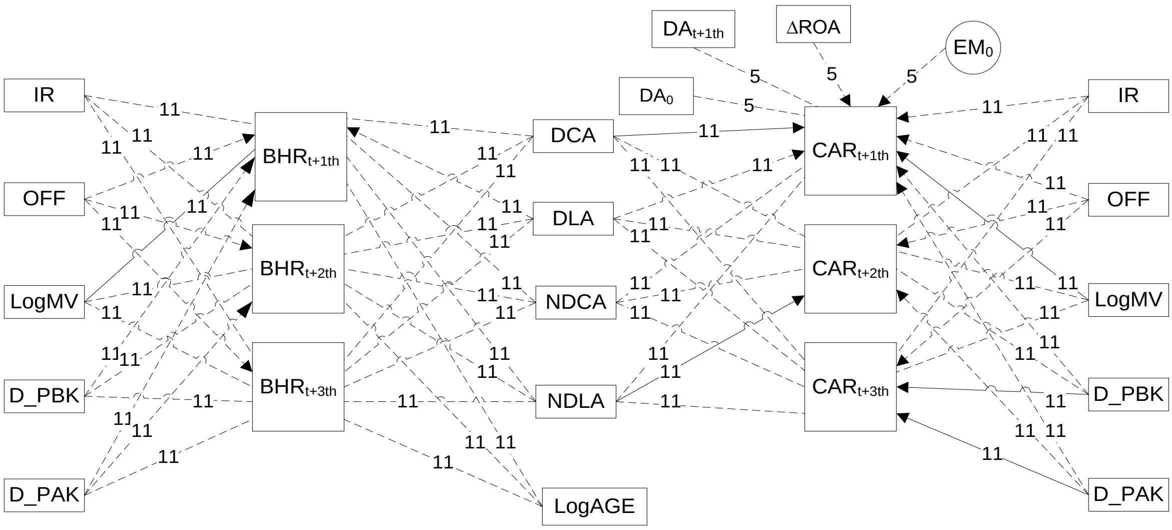
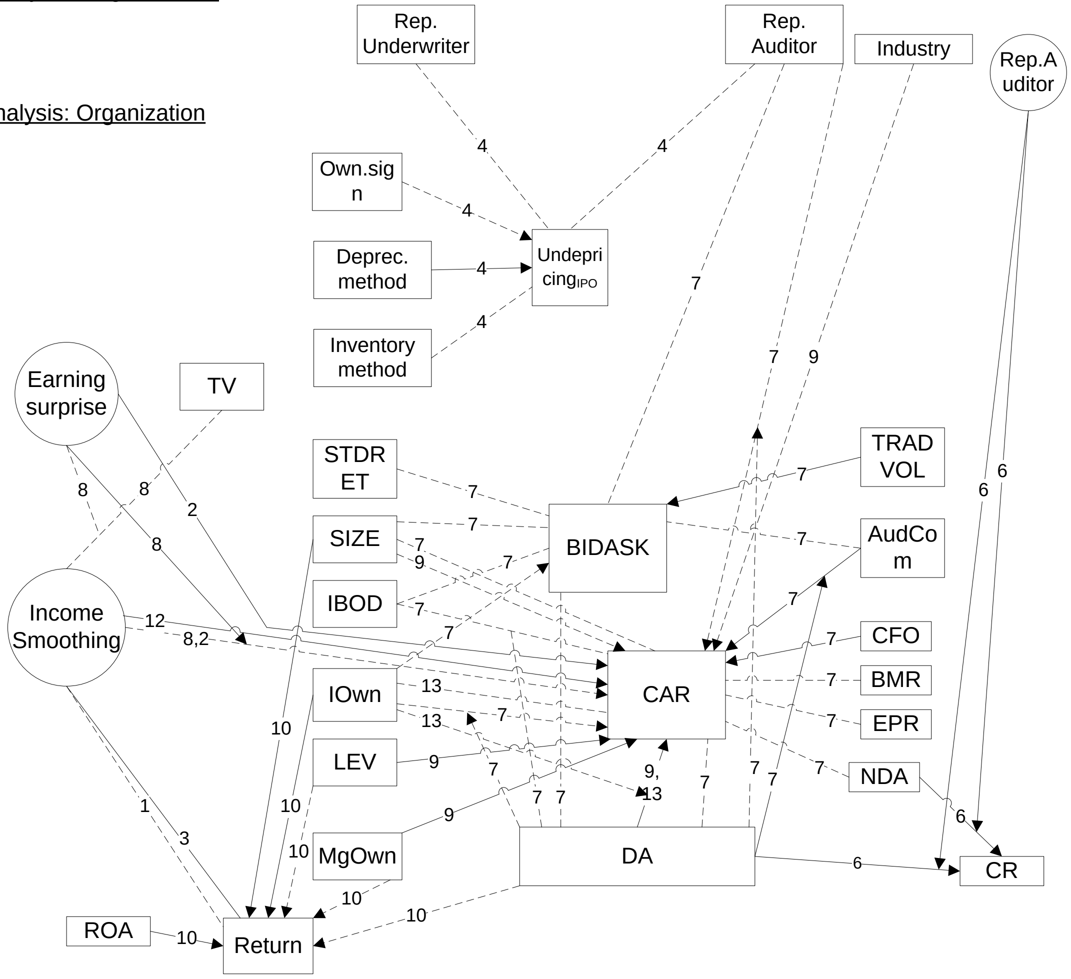
Appendix 7A Discretionary Behavior

Unit of analysis: organization



Appendix 7B Discretionary Behavior

Unit of analysis: Beyond organization



Unit of analysis: Organization Subunit

–

Constructs:

1. Rep. Auditor: Auditor reputation, sample divider
2. Earning surprise: Sample divider
3. Income smoothing: Sample divider (smoother vs. non-smoother)
4. IPO: Initial public offering

Dependent variables:

1. BHR_{t+n}: Buy and hold return after IPO
2. BIDASK: Bid-ask spread
3. CAR: Cumulative abnormal return
4. CAR_{t+n}: Cumulative abnormal return after IPO
5. CR: Cumulative return.
6. Return: Stock return
7. TVA: Trading volume activity
8. Under-pricing: The gap between first closing price in secondary market and initial price in primary market

Independent variables:

1. ΔROA: Changes of return on asset
2. AudCom: The dummy of audit committee
3. Rep. Auditor: The dummy of auditor reputation
4. BMR: Book-to-market ratio
5. CFO: Operating cash flow
6. D_PAK: The dummy of IPO date after crisis
7. D_PBK: The dummy of IPO date after crisis
8. DA: Discretionary accrual
9. DA_0: Discretionary accrual at IPO date
10. DA_{t+1th}: Discretionary accrual at year after IPO
11. DCA: Discretionary current accrual at IPO date
12. DLA: Discretionary long-term accrual at IPO date
13. EPR: Earning-to-price

14.	IBOD:	Independent board
15.	Industry:	The dummy of industry
16.	IOwn:	Institutional ownership
17.	IR:	Initial return
18.	LEV:	Leverage
19.	LogAGE:	Company age
20.	LogMV:	Firm market value
21.	Deprec. method:	Depreciation method
22.	Inventory method:	Inventory method
23.	MgOwn:	Managerial ownership
24.	NDA:	Non-discretionary Accrual
25.	NDCA:	Non-discretionary current accrual
26.	NDLA:	Non-discretionary long-term accrual
27.	OFF:	Offering price
28.	Rep. underwriter:	Underwriter reputation
29.	ROA:	Return on asset
30.	Own. sign:	Ownership signal
31.	SIZE:	Firm size
32.	STDRET:	Stock return deviation standardized
33.	TRADVOL:	Average of trading volume

Moderating variables:

1.	DA:	Discretionary accrual

Sources:
1. Salno and Baridwan (2000)
2. Assih and Gudono (2000)
3. Prasetio *et al.* (2002)

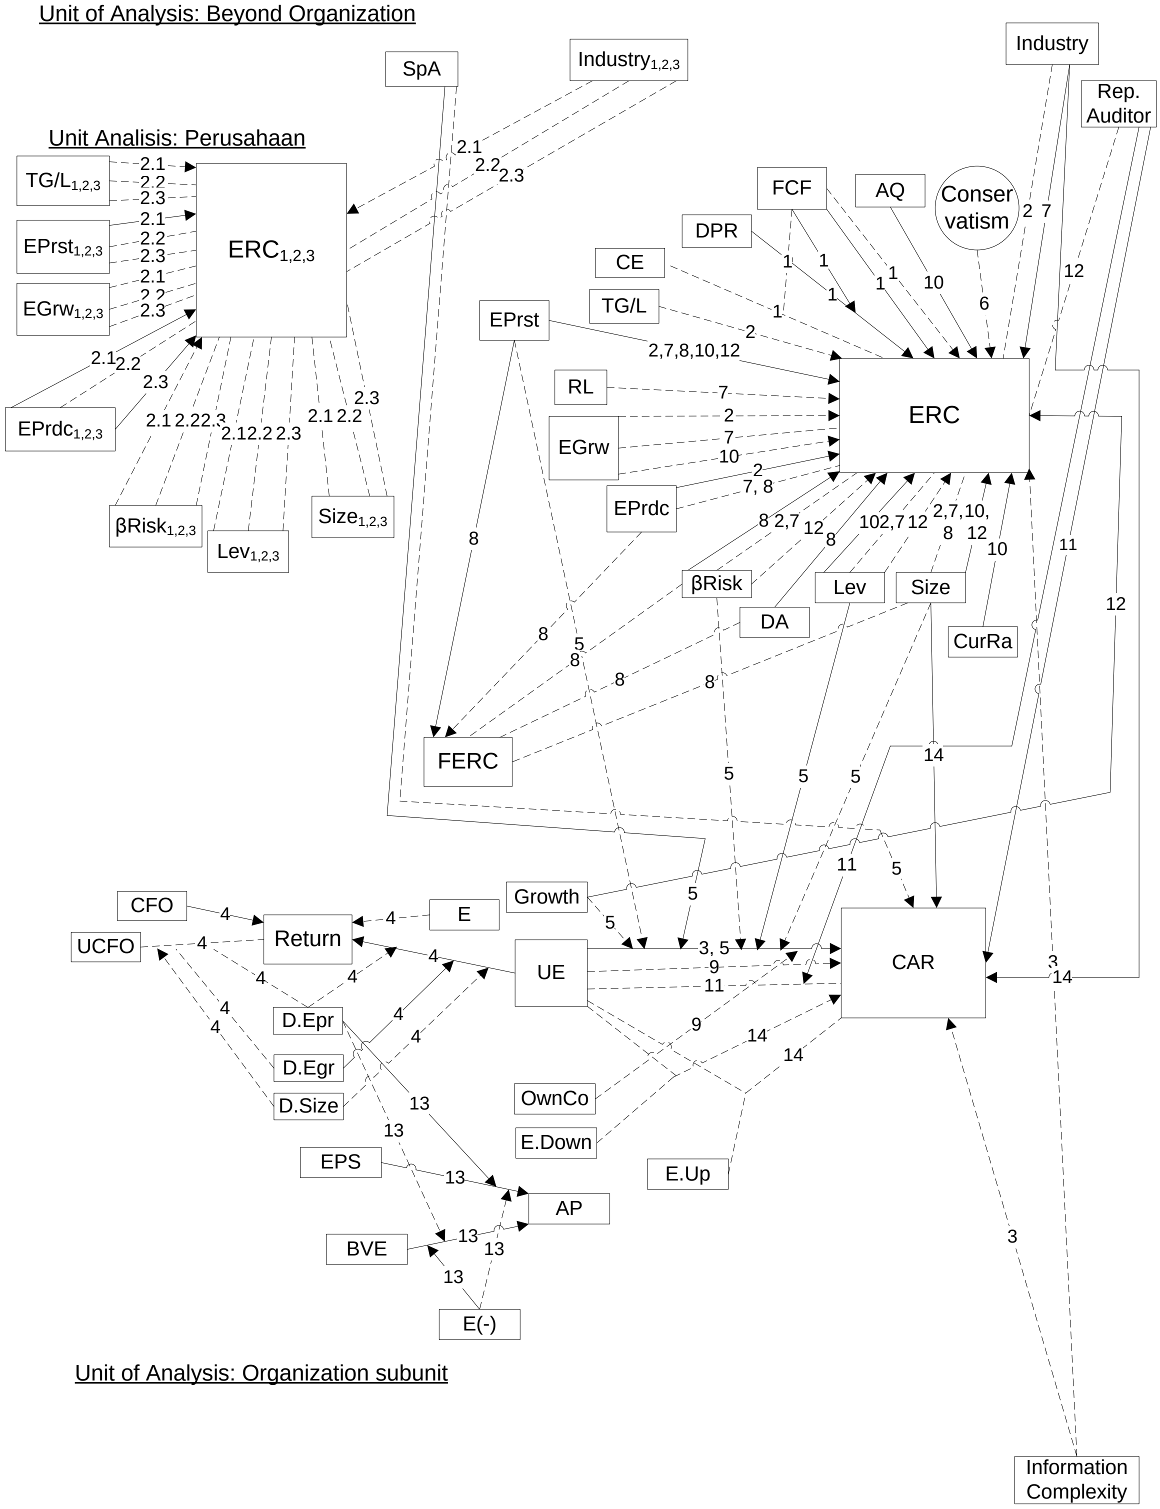
12. Oktorina and Hutagaol (2009)
13. Joni and Hartono (2009)

Appendix 8 Earnings Response Coefficient



Constructs:
1. Conservatism: Sample divider (conservative and other)

Dependent variable
1. AP: Adjusted stock price
2. CAR: Cumulative abnormal return
3. ERC: Earnings response coefficient
4. $ERC_{1,2,3}$: Earnings response coefficient for particular sample
5. FERC: Future ERC
6. Return: Stock return

Independent variables:
1. AQ: Accrual quality
2. BVE: Book value of equity per share

3. CE: Capital expenditure
4. CFO: Operating cash flow
5. CurRa: Current ratio
6. DA: Discretionary accrual
7. DPR: Dividend pay-out ratio
8. Earnings: Firms income
9. EGrw: Earnings growth
10. $EGrw_{1,2,3}$: Earnings growth for particular sample
11. EPrdc: Earnings predictability
12. $EPrdc_{1,2,3}$: Earnings predictability for particular sample
13. EPrst: Earnings persistency
14. $EPrst_{1,2,3}$: Earnings persistency for particular sample
15. EPS: Earnings per share
16. FCF: Free cash flow
17. Industry: The dummy for industry
18. $Industry_{1,2,3}$: The dummy for industry for particular sample
19. Information complexity
20. Lev: Leverage
21. $Lev_{1,2,3}$: Leverage for particular sample
22. Rep. Auditor: Auditor reputation
23. RL: Reporting lag
25. $Size_{1,2,3}$: Firm size for particular sample
26. SpA: Auditor specialization
27. TG/L: Foreign currency gain/loss
28. $TG/L_{1,2,3}$: Foreign currency gain/loss for particular sample
29. UCFO: Unexpected operating cash flow
30. UE: Unexpected earnings
31. βRisk: Risk
32. $βRisk_{1,2,3}$: Risk for particular sample

Moderating variables:
1. Rep. Auditor: Auditor reputation
2. D.Egr: Dummy for earnings growth
3. D.EPr: Dummy for earnings persistency
4. D.Size: Dummy for firm size
5. E(-): Dummy negative income
6. E.Down: Unexpected negative income
7. E.Up: Unexpected positive income
8. FCF: Free cash flow
9. Growth: Firms growth
10. OwnCo: Ownership concentration
11. SpA: Auditor specialization

Sources:
1. Uyara and Tuasikal (2003)
2. Chandrarin (2003), which divided into 2.1, 2.2, and 2.3
3. Kusuma (2003)
4. Diana and Kusuma (2003)

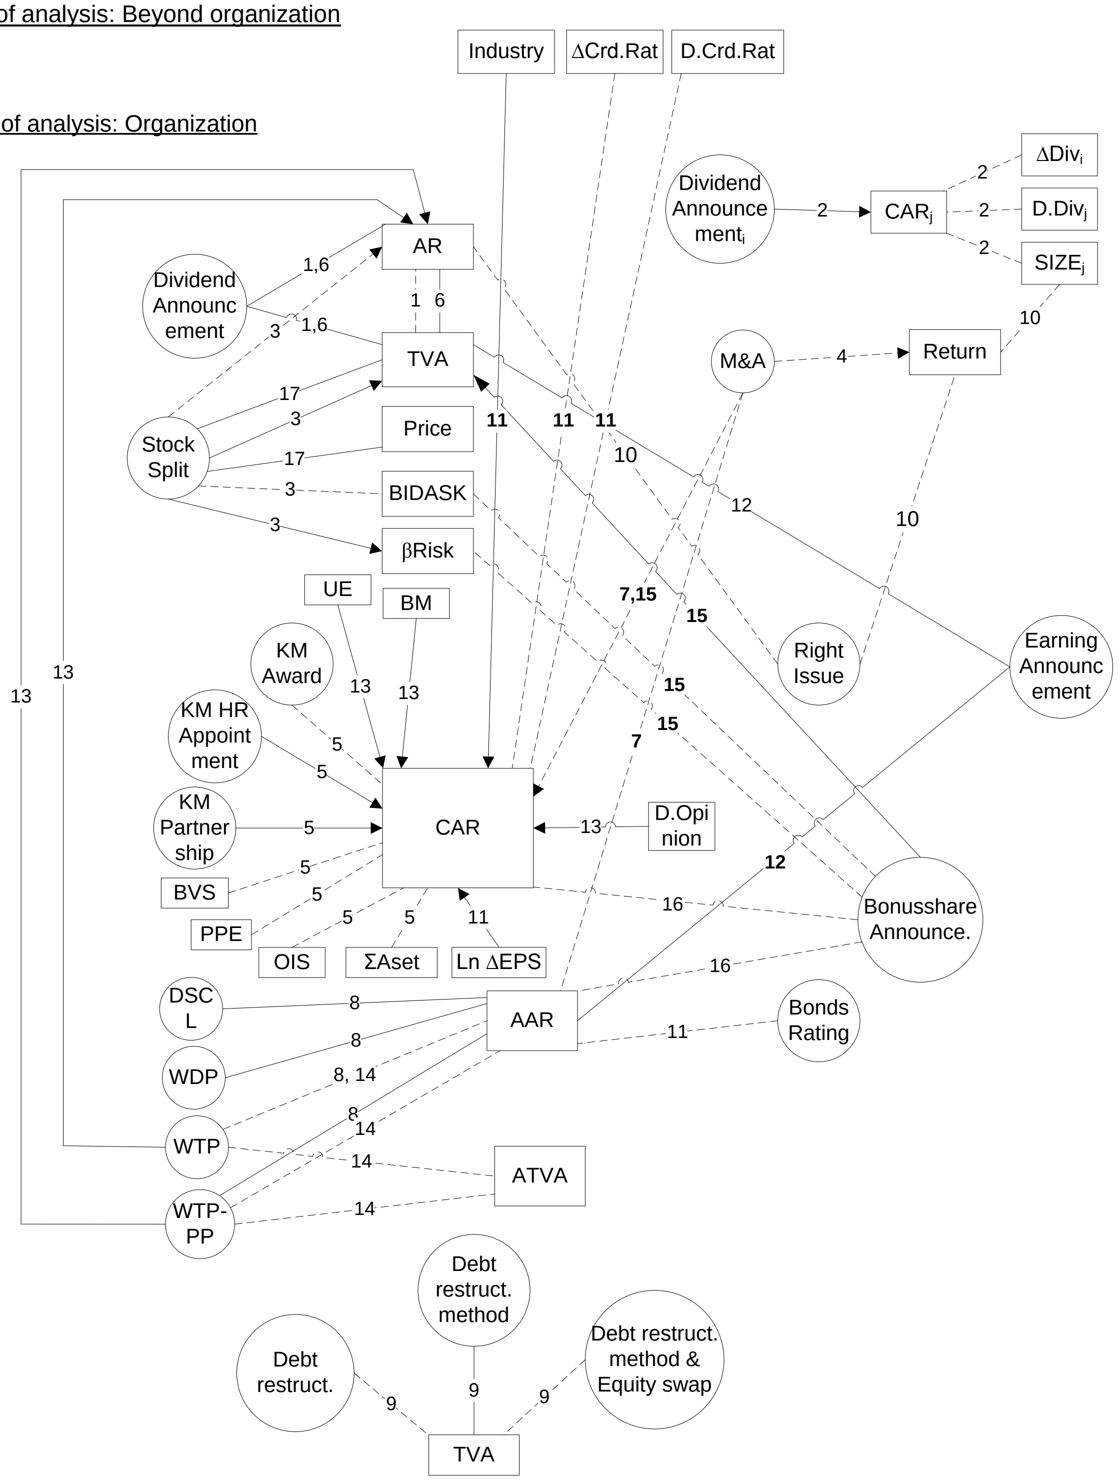
Appendix 9 Accounting Information Content

Unit of analysis: Beyond organization

Unit of analysis: Organization



Unit of analysis: Organization subunit

–

Constructs:

1. Bonds rating: Bonds rating announcement
2. Bonus-share announcement: Bonus-share announcement
3. Dividend announcement: Dividend announcement
4. Dividend announce$_i$: Dividend announcement of particular sample
5. DSCL: Disclaimer audit opinion
6. Earning announcement: Earning announcement
7. KM Award: Knowledge management award
8. KM HR Appointment: Publication of knowledge management expert appointment

9.	KM Partnership:	Publication of knowledge management partnership
10.	M&A:	Merger and acquisition announcement
11.	Debt restruct. method& Equity swap:	Sample divider based on the uses of debt restructuring method and equity swap
12.	Debt restruct. method:	Sample divider based on the uses of debt restructuring method
13.	Debt restruct.	Sample divider based on the existence of debt restructuring
14.	Right issue	Right issue announcement
15.	Stock split:	Stock split event
16.	WDP:	Qualified audit opinion
17.	WTP:	Unqualified audit opinion
18.	WTP-PP:	Unqualified audit opinion with explanatory paragraph

Dependent variables:

1.	AAR:	Average abnormal return
2.	AR:	Abnormal return
3.	ATVA:	Abnormal trading volume
4.	BIDASK:	Bid-ask spread
5.	CAR:	Cumulative abnormal return
6.	CAR_j:	Cumulative abnormal return for particular sample
7.	Price:	Stock price
8.	Return:	Stock Return
9.	TVA:	trading volume
10.	βRisk:	Firm risk

Independent variables:

1.	ΔCrd.Rat:	Credit rating changes
2.	ΔDiv_i:	Dividend changes of particular firm
3.	BMR:	Book to market ratio
4.	BVS:	Book value per share
5.	D.Crd.Rat:	Dummy for credit rating
6.	$D.Div_j$:	Dummy dividend changes of particular firm
7.	D.Opinion:	Dummy for audit opinion
8.	Industry:	Dummy for industry
9.	Ln ΔEPS:	EPS Changes
10.	OIS:	Operating income before depreciation
11.	PPE:	Property and plant
12.	$SIZE_j$:	Firm size of particular firm
13.	UE:	Unexpected earning
14.	ΣAset:	Total asset

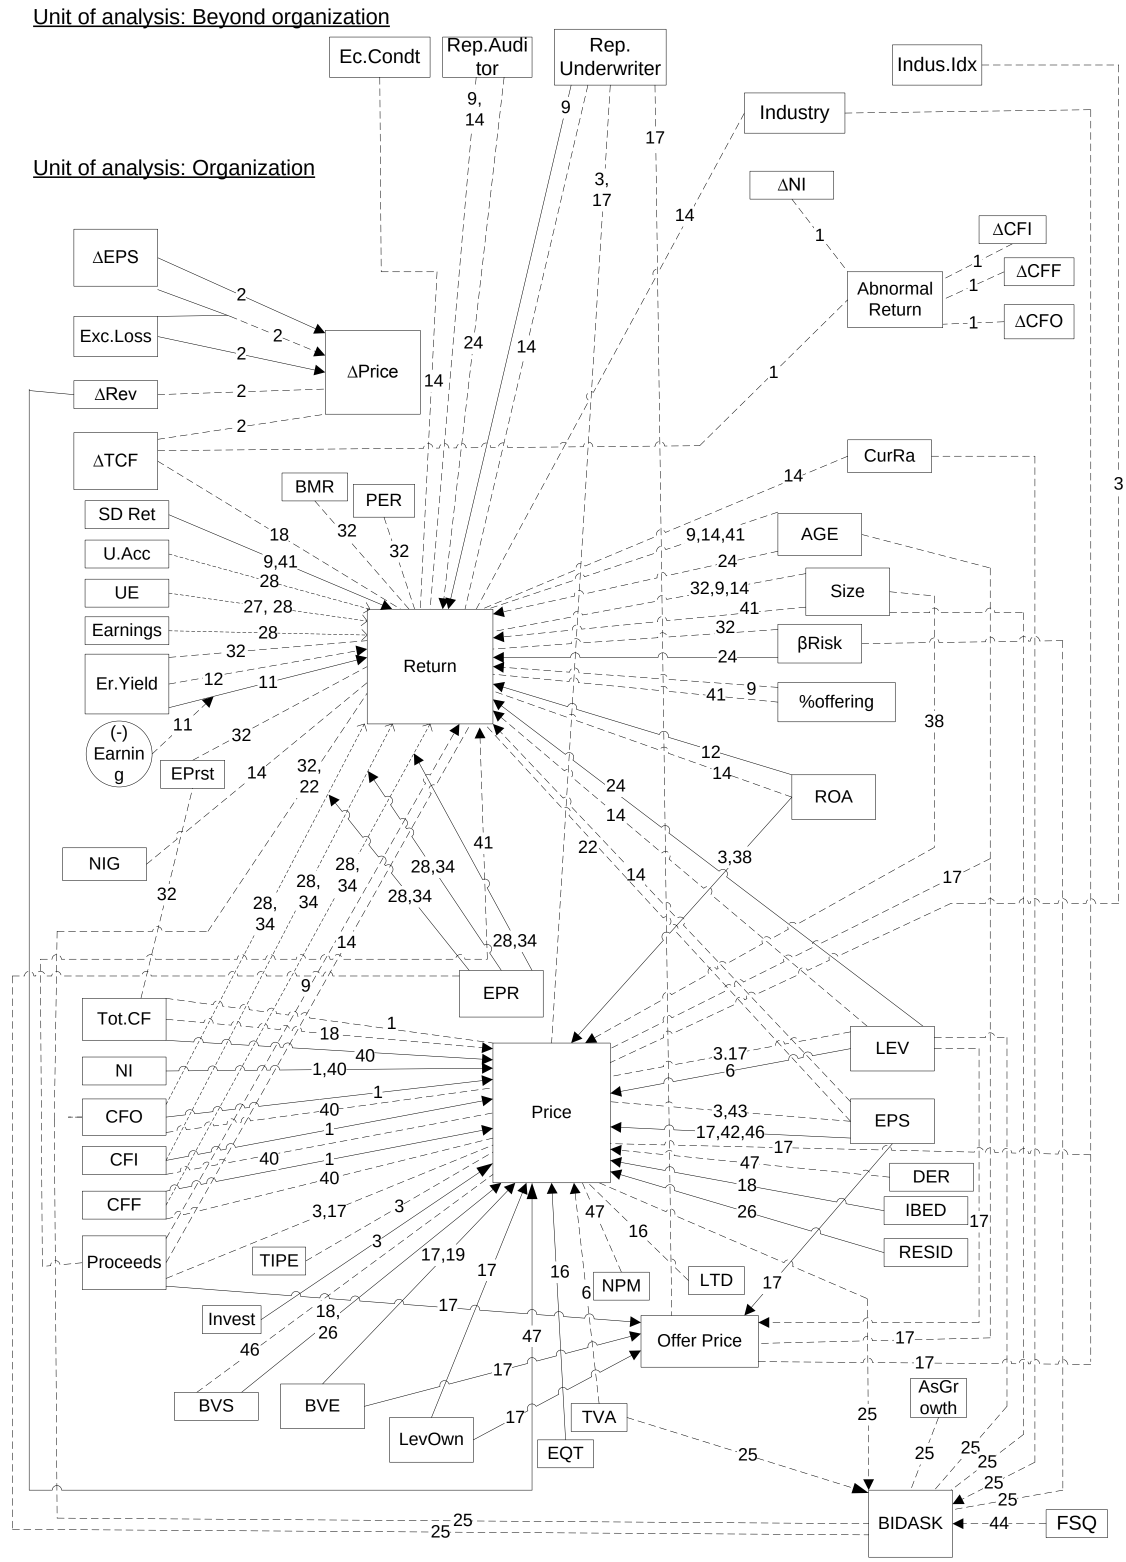
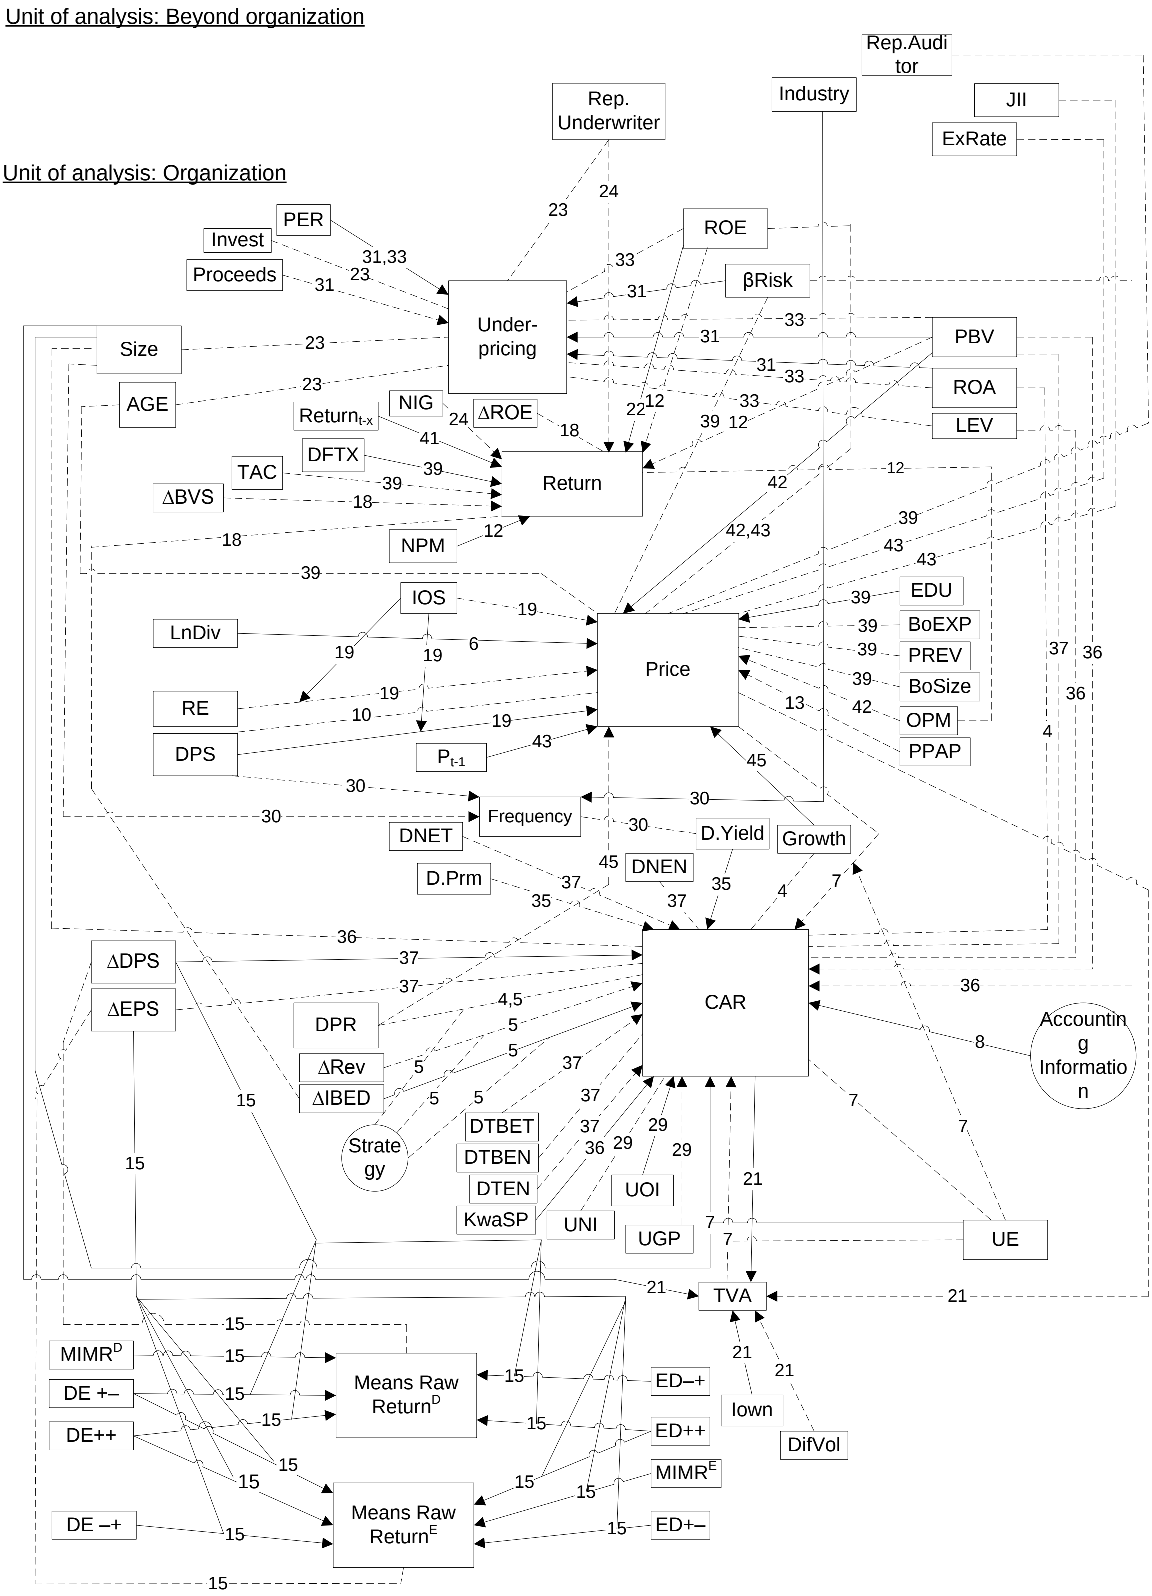
Appendix 10 A Value Relevance Study

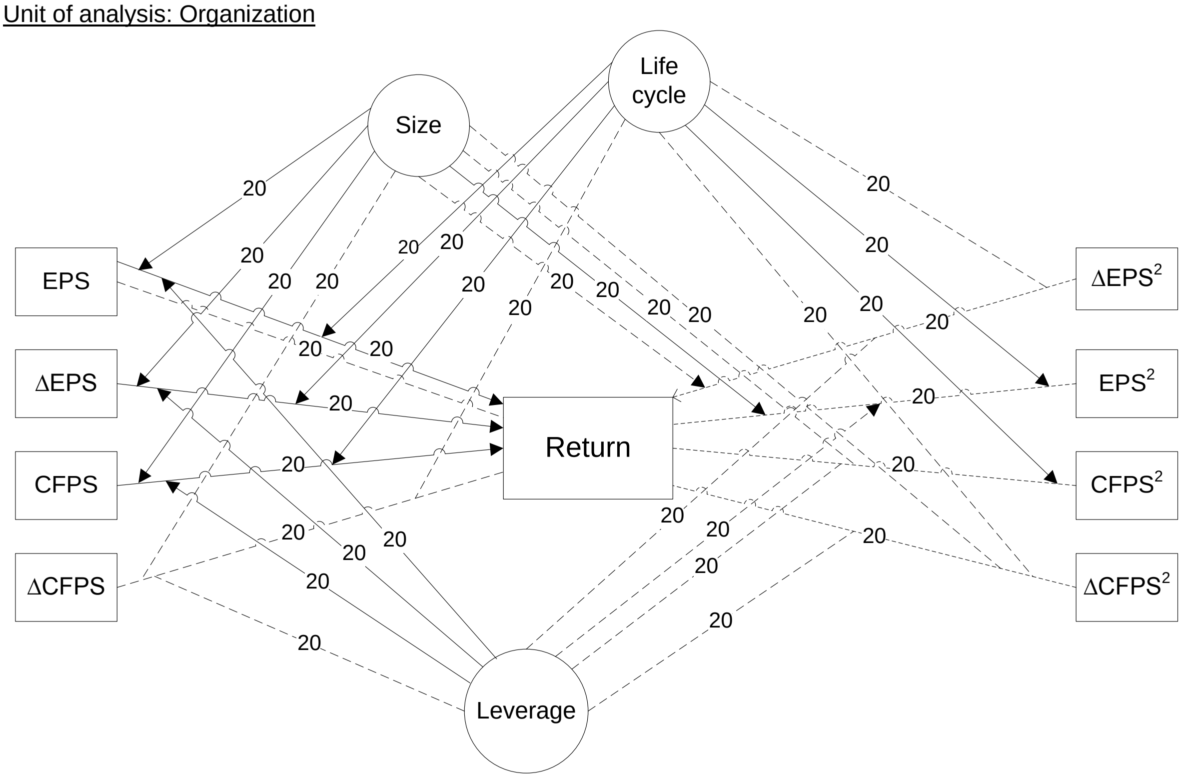


Appendix 10 B Value Relevance Study



Appendix 10 C Value Relevance Study

Unit of analysis: Organization



Unit of analysis: Organization subunit

–

Constructs:

1.	(-) *Earning*:	Negative earnings
2.	Accounting information	
3.	Strategy:	Sample divider based on the strategy used

Dependent variables:

1.	Δ Price:	The price changes
2.	AR:	Abnormal return
3.	CAR:	Cumulative abnormal return
4.	Frequency:	Trading frequency
5.	$MRR^{D(E)}$:	Average raw return around dividend announcement
6.	Price:	Stock price
7.	Return:	Stock return

Independent variables:

1.	%Offering:	Ownership percentage offered in IPO
2.	Δ EPS:	EPS Changes
3.	Δ NI:	Net income Changes
4.	ΔBVS:	Book value per share changes
5.	ΔCFF:	Financing cash flow changes
6.	ΔCFI:	Investment cash flow changes
7.	ΔCFO:	Operating cash flow changes
8.	ΔDPS:	Dividend per share changes
9.	ΔIBED:	The changes of income before *extraordinary item* and *discontinued operation*
10.	ΔRev:	Revenue changes
11.	ΔROE:	R*eturn on equity changes*
12.	ΔTCF:	Total cash flow changes
13.	AGE:	Firm age
14.	AsGrowth:	Asset growth
15.	BMR:	*Book-to-market ratio*
16.	BoExp:	Board experience
17.	BoSize:	Board size
18.	BVE:	Book value of equity
19.	BVS:	Book value per share
20.	CFF:	Financing cash flow
21.	CFI:	Investment cash flow
22.	CFO:	Operating cash flow

23. CurRa: *Current ratio*
24. D.Prm: Dividend Premium
25. D.Yield: Dividend *Yield* (DPS/stock price)
26. DE (+–/++/–+): Dummy of dividend announcement before earning announcement for the condition of dividend increase and income decrease/ dividend increase and income increase/dividend decrease and income increase.
27. DFTX: Deferred tax
28. DNEN: Dummy for dividend increase and income increase
29. DNET: Dummy dividend increase and income decrease
30. DPR: Dividend payout ratio
31. DPS: Dividend per share
32. DTBEN: Dummy for dividend unchanged and income increase
33. DTBET: Dummy for dividend unchanged and income decrease
34. DTEN: Dummy for dividend decrease and income increase
35. Earnings: Accounting income
36. Ec.Condt: *Dummy* for economic condition
37. ED (+–/++/–+): Dummy of earning announcement before dividend announcement for the condition of income increase and dividend decrease/income increase and dividend increase/income decrease and dividend increase
38. EDU: Board education
39. EPS: *Earnings per share*
40. EQT: Stockholder equity
41. Er.Yield: Earnings yield (EPS/stock price)

The relationship between ownership structure and firm financial performance

Evidence from Jordan

Tariq Tawfeeq Yousif Alabdullah
Accounting Department, College of Administration and Economics, University of Basrah, Iraq

Received 11 April 2016
Revised 8 January 2017
Accepted 19 February 2017

Abstract

Purpose – Previous studies that dealt with corporate governance have witnessed gradually significant growth that created some new trends. The purpose of this paper is to be involved in such trends through examining the link between ownership structure as one of the important corporate governance mechanisms and firm performance in Jordan as one of emerging economies.

Design/methodology/approach – The current study used the multiple regression method to analyze available data for non-financial firms listed in the Amman Stock Exchange for the fiscal year 2012.

Findings – The findings revealed that managerial ownership has a positive impact on performance. On the other hand, the findings surprisingly showed no evidence to support the impact of foreign ownership on performance. Moreover, there is a significant evidence to support the fact that company size has no impact on firm performance. The findings also revealed that industry type has no impact on firm performance.

Practical implications – The practical implications of the current study demonstrated that good corporate governance is imperative to all organizations and must be encouraged for the interest of all stakeholders. Unlike the majority of the previous studies, the current study unexpectedly found that foreign ownership is not significantly contributing to the firm performance. Thus, Jordanian Government and other related/responsible parties should formulate policies for the foreign investors.

Originality/value – Interestingly, from developed and developing countries perspective, the study is the first of its kind that exclusively chose the mechanisms of ownership structure in its relationship with firm performance represented by market share, where no previous study has tested foreign ownership in such relationship. In that, this study is the first study in emerging economies to investigate such a link. Such new insights on this relationship by current study provide helpful information that is of great value to the government, academics, policy makers, and other stakeholders.

Keywords Industry type, Firm performance, Firm size, Ownership structure

Paper type Research paper

Introduction

Corporate governance has got wide attention as one of the most researched issues in the organizational and other fields (Becht *et al.*, 2003; Daily *et al.*, 2003; Shleifer and Vishny, 1997). Corporate governance field addresses a wide variety of topics in its relationship with financial performance (see Bhagat and Bolton, 2008; Brown and Caylor, 2006; Chaghadari, 2011). Nevertheless, corporate scandals and failures in several corporations, such as the cases of Enron, WorldCom, and Arthur Andersen, and other scandals, continue to fuel the argument over whether companies should issue or use new perspectives as new trends to measure firm performance to be as essential part of their strategic goals to eventually maximize shareholders' wealth (Alabdullah, 2016; Alabdullah *et al.*, 2014a, b, 2016; Khanchel, 2007; Marr and Schiuma, 2003). This also will have a lot of concerns about the way corporations are governed and what performance measurements can effectively reflect firm performance in its relationship with corporate governance structures. Corporate governance is related to the structures and processes through which parties interested in the overall well-being of the company take measures to look after the stakeholders' interests. Precise corporate governance is centered on the mechanisms, transparency, principles of accountability, fairness,

and responsibility in the management of the company. The existence of corporate governance in a company is an attempt to alleviate principal-agent problems regarding the matter of separation of ownership and control (Chen and Wei, 2009; Jensen and Meckling, 1976). From the perspective of agency theory, it explains the conflict of interests and the arising agency costs between shareholders and managers. The separation of ownership and control has been considered as one of the most contentious and important issues in the management, accounting, and financial literatures.

Prior work revealed that one of the most important components in the structure of corporate governance mechanisms is ownership structure, such as the managerial ownership and foreign ownership (Mai *et al.*, 2009), together with their relationship with firm performance (Abor and Biekpe, 2007). Furthermore, a review of the literature led to the decision of including and investigating two control variables in the multiple regression models. These are firm size (Alabdullah *et al.*, 2014a, b) and industry type (Ho and Wong, 2001). In the same vein, therefore, as mentioned by Brooks (2014), firm size as a control variable is important to be tested in the model because it may have a significant effect on the dependent variable. Thus, firm size and industry type as control variables were introduced in this study. They have been used constantly by several previous studies as control variables (Ang *et al.*, 2000; Bhagat and Black, 2001; Watts and Zimmerman, 1978) and in the field of corporate governance and firm performance (Connelly *et al.*, 2012). In the same vein, Ferrier *et al.* (1999) showed the importance of firm size as a control variable to measure market share, in that, as they explained, the firm size has its effect on the market share, and the competitive advantage among companies has a different size. However, using control variable in the analysis is important because it may have an effect on results (Guest, 2009). Scholars and researchers of corporate governance, starting from Ross (1973) and Fama (1980), have focused on how to deal with the principal-agent problem that occurs from the separation of ownership and control. The recent crises faced by so many countries-related companies have again stimulated academics, policy makers, and other interested stakeholders, both in the private and public sectors, to take interest in adopting strong corporate governance. These recent events and their challenges have encouraged taking different measures across the world such as the Act of Sarbanes-Oxley in 2002 which regulates the corporate governance system to ensure compliance to principles of good corporate governance (Alabdullah *et al.*, 2014a, b). Recently, to enhance development and economic growth, the Jordanian Government established the first corporate governance code in 2009 (Abed *et al.,* 2012; Makhlouf *et al.*, 2014) to intervene in the case of poor financial performance (Alabdullah *et al.*, 2014a, b) and other forms of mal-management (Al-Zawahreh and Cox, 2009) both in industrial and service sectors in Jordan. Moreover, as mentioned by Alabdullah *et al.* (2016), Jordanian non-financial firms have faced several problems and declining starting from 2011. They showed that Jordan economy, especially non-financial firms, have faced several problems and challenges because of the regional instability, high level of unemployment, a dependency on remittances, and grants from Gulf economies besides continued pressure on natural resources.

Stakeholders and other interested parties have started to realize the important role of dealing with good practices of corporate governance to eventually protect their interests. Thus, good corporate governance leads to better firm performance, in that, firms dealing with better practices of corporate governance must perform better than those having worse practices of corporate governance. The Jordanian Government identified corporate governance system as a requirement for contemporary development and economic growth. Previous studies on corporate governance have undergone a notable development over the past few decades, especially in developed economies where data are available. Different theorists of corporate governance discipline have tried to investigate the relationship between corporate governance mechanisms and the general well-being of a company.

Majority of previous studies have admitted that corporate governance has significant impacts on firm performance. For example, Kren and Kerr (1997) admit that increasing the share stock for the managers/increased managerial ownership is the instrument to promote improved performance of the firm. Recently, there have been a wave of intensive studies in developed countries that focused on/investigated the firm performance. Nonetheless, a little attention has been given for firm performance in the developing countries especially in Jordan (Alabdullah *et al.*, 2014a, b). Therefore, in this context, the current study attempts to provide empirical evidence on the relationship between ownership structure as an important mechanism of corporate governance and firm performance in Jordan. Using data from the Amman Stock Exchange (ASE) over a sample of 109 listed companies, it was shown that there is a significant positive relationship between managerial ownership and market share. On the other hand, foreign ownership has no effect on firm performance. The study further revealed that firm size has no effect on market share. It was found that industry type also has no effect on market share. This study contributes to the existing literature on corporate governance-financial performance relationship in a number of ways. First, it uses, for the first time, market share as a measurement to measure firm financial performance in its relationship with ownership structure in all contexts (including Jordanian ones), where no previous study has tested foreign ownership in such relationship. In that, from both developed and developing countries' perspective, the present study uniquely contributes to the existing literature that investigated corporate governance and firm performance. Market share has been chosen as a proxy to represent firm performance but not in the area of corporate governance. For example, Eccles (1991) and Hansen and Wernerfelt (1989) assure that market share is a proxy to measure firm performance. Mayer (1997) shows that market share is a measurement for firm performance. Second, the finding also reveals that ownership structure has some influence on market share. Third, the current study chooses the market share measurement as an indicator to the firm performance, measured as net sales of the firm divided by the total sales of the industry (Cheung and Wei, 2006; Hansen and Wernerfelt, 1989; Oxenfeldt, 1959), knowing that the market share is also good as an indicator characterizing the firm financial performance. Market share measurement is valid to be used in the present study because as argued by Oxenfeldt (1959), market share indicator is valid and more suitable in the safe country characterized by its stable market. Thus, this is quite suitable in the Jordanian context. Jordan is considered as one of competing and stable countries in the region due to its high safety and stability (Alkhatib and Marji, 2012). Since market share is calculated as a net sale of the firm divided by total sales of the industry, using this measurement will help avoid the matter of manipulation, if any. The justification is that market share measurement is dealing with sales, where sales processes are either in cash or on credit. This means that there would be a case of dealing with only two accounts: cash and receivables. More detailed, this would establish that such indicator avoids dealing with expenses. In this case, manipulation will be exclusively in process-related expenses rather than sales. It is worth mentioning that manipulation would occur with expenses, not with sales. Ball (1972) and Lindhe (1963) show that managers of some firms tend to change in accounting technique as a way of manipulation to smooth corporate incomes, which is called as income smoothing behavior. They showed that such behavior deals with expenses through manipulating the income, for example, companies changed to accelerated depreciation to smooth income as a way of manipulation. More explicitly, as mentioned by Atik (2009) from accounting perspective, although income statement is considered as a very important tool that generates information about companies and their operations' success, income statement has one vital limitation. This limitation is that it is affected by the accounting methods. For instance, a company may see that it is better to accelerate depreciation of their assets, while another may use a straight line way to do so. If we suppose that all other factors are equal, the income of the first will be lower than that of the second even if the companies are basically the same. Overall, manipulation is through expenses rather than sales, such as using depreciation and inventory evaluation like "first-in, first-out" and "last-in, first-out" (Atik, 2009; Hughes and Schwartz, 1988). There were several of previous studies depending on utilizing measurement, for instance, ROA, ROE, and Tobin's *Q*, as profitability measurements to measure firm financial performance and all such measurements include either total assets or net income. Hence, this might lead to the probability of these profitability measurements to be included with income smoothing (manipulation) and as a result leads to unreal picture of firm performance.

The current study is structured as follows: after the introduction, the literature review and research hypotheses are explained in the second section. The third section sheds light on the sample, data, and methodology used in the current study. The fourth section provides results of the regression analysis, while the last section shows a number of concluding remarks.

Literature review and research hypotheses

A wave of previous studies has focused on the relationship between corporate governance and firm performance by providing several empirical evidence related to the mechanisms of corporate governance. All such studies whether in developed or developing countries have not investigated the relationship between ownership structure represented by managerial ownership and foreign ownership, and market share as a measurement of firm financial performance. Previous literature has revealed that managerial ownership in the company is a vital factor that alleviates agency conflicts and promotes company performance (Abor and Biekpe, 2007; Al-Khouri, 2006; Bai *et al.*, 2004; Gedajlovic and Shapiro, 2002; Hiraki *et al.*, 2003; Jaafar and El-Shawa, 2009; Klein, 1998; Kren and Kerr, 1997; Kumar and Singh, 2013; Sanders, 1999; Vafeas and Theodorou, 1998) . For example, Kren and Kerr (1997) argued that increasing managerial ownership is the important tool to promote improved performance of the company. Kumar and Singh (2013) investigated the relationship between managerial ownership and firm performance, and they found that there is a significant positive relationship between these two variables. At the international and local levels, in both developed and developing countries, the only study conducted by Alabdullah *et al.* (2014a, b) chose market share to represent firm financial performance but in its relationship with board characteristics. In the Jordanian context, a study conducted by Zeitun (2009) investigates the impact of government ownership and ownership concentration on firm performance and the findings revealed that they played a significant role in the firm performance. In the Bahrain context, Al-Matari *et al.* (2014) examine the relationship between size of audit committee, independence of audit committee and size of executive committee, and firm performance. The finding revealed a positive relationship between them and firm performance. However, globally, the current study is the first to investigate ownership structure with firm financial performance represented by market share.

Agency theory deals with the problem arising between a principal (stockholders) and agent (managers), when the managers hold an inadequate equity in the firm. In that, a small level of ownership held by managers leads to failure of maximizing shareholders' wealth and this leads to the fact that they have incentive to consume perquisites. Jensen and Meckling (1976) argue that agency costs will increase when the managers hold a small proportion of company's share because the managers in such a case will pursue to use firm's assets to enhance their benefits rather than maximize stockholders' wealth. Previous studies have revealed that increasing managerial ownership in the firm is an important element that decreases agency problems and promotes managers to enhance firm performance (Arora *et al.*, 2016; Kumar and Singh, 2013). Also, Vafeas and Theodorou (1998) argue that when managers own a high proportion of managerial ownership, they will have extreme eagerness to maximize firm performance as the same interest that shareholders have.

On the other hand, there are other previous studies that revealed a negative relationship between managerial ownership mechanism and firm performance, such as Acharya and Bisin (2009). Some previous studies (see Demsetz and Villalonga, 2001) demonstrate that there is no association between managerial ownership and firm performance.

Following agency theory (Jensen and Meckling, 1976), the current study predicts that increasing managerial ownership will lead to increased firm performance:

H1. There is a positive relationship between managerial ownership and market share.

Besides, the literature admitted that the foreign ownership mechanism in the firm enhances firm performance (Abor and Biekpe, 2007; Bai *et al.*, 2004; Balasubramanian *et al.*, 2010; Chhibber and Majumdar, 1997; Durnev and Kim, 2005; Gedajlovic and Shapiro, 2002; Kang and Shivdasani, 1995; Tornyeva and Wereko, 2012; Yoshikawa and Phan, 2003). Previous studies in the literature admit that the anticipation of foreign ownership in the corporation enhances the extent of firm performance (see Gedajlovic and Shapiro, 2002). Tornyeva and Wereko (2012) admit that there is a positive relation between foreign ownership and corporate performance. Therefore, the present study predicts that increasing foreign ownership will be associated with increased firm performance. Chhibber and Majumdar (1997) examined the link between foreign ownership and company performance in 1,000 Indian companies listed on the Bombay Stock Exchange. The findings revealed that foreign ownership has a positive and significant impact on company performance represented by return on sales and return on assets. Other studies also explained the vital role for the foreign ownership on company performance, for example, Yoshikawa and Phan (2003) examined corporate governance reform and the performance implications of ownership driven in Japan. They showed the effect of changes in foreign ownership and board of directors' performance of reforms in Japan. Following the findings of previous studies, the present study predicts that increasing foreign ownership will lead to increased firm performance:

H2. There is a positive relationship between foreign ownership and market share.

Data and methodology

The current study investigates the link between corporate governance represented by ownership structure and firm performance expressed by market share in Jordan. The study focused on companies listed on the ASE as it is one of the largest stock exchanges in the Middle East. It is worth mentioning that the first Company Law in Jordan was Law No. 12 in 1964 and moreover, it is the first administration of the first Commercial Law enacted in 1966. In addition, one of the major features that makes Jordan an important center in the Middle East is its strategic and vital location among the countries of the region and because it is an economic channel to large markets with more than one billion consumers. Despite the importance explained above about the Jordan and the significant role played by this country as one of the important emerging economies, Jordanian non-financial sector nevertheless suffered from problems and setbacks that had impact on its performance specifically in the last few years (Alabdullah *et al.*, 2014a, b). The present study chooses a sample consisting of a non-financial sector (service and industrial sectors) for listed Jordanian companies as cross-sectional study. This study collected the data from the annual reports for 2012. Choosing such a year lies in the justification that in the last few years, Jordanian listed companies suffered from problems on its performance. Furthermore, as revealed by Alabdullah (2016) and the indicators by The World Bank (2016), non-financial sector faced declining in GDP in last ten years (Figure 1).

In addition, the data in this year are sufficient and available to serve the objective of the present study. According to the companies belonging to the financial sector:

(1) health care services;

(2) educational services;

(3) hotels and tourism;
(4) transportation;
(5) technology and communication;
(6) media;
(7) utilities and energy;
(8) commercial services;
(9) pharmaceutical and medical industries;
(10) chemical industries;
(11) paper and cardboard industries;
(12) printing and packaging;
(13) food and beverages;
(14) tobacco and cigarettes;
(15) mining and extraction industries;
(16) engineering and construction;
(17) electrical industries;
(18) textiles, leathers and clothing; and
(19) glass and ceramic industries.

The current research analyzes data on a sample of 109 companies listed at ASE.

This study is the first to measure financial performance (dependent variable) through market share in its relationship with ownership structure. The internal corporate governance represented by ownership structure mechanisms, namely the managerial ownership (MO) and foreign ownership (FO) as independent variables and the dependent one is market share to represent financial performance. In addition, firm size (FS) and industry type (ID) are the control variables. Table I shows a summary of variables measurement.

The model used in the current study for analysis included specific variables, which are also probably to have impact on the firm performance (market share). These variables are size and the industry type. To examine the relationship between ownership structure and firm performance in developing countries, a cross-sectional study was adopted in the analysis through collecting the real data from the annual reports for the year 2012. A multiple linear regression analysis was estimated linking the direct relationship between the independent and dependent variables, after controlling for some firm-specific

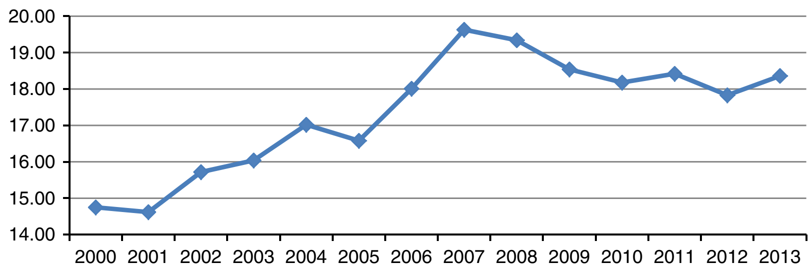

Figure 1.
Non-financial sector (share in GDP)

No.	Variables	Acronym	Measurement
1	Dependent variable market share (%)	MS	Market share: net sales divided by the total sales of the industry
Independent variables			
2	Managerial ownership (%)	MO	Managerial ownership is measured as the percentage of total shares held by firm directors and officers
3	Foreign ownership (%)	FO	The percentage of the share owned by foreign shareholders to total number of shares issued
Control variable			
4	Firm size (number)	FS	Natural logarithmic of the firm's total assets
5	Industry type (number)	ID	Dummy variable with 1 if it is an industrial firm and 0 if it is a service firm

Table I. Summary of variables measurement

characteristics that lie in firm size and industry type. The model of this study is defined by the following equation:

$$MS = \alpha + \beta_1 MO + \beta_2 FO + \beta_3 FS + \beta_4 ID + \varepsilon$$

The variables used in the current study in the sample, their definition, and measurement are shown in Table I.

This study examines the relationship between market share (MS) and MO, FO, FS, and ID. To investigate the effect of these exogenous variables on firm performance, this study adapts a lagged regression model, wherein the independent variable of current year (X_t) predicts the dependent variable of next year (Y_{t-1}):

$$MS_{2013} = \alpha + \beta_1 MO_{2012} + \beta_2 FO_{2012} + \beta_3 FS_{2012} + \beta_4 ID_{2012} + \varepsilon$$

Results and discussion

This section explains the descriptive analysis of the study variables: dependent and independent variables for the 109 industrial and service companies that belong to non-financial sector listed at ASE by using descriptive statistics represented by mean, standard deviation, minimum, and maximum. Table II presents the distribution of the all variables in this study. Based on the results of descriptive statistics, the dependent variable which is market share showed that the mean market share of Jordanian non-financial companies is 45.85 percent with a standard deviation of 0.288. Furthermore, minimum rate of market share in the Jordanian industrial and service companies is 5.1 percent with maximum level of market share equal to 91 percent. Moreover, the descriptive analysis reveals that the mean for managerial ownership is 4,398.81 with a standard deviation of 0.292. For the foreign ownership of the companies in the sample, the result shows that the mean is 24.8 percent with a standard deviation of 0.319. In Table II, the results also reveal

Variables	Mean	SD	Minimum	Maximum	Skewness	Kurtosis
Market share	0.458	0.288	0.051	0.910	0.352	−1.293
MO	0.439	0.292	0.000	1	0.196	−1.113
FO	0.248	0.319	0.000	0.900	1.149	−0.286
FS	7.291	0.599	5.69	9.09	0.433	0.914
ID	0.293	0.457	0.00	1.00	0.919	−1.177

Table II. Descriptive analysis

that the values for the skewness and kurtosis show that our sample is normally distributed since they are within the acceptable range of normality for both skewness and kurtosis. According to Brooks (2014), the normality of data can be achieved if standard kurtosis is within ±3 and standard skewness ±1.96. In addition, the current study resorts to choose industry type, a control variable regarding the issue of different nature of the firms' work that exists within the sector.

The correlation between the dependent and independent variables is explained in Table III. The result reveals that two independent variables have negative relationship with market share, with values MO −0.536 and FO −0.080. Furthermore, I examined the multicollinearity level between the independent variables which must be less than 80 percent as suggested by Yoshikawa and Phan (2003). I find the data did not have multicollinearity problems, which usually require 80 percent or more to point out that the correlations between the variables (independent variables) have multicollinearity problems. Table VI reports the correlations of the variables. Moreover, I investigated the multicollinearity through using two other indicators, namely variance inflation factor (VIF) and tolerance as shown in Table VII. It reveals that all the values of tolerance for the variables are more than 0.1 with the VIF values that is less than 10, as suggested by Hair *et al.* (2010). Although other previous studies in the literature such as Shihab *et al.* (2010) set the maximum value of VIF to be 2.5, the present study reached this level that did not exceed 2.5. This means that all results, as shown in Table IV, point out that data in the present study are absence of multicollinearity problems thus the model contains no multicollinearity.

In the present study, to investigate the direction of the relation between predictors and criterion variables, linear regression analysis was used to do so. This statistical method has been used in several studies in the literature for several science disciplines (Nathans *et al.*, 2012; Raftery *et al.*, 1997). In Table V, regression analysis results reveal that R^2 value is 0.297 for market share. In that, R^2 value is explaining 30 percent of the independent variables

	MO	FO	ID	FS	MS
MO	1

Table V.
R^2 of market share

(MO and FO) on the dependent one: market share. After analysis, as shown in Table V, the study found that corporate governance mechanisms (IVs) jointly influence firm financial performance (DV).

The current study examined the autocorrelation by using Durbin-Watson (DW) test. In this regard, the DW of 1.757 is a good value because it falls between the acceptable range of 1.5-2.5 as mentioned by Knoke (2003), and it reveals that the sample of the current study has no autocorrelation problem in its data. Regression analysis was run for all variables that have been selected in the present study represented by the MO and FO (independent variables), FS and ID as control variables, and market share (dependent variable); the output reveals that managerial ownership has a positive relationship with market share (MO, $\beta = 0.541$), whereas foreign ownership has negative relationship ($\beta = -0.096$). For the others (control variables), FS (log of total assets) has a positive relationship and industry has a negative relationship with market share (FS, $\beta = 0.005$; ID, $\beta = -0.010$).

The regression analysis results reveal that FS and ID are insignificant with financial performance (market share). In addition, the results related to managerial ownership showed that there is highly significant positive relationship between managerial ownership and firm market share ($\beta = 0.541$, t-value $= 6.542$, $p < 0.00$). This indicates that the firm financial performance is significantly influenced by managerial ownership in the Jordanian non-financial listed companies. This result is in line with what has been set in the objectives of the current study. The study can deduct significant relationship between managerial ownership and market share. This result provides support to prior studies that were conducted in both developed and developing countries (see Abor and Biekpe, 2007). Therefore, *H1* is supported. This result demonstrates that the more managerial ownership in non-financial companies in Jordan, the more market share (better performance). This result is consistent with agency theory perspective. In that, such a result matches with the result in the previous studies which admit that managerial ownership improves firm performance. The testing hypotheses of the present study find surprising results in respect to the association between foreign ownership and financial performance (market share). There is insignificant relationship between these two variables at FO at $p < 0.00$, t-value $= -1.161$, and $\beta = -0.096$. Globally, this result is unique because no previous study found insignificant relationship between foreign ownership and firm performance.

This result is inconsistent with the literature that deals with the relationship between foreign ownership and firm performance. Previous studies found a positive relationship (see Abor and Biekpe, 2007). For instance, Stulz (1999) shows that the higher foreign ownership leads to get lower agency cost. However, I find contradiction in the common belief that foreign ownership is a good mechanism to reduce agency cost and to enhancement of firm performance, which indicate that agency theory is limited/unable in its explanation of the link between foreign ownership and firm performance. The findings revealed insignificant effect of foreign ownership on firm performance in non-financial companies in Jordan. Therefore, *H2* is not supported. The reason is although Jordanian Government issued regulations (such as privatization) since 1996 as mentioned by Abu-Shams and Rabadi (2003), still traditional business dominates the majority of Jordanian business as stated by Rajoub (2013) and thus the country did not achieve attraction of foreign investments as anticipated. The current study found that foreign ownership is not positively contributing to the firm performance, which implies that foreign investors are still minor since Jordanian businesses are not attractive enough due to its volatile return and high risk. To tackle this issue, the government should formulate special programs (policiesfor the foreign investors). The testing hypotheses of the present study regarding the association between every independent variable and dependent ones are shown in Table VI.

Additional regression analysis has been done by the current study by using lagged independent variables to test whether managerial ownership improves future performance as the question made by the current study. This analysis revealed that the findings show that FS and ID are also insignificant with financial performance. Besides, the results related to managerial ownership showed that there is a significant positive relationship between managerial ownership and firm market share and it is higher than the one that is revealed in the previous model (the model that examines the concurrent relationship between ownership structure and firm performance, the concurrent relationship). It showed that $\beta = 0.555$, t-value $= 6.717$, and $p < 0.00$, while the first model showed that $\beta = 0.541$, t-value $= 6.542$, and $p < 0.00$). This indicates that managerial ownership improves future performance. The results of the testing hypotheses in respect to the relationship between foreign ownership and financial performance (market share) still show insignificant relationship between these two variables at FO at $p < 0.00$, t-value $= -1.210$, and $\beta = -0.099$, whereas in the first model it was $p < 0.00$, t-value $= -1.161$, and $\beta = -0.096$. Globally, this result is unique because no previous study found insignificant relationship between foreign ownership and firm performance, as shown in Table VII.

Conclusion

The objective of this study is to investigate the effect of ownership structure as one of important corporate governance mechanisms on firm financial performance using cross-section data of a sample of 109 listed Jordanian non-financial companies from the website of ASE. After analysis, the current study found the following key issues:

(1) There is a positive and significant relationship between managerial ownership and market share. This supported the notion of agency theory that managerial ownership has its positive impact on firm performance. As the current study implies that there is a positive and significant relationship between this mechanism and firm financial performance.

(2) There is no significant relationship between foreign ownership and market share. This indicates that the relationship between such mechanism and firm financial performance is insignificant.

(3) The current study also revealed that there is no impact of the control variables: firm size and industry type on market share.

Table VI. Regression statistical analysis

Variables	Market share Standardized coefficients β	t-value	Sig.
MO	0.541***	6.452	0.000
FO	−0.096	−1.161	0.248
FS	0.005	0.058	0.954
ID	0.010	−0.028	0.904

Notes: $^*p < 0.10$; $^{**}p < 0.05$; $^{***}p < 0.01$

Table VII. Lagged regression analysis

Variables	Market share Standardized coefficients β	t-value	Sig.
MO	0.555***	6.717	0.000
FO	−0.099	−1.210	0.229
FS	0.003	0.041	0.967
ID	0.013	−0.159	0.874

The contribution of the current study to the literature lies in its investigation of the relationship between ownership structure and firm financial performance represented by market share. In doing so, the present study contributes to the literature, via this link, through using uniform and useful measurements. Therefore, this study globally contributes to the field of corporate governance and firm performance by investigating the link between ownership structure and market share in one of emerging economies, Jordan. In that, it should be noted that the current study is the first of its kind to provide new insights on the relationship between these two variables. It therefore provides a new investigation considered as extending for prior studies in this discipline to the best of researcher's knowledge; no prior study has been conducted in both developed and developing countries including Jordan.

Second, in non-financial Jordanian companies (service and industrial sectors), the current study shows that agency theory is unable to explain the link between foreign ownership and firm performance. This suggests a dire need for issuing the key and precise policies regarding the role of foreign ownership in non-financial companies in the Jordanian context.

This study provides theoretical implications regarding the firm financial performance (dependent variable). It takes into account an important thing regarding choosing the measurement of the dependent variable. This study chooses market share to avoid income smoothing behavior, as such measurement is suitable to be chosen in the Jordan context. Thus, this study is a response to calls for new study into the field of corporate governance and firm performance because as demonstrated by Marr and Schiuma (2003), the firm performance issue is still in a dire need for more contributions to overcome the lack in company performance's measurements. Therefore, the current study internationally contributes to the field of firm performance through choosing market share indicator to measure firm performance, especially in its relationship with foreign ownership mechanism.

Finally, for the future research in both developed and developing countries, consideration must be taken to investigate the relationship between these two variables (ownership structure and market share) to identify the results from different perspective and from different levels of development in the countries. In addition, future research should investigate other variables, such as institutional and family ownership. Furthermore, future research should investigate the framework of the study for more than one year. In that, they should use time series or panel data which might get new results to enrich the framework drown by the current study.

Review

The Importance of financial reporting to capital market development in Ghana

Williams Abayaawien Atuilik* and Hussein Salia

Department of Accounting, School of Business, Heritage Christian University College, Amasaman – Accra, Ghana.

Received 25 March, 2017; Accepted 10 July, 2018

The finance literature suggest that investment decisions are largely influenced by the quality of corporate financial information released by firms in their financial statements, and that capital market participants use corporate financial information released by firms for investment decisions. Factors that influence the development of capital markets in developing markets include: appropriate legal and regulatory framework, effective securities exchange commission, an active stock exchange market, availability of accurate and reliable information about firms' financial performance and position. An improved financial reporting environment that produces accurate and high-quality financial reports on a timely basis contributes significantly to the development capital markets in developing economies. It is therefore important that the Institute of Chartered Accountants Ghana (ICAG), regulator of accounting practice in Ghana should strengthen its regulatory role to ensure that accountants in Ghana helping generate financial information for firms listed on the Ghana Stock Exchange are sufficiently knowledgeable and skilled in matters regarding financial reporting and provide financial reports guided by sound reporting ethics and the principle of integrity.

Key words: Accounting standards, capital markets, financial reporting.

INTRODUCTION

Extensive research has been done in the finance literature and the results suggest that investment decisions made by investors are partly influenced to a large extent by corporate financial information released by firms, and so capital market participants such as brokers and investors tend to follow closely the release of corporate financial information by corporate entities (Ball and Brown, 1968; Lev, 1989; Myring, 2006; Habib, 2008; Acquah-Sam and Salami, 2014). The corporate finance literature is replete with a number of theories, including: pecking order theories, arbitrage pricing theories, efficient market hypothesis theories, signaling models, capital asset pricing theories, and theories on dividend policy (Frank and Goyal, 2003; Larcker and Lys, 1987; Malkiel and Fama, 1970; Myers and Majluf, 1984; Sharpe, 1964; Skinner, 2006). All these important theories suggest that stock prices change in response to knowledge of a number of financial variables obtained from corporate financial information. Some of the important variables that are obtained from corporate financial information include earnings, dividends, cash flow projections, net assets, returns on investments, levels of debt among others.

*Corresponding author. E-mail: atuilik@yahoo.com.

These variables are either reported in the financial statements or are derived from information contained in the financial statements. The purpose of this paper is to address the role of financial information in capital market development and use this as basis to argue the need for ensuring improved quality of disclosures in financial statements.

Factors that influence the development of capital markets

The capital market refers to interactions among firms or organisations with funding needs and investors with surplus funds for investments whereby firms raise debt and equity capital for their operations, and investors make funds available to firms either in the form of debt or equity investments at a return. In highly developed capital markets, firms are able to raise debt or equity capital from the market much easily and investors are able to place their surplus funds much easily. The converse is the case for less developed capital markets where it is difficult for firms to raise capital and those who have surplus funds do not have readily available channels for placing those funds for productive ventures. There are a number of factors that may possibly influence the level of development of capital markets. According to Osei (1998) and Gnanarajah (2015), the appropriate legal and regulatory infrastructure, such as an effective Securities Exchange Commission, an active stock exchange market, and the availability of accurate and reliable corporate financial information about firms' financial performance and financial position are key influencers of the level of development of the capital market. Thankfully, Osei (1998) observed that there seems to be appropriate and effective legal and regulatory structures in Ghana to promote the development of the Ghanaian capital market. What was found to be a problem is non-reflection of all available financial information on stock prices (Salami and Acquah-Sam, 2013). Embedded in this problem is the question of the reliability of the financial information generated by firms listed on the Ghana Stock Exchange. It is in this regard that it is necessary to take steps first to improve the credibility of the financial information generated by firms listed on the Stock exchange, and then to ensure that the financial information available is actually used by investors to make investing decisions. Generating reliable financial information by firms listed on the Ghana Stock exchange is thus a necessary step towards uplifting Ghana's capital market.

The role of financial information in capital markets development

Firms usually provide financial information through the financial reports they publish. The financial reports often comprise: financial statements, management discussion of those financial statements and other regulatory filings. Some firms engage in additional voluntary communication, such as management forecasts, analysts' presentations, other corporate reports and press releases on key issues. Some publish these reports in hard copy and file same with the regulators while other firms additionally post all this information on their web sites. There are also some disclosures about firms provided by information intermediaries, such as financial analysts, industry experts, and the financial press. There is a preponderance of evidence in the finance literature indicating that capital market participants depend on financial information to make various decisions (Agyei-Mensah, 2013; Bernard, 1992; Bernartzi et al., 1997; Bhattacharya, 1979; Fama, 1965; Fama, 1970; Gnanarajah, 2015; Kothari, 2001).

It has been suggested that no perfect stock market exists anywhere in the world, and that most stock markets exhibit weak form market efficiency (Hasanov and Omay, 2007; Magnusson and Wydick, 2002). Weak form efficiency imply that the market uses historical corporate financial information in making investment decisions. The implication is that through the financial reports and disclosures prepared by accountants for firms, capital market participants are provided with information that forms a basis for making fair decisions regarding stock prices in order to make and execute reasoned investment and financing decisions. There is overwhelming evidence from the literature that argues that market participants including, regulators, creditors, and the investing public often rely on corporate financial information to value stock prices and make investment decisions (Appiah-Kusi and Menyah, 2003; Bennard, 1992; Chambers and Renman, 1984; Fama, 1965; Fama et al., 1969; Gnanarajah, 2015; Habib, 2008; Healey and Palepu, 2001; Holthausen and Larcker, 1992; Osei, 2002). What this means is that steps need to be taken to ensure that firms prepare their financial statements in a credible manner. This has implication for the regulation of the practice of accountancy in Ghana.

The regulators of accountancy practice must ensure that persons who prepare the financial statements of firms are qualified to do so, and do actually prepare the financial statements of firms in line with appropriate standards. The questions that beg for answers are: Does the regulator of accounting practice in Ghana ensure that only qualified persons are engaged to prepare financial statements for firms listed on the stock exchange? Do the firms use the appropriate standards to prepare their financial statements? Are the financial statements of listed firms audited by qualified accountants in line with appropriate standards for auditing? It is only when these questions are answered in the affirmative that that one can begin to expect quality corporate financial information from listed firms that should subsequently induce high quality capital market decisions.

Nyor (2012) asserts that financial statements prepared using global financial reporting benchmarks help investors better equip and appreciate risk associated with decisions about flows of economic capital. This is confirmed by the findings that market participants use financial information to make general investments decisions to reduce financial risks and optimize returns on investments (Healey and Palepu, 2001; Onulaka, 2014). From the foregoing, one can only conclude that the disclosure of reliable financial information by corporate entities is a “sine qua non” for the development of the capital market. Against the background of the critical role of quality financial information in the development of capital markets, it is critically important to improve the quality of the financial disclosures by listed firms through improved financial reporting. The question is, how can this be done? This can be achieved by requiring listed firms to report in line with approved accounting standards and ensuring strict compliance by the regulator of the practice of accountancy.

Accounting standards

Accounting standards prescribe the accounting treatment for financial transactions and the minimum disclosure requirements with respect to those financial transactions. Having a standardized set of prescriptions for purposes of reporting eliminates arbitrariness and opportunities for manipulation in terms of reporting and consequently improves the quality of financial reports. Hail et al. (2010) argued that high-quality accounting standards lead to improved financial reporting which in turn leads to improvement in corporate decision making. It is thus expected that the application of Financial Reporting Standards (IFRSs) should lead to improved financial reporting.

Improving Financial Reporting

According to Kothari (2000), the rise in the volatility of stock returns across the globe in the past couple of years has been of concern to many commentators and has led to the questions as to whether greater transparency in financial statement information could reduce volatility and produce more accurate stock valuations? And whether more transparent financial statements of financial services firms (for example, banks) could improve lending and credit evaluation decisions and contain the risks of a banking crisis? These issues are of central interest to all market participants and, in particular, to the Securities and Exchange Commission (SEC). It is for these reasons that Institute of Chartered Accountants Ghana (ICAG) in collaboration with SEC (and other regulatory bodies) mandated all listed companies in Ghana to adopt the International Financial Reporting Standards (IFRSs) as their financial reporting framework since 2007. It is important that financial reports presented by firms communicate corporate performance accurately and reliably. Barton (2005) and Agyei-Mensah (2013) suggested that for financial information to be useful, they must possess the characteristics of relevance, reliability, comparability, and understandability. One mechanism for ensuring improved financial reports is the adoption of International Financial Reporting Standards (IFRSs) by reporting firms. The need for improving financial reporting with particular respect to firms listed on the Ghana Stock Exchange is more urgent against the findings that the Ghana Stock Exchange exhibits weak form market efficiency (Ntim et al., 2007; Osei, 1998; Salami and Acquah-Sam, 2013).

Advantages of adoption of IFRS

The adoption of IFRS by reporting entities present tremendous advantages. Epstein and Jermakowicz (2010) and Onulaka (2014) argued that convergence facilitates the free flow of capital across boundaries as it eliminates accounting risk and reduces listing requirements and costs on international stock exchanges. Marfo-Yiadom and Atsunyo (2014) advanced a similar argument, that financial statements presented in compliance with IFRS facilitate the integration of international markets. They argued that IFRS-based financial statements are often more appealing to the international audience due to the higher level of comparability and quality. Given that national domestic accounting standards are harmonized with the IFRS, the likelihood of any unfamiliar national domestic accounting standards will be eliminated. Wyatt (1989) also found that convergence of Generally Accepted Accounting Principles (GAAP) with IFRS yields a number of benefits including: “increased cross- border financing; emergence of true multinational companies; a heightened willingness to cooperate across borders to enhance national, regional and even global economic strength; an awareness by securities regulators around the world of the necessity for comparable data” (p. 108). Epstein (2009) confirms that “there is certainly empirical research evidence to support the notion that uniform financial reporting standards will increase market liquidity, decrease transaction costs for investors, lower cost of capital and facilitate international capital formation and flow” (p. 31). There are however some challenges in implementing IFRSs in the form of the cost to migration, the problem of change, the need to close the knowledge gap between existing reporting regime and IFRSS, and keeping up with constant changes in IFRSs. The benefits seem to outweigh the disadvantages.

The Ghana's experience

Recognizing the important role of quality financial reports in the development of the capital market in Ghana, ICAG being the body responsible for regulating the practice of accounting in Ghana made a number of interventions towards promoting good financial reporting practices in general.

According to Assenso-Okofo et al. (2011), in January 2007, the ICAG, in collaboration with other Regulatory Bodies -Bank of Ghana, National Insurance Commission, and Securities and Exchange Commission- launched the adoption of IFRS in Ghana. By this adoption, all Public Interest Entities [PIEs] (the banks, insurance companies, listed companies and profit-oriented state-owned enterprises) are required to apply IFRS as their financial reporting framework. The adoption of IFRS was led by ICAG with great support from the Regulatory Bodies mentioned above. It is gratifying to note that as at end of April 2013, all the listed entities had adopted IFRSs as the framework for preparing and presenting their financial statements.

Agyei-Mensah (2013) analysed the pre-adoption and post adoption financial statements of firms listed on the Ghana Stock Exchange and concluded that all firms had substantially complied with the reporting requirements of the adopted IFRSs framework. He concludes also, that there was significant improvement in the quality of information in the financial statements of listed firms after the adoption of IFRSs. It thus be concluded that the adoption of IFRSs by listed firms has resulted in the presentation of more credible financial statements, consequently leading to increased investor confidence in the Ghanaian capital market.

ICAG has also introduced audit Quality Assurance Monitoring unit (QAM) to ensure that auditors apply the appropriate auditing standards; the International Standards on Auditing (ISAs) and require their clients to comply with IFRSs as the framework for financial reporting. The introduction of the QAM unit is an important step aimed at fulfilling ICAG's regulatory obligation. The results from a survey conducted by the ICAG in 2016 ON Small Medium Size Audit Practices (SMPs), confirmed by the reports of QAM, indicate that all of the listed companies on the Ghana Stock Exchange are audited by one of the Big Four audit firms (ICAG, 2017). This imply availability of high quality resources for the conduct of the audit of listed firms.

These interventions are expected ultimately to improve the quality of financial disclosures by listed firms and hence provide more accurate and reliable information to capital market participants for decision making. The quarterly publication of financial statements supported by the 'facts behind the figures' regime encouraged by the Ghana Stock exchange adds to the timeliness of information available to market participants. As Chambers and Renman (1984) suggest, the timeliness of availability of financial information to capital market participants is critical to capital market development.

Similarly, Abedana and Gayomey (2016) found that timely publication of financial information significantly enhances the quality of accounting numbers and their value relevance to investors, thereby impacting positively on capital markets. The extent to which listed companies should provide interim reports is another important issue in the discussion on disclosure requirements. The annual reporting regime where financials are released annually is on its way to becoming less useful and in its place, is quarterly reporting regimes. The main critique on mandatory quarterly reporting regimes from a practical point of view, however, is the disproportionate costs associated with the higher reporting frequency, which according to opponents, is not compensated by potential benefits (especially for smaller firms). For example, Ozturk (2008) has identified high costs including cost of sponsoring staff attending conferences and seminars, organizing in-house training, personnel cost for preparers and auditors of financial statements that are IFRSs compliant, as the major hindrances to frequent reporting.

The way forward

Having adopted IFRSs, one critical issue that needs the attention of listed firms is compliance with the recognition, measurement and disclosure requirements of the IFRSs. Listed firms need to train their reporting accountants on the IFRSs. Audit firms also need to insist that the financial reports of their clients, especially those listed on the stock exchange are in compliance with the requirements of IFRSs. In this regard, the joint efforts of ICAG, SEC, the Stock Exchange and other regulators at ensuring compliance cannot be over emphasized.

The findings of the SMPs survey conducted by ICAG in 2016 (ICAG, 2017) reveals that accounting practitioners who practice in the Small to Medium Size practice firms need a lot of support to improve the quality of practice. Most of the practitioners requested support from ICAG in the form relevant CPDs that provided current updates on IFRSs, provision of implementation frameworks for IFRSs, regular and increased quality assurance and monitoring service by QAM to support small firms to improve their practices, regular reviews of firms to weed out non-qualified firms that practice illegally. Whiles as has been noted already, the SMPs do not audit the listed firms, accountants that work for the listed firms share similar characteristics and have some influence on the quality of financial reporting of the listed firms. It is therefore important that ICAG as regulator pay more attention to the work of QAM and possibly expand the ambit of QAM to oversee the work of accountants in industry. This will ensure that accountants are well resourced and motivated to keep proper books of accounts, prepare appropriate and credible financial statements from those books of accounts in compliance with relevant standards.

Perhaps a reporting regime that should be considered by listed entities going forward is integrated reporting. According to the International Integrated Reporting Committee (IIRC), integrated reporting is a process that results in communicating the value creation of an entity over time through an Integrated Report. The IIRC defines an Integrated Report as “a concise communication about how an organization’s strategy, governance, performance, and prospects lead to the creation of value over the short, medium, and long-term” (www.theiirc.org) Integrated reporting provides information not only on the financials of an entity, but also information on strategy, governance, performance, and prospects. The primary benefit of integrated reporting is that it allows a company to better understand, manage and report on multiple dimensions of value. A properly designed set of performance measures often included in integrated reports will give management the incentive and urge to improve performance. For other stakeholders, the report is intended to provide more and better information to increase stakeholder understanding of the company—its management, strategy and operations, and its perils and prospects. It has been suggested that the integrated report will become an organization’s primary report, which links in with various supporting, more detailed, reports.

Conclusion

Improved financial reporting that produces accurate high-quality financial reports on a timely basis is critically important for the development of capital markets especially in developing capital markets as good investment decisions are anchored on high-quality corporate financial information. In this regard, the regulator of the accounting profession should take concrete steps to ensure that accountants who keep the financial records and prepare financial reports for listed firms are sufficiently knowledgeable and skilled in the matters of financial reporting and are guided by sound reporting ethics and the principle of integrity when preparing financial statements. This should be done through collaboration with all relevant stakeholders, especially, other regulatory bodies such as the Securities & Exchange Commission, the Insurance Commission, the Bank of Ghana, and the Ghana Stock Exchange. ICAG should also strengthen its quality assurance and monitoring function and extend it to cover accountants working for firms listed on the Ghana Stock Exchange.

JIANLEI HAN, JING HE, ZHEYAO PAN, AND JING SHI

Twenty Years of Accounting and Finance Research on the Chinese Capital Market

The Chinese capital market has attracted increasing academic attention due to its rising global influence, ongoing regulatory reforms, and distinct institutional background. In this paper, we review scholarly accounting and finance research pertaining to the Chinese capital market in Mainland China published in Tier 1 and Asia-Pacific regional journals during the 1999–2018 period. Our review is based along four dimensions: top-cited articles, main research fields, frequently contributing authors, and emerging research trends. We find that the increasing presence of China in global capital markets, along with its ongoing economic reforms, provides academics with opportunities to investigate distinct institutional environments and utilize natural experiments. This has led to the formulation of novel accounting and finance research questions, greatly advancing our understanding of accounting and finance research.

Key words: Accounting; Chinese capital market; Finance; Research; Review.

Accounting and finance research on the Chinese capital market has attracted the attention of an increasing number of academic researchers. Since the Shanghai Stock Exchange and the Shenzhen Stock Exchange, the two main stock exchanges in China, were established in the 1990s, the Chinese capital market has experienced rapid growth and become one of the most important players in global financial markets. Notably, China now has the second largest stock market and the third largest bond market in the world, significantly increasing its global influence and contribution to global economic development.

The distinct features of the Chinese capital market allow academic researchers to examine unanswered research questions and report new research findings, which contribute to our understanding of capital markets and complement the knowledge of financial systems in other institutional environments. For instance, unlike developed markets, China's financial system is centrally controlled, bank-dominated, and uniquely relationship-driven (Allen *et al.*, 2005). These features offer researchers a unique opportunity to study how a country's institutional

Jing Shi (jing.shi@mq.edu.au) is with Shandong University of Finance and Economics and Macquarie University.

The authors are grateful for comments and suggestions from Joyce Xin Yu and Tom Smith. The usual disclaimer applies.

background fundamentally affects corporate policies and investor behaviours. In this spirit, research on the Chinese capital market enhances our understanding of other emerging or transitional economies.

China's capital market is experiencing dynamic development through a series of structural breaks. Specifically, Chinese regulators have implemented various financial reforms to monitor the capital market, protect market participants, and allocate financial resources. The ongoing financial reforms allow researchers to examine empirically the effects of regulatory policies on corporate decisions or outcomes. Those reforms also supply researchers with a wealth of natural experiment settings to examine accounting and finance research questions, report more plausible casual inferences, and formulate novel research areas and directions. Furthermore, since joining the World Trade Organization (WTO) in 2001, China has expanded the openness of its capital market, attracting both domestic and foreign investors. Thus, the findings of academic research provide academics, practitioners, and investors with insights and knowledge on one of the world's largest capital markets. The increasing importance of the Chinese capital market and the distinctiveness of the Chinese institutional environment provide great opportunities to address important and interesting accounting and finance research questions.

Our objective is to provide an overview of the accounting and finance research on China's capital market for the 1999–2018 period by identifying top-cited articles, summarizing the main research fields, highlighting frequently contributing authors, and discussing emerging research trends and future directions.

We analyze academic papers in both Tier 1 journals and Asia-Pacific regional journals. For the Tier 1 journals, we focus on a list of 24 business journals developed by the Naveen Jindal School of Management at the University of Texas at Dallas.[1] We additionally consider five well-respected international journals. Specifically, the Tier 1 journals we focus on are (in alphabetical order by journal abbreviation): *American Economic Review* (AER), *Academy of Management Journal* (AMJ), *Administrative Science Quarterly* (ASQ), *Contemporary Accounting Research* (CAR), *Journal of Accounting and Economics* (JAE), *Journal of Accounting Research* (JAR), *Journal of Finance* (JF), *Journal of Financial Economics* (JFE), *Journal of Financial and Quantitative Analysis* (JFQA), *Journal of International Business Studies* (JIBS), *Management Science* (MS), *Organization Science* (OS), *Review of Accounting Studies* (RAS), *Review of Finance* (RF), *Review of Financial Studies* (RFS), *Strategic Management Journal* (SMJ), and *The Accounting Review* (TAR).[2]

[1] In our discussion of accounting and finance research on the Chinese capital market, we exclude the following 11 journals listed by the Naveen Jindal School of Management, namely: *Information Systems Research*, *Journal of Consumer Research*, *Journal of Marketing*, *Journal of Marketing Research*, *Journal of Operations Management*, *Journal on Computing, Manufacturing and Service Operations Management*, *Marketing Science*, *MIS Quarterly*, *Operations Research*, and *Production and Operations Management.* According to our analysis, these journals did not contain accounting or finance publications on the Chinese capital market during our sample period.

[2] We also examine publications in the top five economics journals (*American Economic Review*, *Econometrica*, *Journal of Political Economy*, *Quarterly Journal of Economics*, and *Review of*

Following Benson *et al.* (2014, 2015) and Linnenluecke *et al.* (2016, 2017), the eleven Asia-Pacific regional journals we focus on are (in alphabetical order by journal abbreviation): *Accounting, Auditing and Accountability Journal* (AAAJ), *Australian Accounting Review* (AAR), *Abacus* (Abacus), *Accounting and Finance* (AF), *Australian Journal of Management* (AJM), *Accounting Research Journal* (ARJ), *International Review of Finance* (IRF), *Journal of Contemporary Accounting and Economics* (JCAE), *Managerial Auditing Journal* (MAJ), *Pacific Accounting Review* (PAR), and the *Pacific-Basin Finance Journal* (PBFJ).

For each journal, we identify papers that contain either ‘China’ or ‘Chinese’ anywhere in the paper. Next, we read the papers to ensure that they indeed address accounting or finance research questions related to the Chinese capital market in Mainland China, the focus of our study. Papers that utilize China as one of two or three countries for research analyses are also included. We delete papers that include China for the purpose of cross-country investigations.

We identify six distinct research fields each for both accounting and finance. The six accounting fields are: auditing (AU), financial accounting (FA), management accounting (MA), regulation and disclosure (RD), social and environmental (SE), and taxation (TA). The six finance research fields are: asset pricing and investments (AI), banking and financial intermediation (BF), corporate finance (CF), derivatives (DE), international finance (IF), and market microstructure (MM).

The dataset contains 436 accounting and finance papers on the Chinese capital market, including 129 papers in Tier 1 journals and 307 papers in Asia-Pacific regional journals. Figure 1 illustrates the rapid growth of papers on China’s capital market across all journals. The growth in the number of papers is evident in both accounting and finance research, increasing from just six in 1999 to 79 in 2017.

Figure 2 shows that while only one paper appeared in Tier 1 journals in 1999, there are 18 papers in 2017. Also, from an initial five papers in regional journals in 1999, there are 61 Chinese market research papers in 2017.

Table 1 presents the frequency distribution of accounting and finance papers we review. Panel A of Table 1 shows that five Tier 1 journals (i.e., CAR, JAE, RAS, RF, and TAR) published more than 1% of their total papers on the Chinese capital market, with TAR publishing 20 papers, accounting for 1.52% of its total papers.

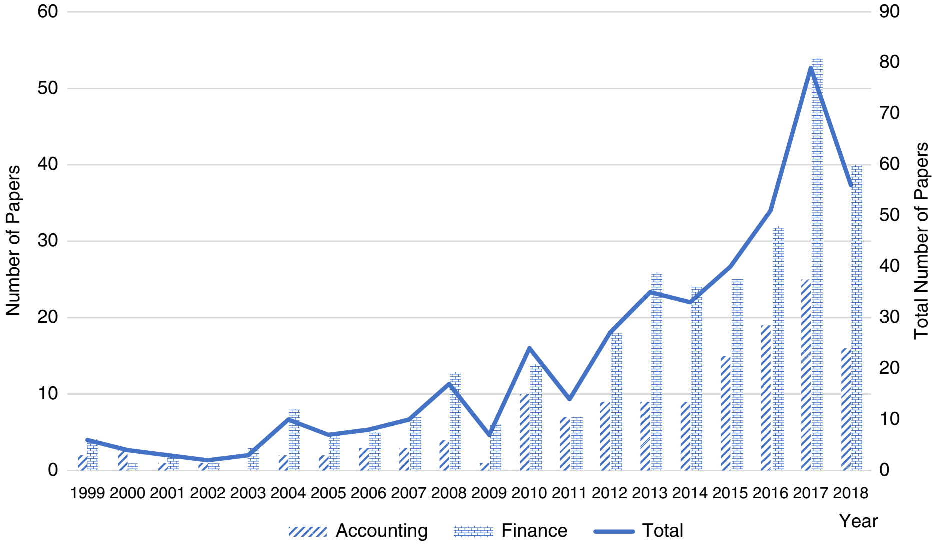
In contrast, Panel B of Table 1 shows that Asia-Pacific regional journals publish far more accounting and finance papers on China’s capital market. For instance, PBFJ published 158 papers on the Chinese capital market, which accounts for 14.89% of its total output over the sample period. The average percentage of accounting and finance papers on the Chinese capital market is 4.22% for Asia-Pacific regional journals, compared to 0.61% for Tier 1 journals.

The growing importance of the Chinese stock market has prompted two Asia-Pacific regional journals to organize special issues on accounting (i.e., *Abacus*) and

Economic Studies). The only publication in these journals on the Chinese capital market is Xiong and Yu (2011), published in the *American Economic Review*.

Figure 1

TIME SERIES DISTRIBUTION OF ACCOUNTING AND FINANCE PAPERS ON THE CHINESE CAPITAL MARKET PUBLISHED IN BOTH TIER 1 AND ASIA-PACIFIC REGIONAL JOURNALS IN 1999–2018



[Colour figure can be viewed at wileyonlinelibrary.com]

finance (i.e., AF) research in China. In 2016, *Abacus* published a special issue (Accounting in China), with a focus on accounting research fields, including auditing (Chen *et al*., 2016; Xiao *et al*., 2016), financial accounting (Banker *et al*., 2016; Chen *et al*., 2016; Lin *et al*., 2016; Mao and Ettredge, 2016), management accounting (Zhou *et al*., 2016), and regulation and disclosure (Ding *et al*., 2016).

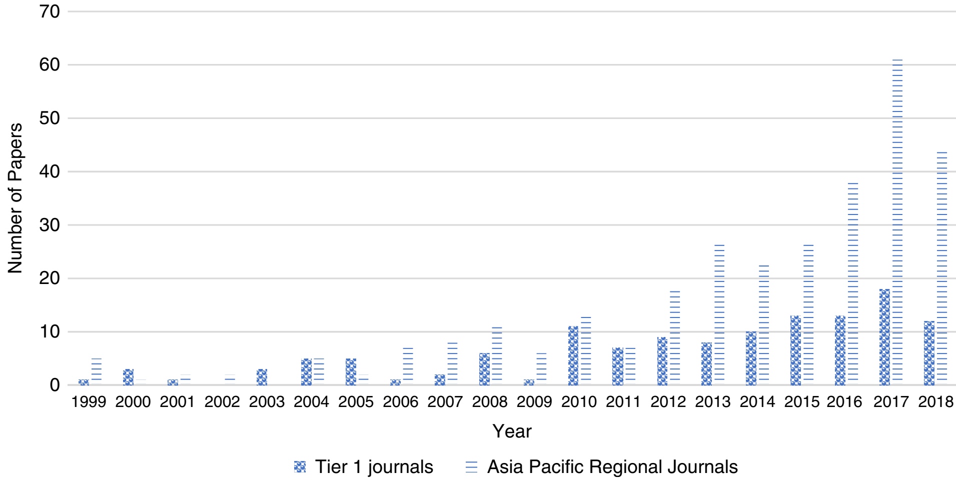
In 2017, AF published a special issue focusing on finance research fields, including asset pricing and investments (Chen *et al*., 2017; Chen *et al*., 2017; Liao *et al*., 2017; Liu *et al*., 2017), banking and financial intermediation (Li *et al*., 2017), corporate finance (Cen *et al*., 2017; Cheng *et al*., 2017; Luo *et al*., 2017; Peng *et al*.; 2017; Zhong *et al*., 2017; Zhu *et al*., 2017), derivatives (Chen *et al*., 2017), and market microstructure (Xiong *et al*., 2017).

TOP-CITED PAPERS

In this section, we examine the top-cited accounting and finance papers on the Chinese capital market in Tier 1 journals and Asia-Pacific regional journals, respectively. The citation counts are drawn from Google Scholar in September 2018 using the software program 'Publish or Perish'. We use Google Scholar citations to ensure consistency of citation counts, as not all of these journals are covered by other applications (e.g., Web of Science or Scopus) for the entire sample period (Benson *et al*., 2014).

FIGURE 2

NUMBER OF ACCOUNTING AND FINANCE PAPERS ON THE CHINESE CAPITAL MARKET PUBLISHED IN TIER 1 AND ASIA-PACIFIC REGIONAL JOURNALS IN 1999–2018



[Colour figure can be viewed at wileyonlinelibrary.com]

Using Google Scholar citations, in Panel A of Table 2 we list the top 30[3] cited accounting and finance papers on the Chinese capital market published in Tier 1 journals during our sample period. The top-cited paper based on total citation count is the JFE paper by Allen *et al.* (2005) on law, finance, and China's economic growth, with 3,301 citations. It is followed by another JFE paper by Fan *et al.* (2007), which examines politically-connected CEOs and initial public offering (IPO) performance in China, with 1,937 citations. Both papers are in the corporate finance field. The top-cited accounting paper on the Chinese capital market across Tier 1 journals is the JAR paper by Aharony *et al.* (2000) on the role of earnings management in Chinese firms' IPO process, with 779 citations.[4]

In Table 3, we list the top-cited accounting and finance papers on the Chinese capital market published in Asia-Pacific regional journals during our sample period. The paper with the greatest total citation count is the PBFJ paper by Qi *et al.* (2000) on the relation of shareholding structure and corporate performance, with

[3] Actually, we have included 31 papers, as Tan and Peng (2003), *Strategic Management Journal*, and Cull and Xu (2005), *Journal of Financial Economics*, are both ranked 5th.

[4] We also rank the articles by citations per year to account for the fact that total citations increase with an article's publication history. Park and Luo (2001), *Strategic Management Journal*, Allen *et al.* (2005), *Journal of Financial Economics*, Fan *et al.* (2007), *Journal of Financial Economics*, continue to be the three most widely cited papers, with citations per year of 109.06, 253.92, and 176.09, respectively. The majority of the articles remain on the list, with five new articles entering into the top 30 articles by citations per year, namely: Liao *et al.* (2014), *Journal of Financial Economics,* Cumming *et al.* (2015), *Academy of Management Journal,* Giannetti *et al.* (2015), *Journal of Finance,* Piotroski *et al.* (2015), *Journal of Accounting Research,* Luo *et al.* (2017), *Academy of Management Journal.*

This table presents the total citation counts and citation counts per year, drawn from Google Scholar in September 2018 using the software program 'Publish or Perish'. Papers with the same number of Google Scholar total citation counts are listed chronologically in the table.

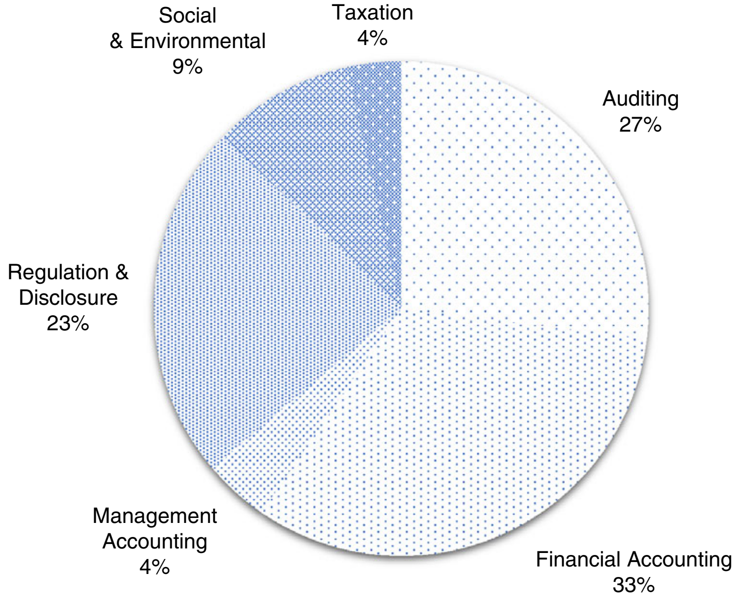
in Tier 1 journals attract more citations, given that they typically address broader and more ground-breaking research questions, and have a wider range of readers. On the other hand, Asia-Pacific regional journals have a much larger and rapidly growing number of papers on China's capital market. Additionally, papers published in regional journals pay more attention to research questions on specific aspects of the institutional environment in China.

FIGURE 3

DISTRIBUTION BY RESEARCH FIELD FOR ACCOUNTING PAPERS ON THE CHINESE CAPITAL MARKET PUBLISHED IN 1999–2018



[Colour figure can be viewed at wileyonlinelibrary.com]

ACCOUNTING RESEARCH AREAS

In this section, we summarize the six main accounting research fields we identify from publications on the Chinese capital market in Tier 1 and Asia-Pacific regional journals. The six accounting fields are: auditing (AU), financial accounting (FA), management accounting (MA), regulation and disclosure (RD), social and environmental (SE), and taxation (TA).

Auditing and financial accounting appear to be the most popular accounting research streams (see Figure 3). For Tier 1 journals, Panel A of Table 4 clearly shows that auditing is the most popular accounting research stream, represented by 23 of 56 accounting papers (41.07%) on the Chinese capital market. This is likely due to the distinctive institutional features of the Chinese auditing market, which gives rise to a wealth of research opportunities. As summarized by Fu and Lu (2014), the auditing market is much less concentrated in China than in the United States; there is a series of structural changes in the market and the Chinese auditing profession is regulated and administered by government agencies.

The most widely cited paper in the auditing area is the JAE paper by Wang *et al.* (2008), which examines state ownership and auditor choice, with 767 citations (see Table 2). Other top-cited auditing papers include another JAE paper by DeFond *et al.* (1999), which considers the effect of enhancing auditor

TABLE 4

MAJ	7	4	1	8	1	–	21
PAR	2	8	–	1	2	–	13
Total	15	27	4	27	10	2	85
Percentage	17.65%	31.76%	4.71%	31.76%	11.76%	2.35%	

The Tier 1 journals are: *Academy of Management Journal* (AMJ), *Contemporary Accounting Research* (CAR), *Journal of Accounting and Economics* (JAE), *Journal of Accounting Research* (JAR), *Organization Science* (OS), *Review of Accounting Studies* (RAS), and *The Accounting Review* (TAR). The accounting research fields are: auditing (AU), financial accounting (FA), management accounting (MA), regulation and disclosure (RD), social and environmental (SE), and taxation (TA). The Asia-Pacific regional journals are: *Accounting, Auditing and Accountability Journal* (AAAJ), *Australian Accounting Review* (AAR), *Abacus* (Abacus), *Accounting and Finance* (AF), *Accounting Research Journal* (ARJ), *Journal of Contemporary Accounting and Economics* (JCAE), *Managerial Auditing Journal* (MAJ), and the *Pacific Accounting Review* (PAR). The accounting research fields are: auditing (AU), financial accounting (FA), management accounting (MA), regulation and disclosure (RD), social and environmental (SE), and taxation (TA). This table presents the number of accounting papers on the Chinese capital market published in each journal over the 1999–2018 period by research field, and the percentage of total accounting papers on the Chinese capital market by research field.

independence, and a TAR paper by Chen *et al.* (2010) on client economic importance and audit quality in China. In contrast, the auditing field in the Asia-Pacific regional journals is ranked third in terms of number of papers, with 17.65% of accounting papers published in this area. The top-cited auditing paper in Asia-Pacific regional journals with the highest total citation count is the AAAJ paper by Shafer (2009) on the impact of ethical climate on the conflict between organizational value and professional value.

Financial accounting is the second most popular accounting stream of research on the Chinese capital market in Tier 1 journals, represented by 33.93% of the total accounting papers. The top-cited financial accounting paper on the Chinese capital market is the JAR paper by Aharony *et al.* (2000), which studies earnings management and IPO firms in China, with 779 citations. However, in the Asia-Pacific regional journals, financial accounting appears to be the most attractive research field and is represented by 27 of 85 accounting papers (31.76%).

In Tier 1 journals, regulation and disclosure is the third most popular field for Chinese market research and is represented by six of 56 accounting papers (10.71%). The top-cited paper is a TAR paper, at 739 total citations, by Chen and Yuan (2004). The authors examine the relation between earnings management and capital resource allocations in China by exploiting an accounting-based regulation of rights issuance. This is followed by a CAR paper by Haw *et al.* (2005), which examines the market consequences of earnings management in the context of security regulations in China. In contrast, in the Asia-Pacific regional journals, the field of regulation and disclosure appears to be more attractive, represented by 31.76% of papers. Across these regional journals, the top-cited regulation and disclosure paper with the highest total citation count at 330, is the MAJ paper by Xiao and Yuan (2007) on corporate voluntary disclosure.

Table 4 and Figure 3 also reveal that management accounting, and taxation are the least studied fields in accounting for both Tier 1 (8.93% of papers) and Asia-Pacific regional journals (7.06% of papers).

FINANCE RESEARCH AREAS

In this section, we summarize the six main finance research fields identified from publications on the Chinese capital market in Tier 1 and Asia-Pacific regional journals. The six finance research fields are: asset pricing and investments (AI), banking and financial intermediation (BF), corporate finance (CF), derivatives (DE), international finance (IF), and market microstructure (MM).

Table 5 and Figure 4 show that corporate finance and asset pricing and investments together account for more than 80% of research interest across all finance research fields. Corporate finance is the most popular finance research stream, accounting for 64.38% and 45.50% of all finance papers on the Chinese capital market in Tier 1 journals and Asia-Pacific regional journals, respectively. This is mainly due to the distinct institutional environment features encountered by Chinese listed firms. For instance, the 2006 share structure reform in China affects corporate policies, while the political connections of executives have a significant impact on both corporate values and managerial behaviour. Moreover, other regulation changes on property rights, accounting standards, and governance mechanisms provide research opportunities in the area of corporate governance.

With 47 corporate finance papers (out of 73 Tier 1 finance papers), the top-cited corporate finance paper with the greatest citation count is a JFE paper by Allen *et al.* (2005) on law, finance, and China's economic growth. Other top-cited corporate finance papers include another JFE paper by Fan *et al.* (2007) on the political connections of CEOs and post-IPO performance and the SMJ paper by Park and Luo (2001) on the utilization of *guanxi* and its impact on firm performance in China.

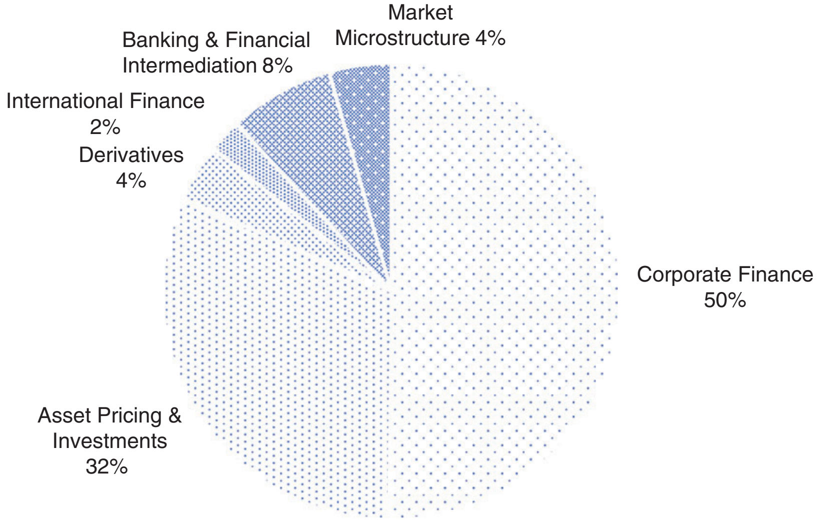
The Tier 1 journals are: *Academy of Management Journal* (AMJ), *Contemporary Accounting Research* (CAR), *Journal of Accounting and Economics* (JAE), *Journal of Accounting Research* (JAR), *Organization Science* (OS), *Review of Accounting Studies* (RAS), and *The Accounting Review* (TAR). The accounting research fields are: auditing (AU), financial accounting (FA), management accounting (MA), regulation and disclosure (RD), social and environmental (SE), and taxation (TA). The Asia-Pacific regional journals are: *Accounting, Auditing and Accountability Journal* (AAAJ), *Australian Accounting Review* (AAR), *Abacus* (Abacus), *Accounting and Finance* (AF), *Accounting Research Journal* (ARJ), *Journal of Contemporary Accounting and Economics* (JCAE), *Managerial Auditing Journal* (MAJ), and the *Pacific Accounting Review* (PAR). The finance research fields are: asset pricing and investments (AI), banking and financial intermediation (BF), corporate finance (CF), derivatives (DE), international finance (IF), and market microstructure (MM). This table presents the number of finance papers on the Chinese capital market published in each journal over the period 1999–2018 by research field, and the percentage of total finance papers on the Chinese capital market by research field.

For Asia-Pacific regional journals, corporate finance is represented by 101 of 222 finance papers. The top-cited corporate finance paper is a PBFJ paper by Qi *et al.* (2000) on the impact of different classes of equity ownership on firm performance, which is also the top-cited paper on the Chinese capital market across regional journals between 1999–2018, with 483 total citations. The top-cited corporate finance paper in AF is Ma *et al.* (2010), which examines ownership, ownership concentration, and firm performance, with 58 citations. The top-cited paper in AJM is Xu *et al.* (2015), which examines the impact of corporate social responsibility (CSR) activities on the cost of equity, with 33 citations. The top-cited paper in IRF

FIGURE 4

DISTRIBUTION BY RESEARCH FIELD FOR FINANCE PAPERS ON THE CHINESE CAPITAL MARKET PUBLISHED IN 1999–2018



[Colour figure can be viewed at wileyonlinelibrary.com]

is Otchere and Zhang (2001), which examines privatization in China, with 19 citations.

Asset pricing and investments is ranked second and is represented by 17 (of 73) top-tier finance papers (23.29%). The top-cited asset pricing and investments paper is an RF paper, at 617 citations, by Feng and Seasholes (2005), which examines the effects of investor sophistication and trading experience on behavioural biases. Asset pricing and investments represents 34.23% of finance papers in the Asia-Pacific regional journals. The top-cited paper is a PBFJ paper by Kang *et al.* (2002) on contrarian and momentum strategies, with 379 citations. This is closely followed by another PBFJ paper by Tan *et al.* (2008) on herding behaviour in China's stock market, with 376 citations.

There are fewer than three papers in each of the four remaining finance research fields in the Tier 1 journals. A total of 19 and 11 papers appear in the fields of banking and financial intermediation and market microstructure in the Asia-Pacific regional journals, respectively. Both derivatives and international finance have fewer than 10 papers.

FREQUENT CONTRIBUTORS

The Chinese capital market has attracted the attention of academic researchers worldwide. The 1999–2018 period has seen a rapid increase in the number of researchers interested in untangling accounting and finance research questions in

TABLE 6

FREQUENT CONTRIBUTORS ACCORDING TO THE NUMBER OF PUBLISHED PAPERS ON THE CHINESE CAPITAL MARKET IN TIER 1 JOURNALS IN 1999-2018.

China's capital market. Table 6 shows the frequent contributors to the literature on the Chinese capital market. Specifically, we rank contributors according to the number of their published papers on China's capital market in Tier 1 journals during the 1999–2018 period. We list the top 22 contributors who fall within the top five total publication counts.

The most prolific author is T. J. Wong, with nine papers on the Chinese capital market published in Tier 1 journals: eight accounting papers and one finance paper across five well-respected journals. This author's work ranges from DeFond *et al.* (1999) dealing with auditor independence and audit market competition, to Hung *et al.* (2015) examining the value of political ties and market credibility, and Piotroski *et al.* (2015) studying the role of political incentives in corporate disclosures.

In addition, Yongxiang Wang, Donghui Wu, and Tianyu Zhang each have six papers on the Chinese capital market in Tier 1 journals. Yongxiang Wang's earliest paper during the sample period is Calomiris *et al.* (2010) exploring the impact of announcing the sale of government-owned shares in China. More recently, Yongxiang Wang's papers include Chen *et al.* (2018) dealing with mandatory CSR disclosure in China, and Jia *et al.* (2018) examining the relationship between minority shareholders and controlling shareholders. Donghui Wu's papers range from Haw *et al.* (2005) on the consequences of earnings management behaviour in Chinese listed firms, to He *et al.* (2017) on social ties and audit quality. Tianyu Zhang's papers include Piotroski and Zhang (2014), which deals with politicians and IPO activities in China, and Lennox *et al.* (2016), which examines the relation between audit adjustments and earnings quality.

There are many other leading researchers whose work has further enhanced our understanding of the Chinese capital market. In accounting research, for example, Chan *et al.* (2010) analyze tax-based accounting and tax noncompliance; Firth *et al.* (2012) look at the organizational form of auditors; Gul *et al.* (2013) examine the influence of individual auditors on audit outcomes; Ke *et al.* (2015) explore the effect of institutional environment on audit quality; Guan *et al.* (2016) analyze the impact of school ties on audit outcomes; and Du *et al.* (2018) investigate performance measures and evaluations in Chinese state-owned enterprises (SOEs). In finance research, for instance, Firth *et al.* (2010) study the role of government shareholders and mutual funds in the split share structure reform; Jia *et al.* (2013), using related party transactions, investigate coinsurance within business groups in China; Qian *et al.* (2015) study information production and use in the context of bank lending; Zhang *et al.* (2016) deal with the political connections of privately controlled firms in China; Haveman *et al.* (2017) examine political embeddedness and firm performance in China; and Li *et al.* (2017) analyze the effect of dividend tax reform in China on corporate dividend payout policies.

EMERGING TRENDS AND FUTURE DIRECTIONS

In this section, we examine accounting and finance papers on the Chinese capital market over the last five years (2014–2018) to identify emerging research trends and provide research directions. Recent papers in Tier 1 and Asia-Pacific regional journals reveal emerging trends in the following area: media, household finance, corporate social responsibility, and political connections. These areas provide promising avenues for future studies.

Media

An emerging field of research on the Chinese capital market is the media's impact on corporate outcomes. The media, as an information intermediary and a corporate monitor, plays a key role in the capital market. China provides a special setting to examine the effect of the media on corporate decision making and performance, as most of the media is state-controlled. Amongst Tier 1 journals, You *et al.* (2017), for example, study how government control affects the role of the media on the corporate governance of publicly listed firms. Papers in Asia-Pacific regional journals, such as Huang (2018) and Zhu *et al.* (2017) examine how media sentiment impacts stock returns.

Future research in this area could examine the potential role played by government-owned media or private media in corporate governance settings. As summarized by Wong (2016), many research questions warrant further investigation. For instance, does increased news credibility reduce information asymmetry of listed firms or improve stock price efficiency? Do critical reports of listed firms perform a governance role in monitoring managers? Do newspapers serve as public channels providing policy directives to listed firms?

Household Finance

The field of household finance has grown rapidly in recent years (Badarinza *et al.*, 2016). With rich household-level data, household finance research is increasingly becoming prominent in China. For instance, Liao *et al.* (2017) show that consumers with higher levels of financial literacy are more likely to hold risky financial assets than those with lower levels of financial literacy, while Liu *et al.* (2017) examine Chinese households' decisions to buy or rent a primary residence from a risk-hedging perspective.

As Campbell (2006) argues, one main challenge of household finance research is the difficulty of measuring household behaviours. Given the recent progress on developing survey data at the household level in China,[6] there are numerous topics for future research. For example, how does household wealth affect capital market participation decisions? Does demography affect households' risk preferences? How diversified are the portfolios held by households? How do households make their mortgage decisions?

Corporate Social Responsibility

Another emerging stream of accounting and finance research in China is concerned with corporate social responsibility. Unlike disclosure requirements in other countries, CSR reporting has been required by the Chinese government since 2008 for a subset of firms (Chen *et al.*, 2018). This change in regulation contributes to the emerging literature in the area of CSR. In Tier 1 journals, Chen *et al.* (2018) examine how mandatory disclosure of CSR impacts firm performance and social externalities in China. Additionally, Marquis and Qian (2014) investigate how and why firms strategically respond to government signals on appropriate corporate activity in China. Furthermore, there are a relatively large number of publications on CSR in China in Asia-Pacific regional journals. For example, Xu *et al.* (2015) examine the market's reaction to CSR disclosure; Carey *et al.* (2017) document that voluntary CSR reporting and audit fees are positively associated in China, while Shafer *et al.* (2016) investigate the relation between social responsibility and tax fraud in China.

The mandatory disclosure of CSR activities in China provides an opportunity to study the impact of mandatory disclosure on the production of private information and market efficiency. Moreover, opportunities exist in this area to investigate the governance role of CSR in Chinese listed firms. It is interesting to understand how different types of investors (e.g., state ownership, institutional investors, and individual investors) react to firms' costly CSR activities; and what is the monitoring mechanism in relation to CSR activities.

[6] For instance, the Survey and Research Center for Household Finance has generated and provided survey data on Chinese household finance since 2013.

Political Connections

The final emerging research area we examine is concerned with the effects of political connections and how they impact the Chinese market. Specifically, most papers focus on examining the value of political connections in publicly listed firms. For example, in Tier 1 journals, Piotroski *et al.* (2015) examine the proposition that politicians and their affiliated firms temporarily suppress negative information in response to political incentives. Additionally, Piotroski and Zhang (2014) show that the incentives created by the impending turnover of local politicians can accelerate the pace of IPO activity in certain politicized environments. In a paper in an Asia-Pacific regional journal, Han and Zhang (2018) investigate the value of politically connected board members for Chinese listed firms, while Peng *et al.* (2017) explore whether the political connections of the board of directors facilitates credit financing. On the other hand, a growing strand of literature focuses on the risk of being politically connected in Chinese firms. For instance, Liu *et al.* (2017) examine the impact of political uncertainty on the asset prices of politically connected firms.

Most of the papers we examine find that political connections create value for Chinese listed firms. However, there are still many unanswered questions. As argued by Wong (2016), future research can focus on how social ties are used in developing political connections. How do politicians develop political networks with bureaucrats in SOEs, and with entrepreneurs in non-SOEs? Under what conditions do politicians have a positive effect on listed firms? Do political connections enable the government to administer certain polices that withstand macro shocks or reduce the risks and costs incurred by the reform itself? How do political incentives interact with the application of International Financial Reporting Standards (IFRS)?

Taken together, although there are many interesting studies and emerging research questions on the Chinese capital market, it remains unclear as to what extent these research findings provide information on some fundamental global accounting and finance questions (Fu and Lu, 2014). For instance, does the capital market in China stimulate economic growth and improve capital allocation efficiency or it is simply a side show? This remains an open question for both China and developed countries.[7] This limitation, however, creates an important long-term research opportunity. As argued by Allen *et al.* (2005), China is a significant counter-example to the findings in the literature. Therefore, China's capital market is a fertile setting for researchers to create new accounting and finance theories to address these questions.

CONCLUSION

This paper provides an overview of the accounting and finance literature on the Chinese capital market from 1998–2018. We review academic papers on China's

[7] Other important questions summarized by Fu and Lu (2014) include, what is the most appropriate measure of accounting qualities? Do accounting numbers and qualities have a first-order effect on firm value, and does it differ between China and the West?

capital market published in Tier 1 journals and Asia-Pacific regional journals. We also present the top-cited accounting and finance papers across Tier 1 journals and Asia-Pacific regional journals, respectively. Moreover, we identify the main accounting and finance research streams on the Chinese capital market, revealing that the financial accounting and corporate finance fields dominate the journals overall. The Chinese capital market has attracted increasing academic attention worldwide, which has led to the formulation of novel accounting and finance research questions, greatly advancing our understanding of accounting and finance research.

Abstract

Purpose – This paper aims to explore the relationship between board characteristics and firm performance for Indian companies.

Design/methodology/approach – Corporate governance structures of 391 Indian companies out of CNX 500 companies listed on National Stock Exchange have been studied for their impact on performance of companies. Panel data regression methodology has been used on data for five financial years from 2010 to 2014 for the selected companies. Performance measures considered are market-based measure (Tobin's Q) and accounting-based measure (return on asset [ROA]).

Findings – The empirical findings indicate that the market-based measure (Tobin's Q) is more impacted by corporate governance than the accounting-based measure (ROA). There is a significant positive association between board size and firm performance. Board independence is found significantly related to firm performance. Number of board meetings is found to be sending positive signal to the market creating firm value. Separation of chief executive officer and chairman of the board is found to be value-creating, and overburdened directors affect firm performance adversely.

Research limitations/implications – Limitations of the study are in terms of methodology and possible omission of some variables. It is understood that the qualitative dynamics happening inside board meetings impact corporate performance. The strategic decision-making process adopted by the boards to fight competition or to increase market share is not easily available in public domain. The decision-making processes and monitoring for implementation of those decisions could impact corporate governance performance relationship. These parameters and their impact on corporate performance are not covered under the scope of the present study.

Originality/value – The paper adds to the emerging body of literature on corporate governance performance relationship in the Indian context by using a reasonably wider and newer data set.

Keywords India, Board structure, Corporate governance, Firm performance

Paper type Research paper

1. Introduction

Corporate governance is a system by which companies are directed and controlled (Cadbury Committee, 1992). Corporate governance is concerned with three aspects of decision-making process in a firm. First, who is empowered to take what decision; second, whose interest gets priority while taking a particular decision; and third, whether (and how) contextual factors such as social, political, economic and legal institutions are impacting the decision-making process and outcomes of these decisions.

In the context of emerging economies, corporate governance mechanisms have been found correlated with firm performance in various theoretical and empirical studies (Khanna and Palepu, 2000; Gibson, 2003; Klapper and Love, 2004; Young *et al.*, 2008; Ehikioya, 2009; Claessens and Yurtoglu, 2013). Well-functioning corporate governance mechanisms in emerging economies are of crucial importance for both local firms and foreign investors that

DOI 10.1108/JIBR-07-2016-0074

are interested in pursuing such tremendous opportunities for investment and growth that emerging economies provide (Rajagopalan and Zhang, 2008). From the perspective of local firms, there is evidence that firms in emerging economies (compared with their counterparts in developed countries) are discounted in financial markets because of their weak governance (La Porta *et al.*, 2000). Improvements in corporate governance can enhance investor confidence in firms in emerging economies and increase these firms' access to capital (Rajagopalan and Zhang, 2008).

The Indian Government initiated market reforms in 1991. Major elements of these reforms resulted in the opening of the Indian economy to multinational companies and foreign investment. Increased foreign investment in India intensified interest in good corporate governance and in particular the application of western governance structure to Indian firms (Jackling and Johl, 2009). India needed capital to finance the expansion of market spaces created by liberalization and outsourcing opportunities. This need for capital amongst other requirements led to corporate governance reforms and major initiatives in this direction. The initial step in this direction was the introduction of Clause 49 in the listing agreement by Securities Exchange Board of India (SEBI) that contained prominence of independent directors amongst other things. Government of India has taken yet another major step in this direction through the introduction of Companies Act 2013 (effective from 1 April 2014); wherein provisions of corporate governance have been made mandatory for Indian companies.

Like other emerging economies, Indian organizations also face domination by family ownership and other forms of domination, such as government or a foreign group. These groups often exercise influence that is disproportionate to their actual shareholding (Pande and Ansari, 2013). In family-owned corporations that widely prevail in emerging economies (like India), boards are typically dominated by family members who enjoy substantial ownership and control and often hold top executive positions with an objective of controlling the firm (Carney and Gedajlovic, 2002). As an implication, board members of family-controlled firms may not be that much efficient in their monitoring role and may give benefit of doubt to incumbent mangers for low firm performance (Gomez-Mejia *et al.*, 2003). In case of Indian firms, families (founders) are present on the boards in 63.2 (65.5) percent, and on an average, founders own over 50 per cent of outstanding shares (Jameson *et al.*, 2014). This leads to different kind of corporate governance issues in India as compared to governance issue in the Anglo-Saxon economies, which is primarily disciplining management that may stop being accountable to the owners who usually are dispersed shareholders.

Denis and McConnell (2003) argued that to overcome problems in corporate governance, different internal or external mechanisms can be applied. Primary internal mechanisms are the board of directors and equity ownership structure of the firm, whereas primary external mechanisms are the external market for corporate control (the takeover market) and the legal system. External and internal governance mechanisms are complements, i.e. countries where market for corporate control are not that much prevalent and enforcement of corporate government regulations through legal system is weak, and provide a strong case for internal governance mechanisms to be at the forefront for improving corporate performance. Hence, considering the current stage of Indian economy where market for corporate control is still developing (Khanna and Palepu, 2000) and there exists a weak legal enforcement regime of corporate governance (Sarkar and Sarkar, 2000), it appears that internal governance mechanisms will have significant bearing on corporate performance.

This study attempts to investigate the impact of an internal governance mechanism, i.e. board of directors, on the firm value for Indian companies.

2. Objectives and methodology

This paper analyses data of CNX500 companies listed at National Stock exchange (NSE) for five financial years starting from financial year 31 March 2010 to 31 March 2014. We aim to find relationship of firm performance with different board characteristics such as:

- board independence;
- board leadership structure;
- board size;
- number of board meetings; and
- busyness of directors.

In this paper, we also propose to find out:

- whether factors such as firm size, age of firm, leverage used by firm and sales growth affect firm performance; and
- whether the relationship between firm performance and different board characteristics is the same for different types of performance measures, namely, an accounting-based measure such as return on asset (ROA) and a market-based measure such as Tobin's Q.

We used panel data methodology to analyze data across firms over the years. Panel data sets are able to identify the estimate effects that are not detectable in pure cross-sectional or pure time series analysis (Ahmed Sheikh and Wang, 2012). The regression has been carried out for complete set of data and also for data subsets to explore differential impacts of corporate governance variables on different types of companies, for example, small vs large companies, companies with small board vs those with large board.

The paper is organized as follows. In Section 3, we review theoretical arguments and empirical evidence with respect to the relationship between structure of board of directors and firm performance. In Section 4, we put forward our arguments for hypotheses development based on the review of previous findings. Section 5 provides description of model, variables and their measures. Section 6 presents data descriptive, followed by results and analysis. Finally, concluding remarks with discussion on limitations of our study and future directions is given in Section 7.

3. Literature review

3.1 The board of directors

As the relationship between board of directors and firm performance is substantially varied and complex, a single governance theory is not adequate to describe it (Nicholson and Kiel, 2007). Main theories developed to understand the relationship between structure of board, its role and firm performance are agency theory, resource dependence theory and stewardship theory. The relationship between board and firm performance has been studied in the context of different functions performed by the board. Board of directors serves two important functions for organizations:

(1) monitoring management on behalf of shareholders (agency theorists); and

(2) providing resources (resource dependence theorists) (Hillman and Dalziel, 2003).

Agency theory (Jensen and Meckling, 1976; Fama, 1980; Fama and Jensen, 1983) considers agency relationship as a contract under which the principal (s) (shareholders) engage the agents (managers) to perform some service on their behalf which involves delegating some decision-making authority to the agent. If both the parties are utility maximisers, there is a good reason to believe that the agent will not always act in the best interest of the principal necessitating monitoring of agents' behaviour by the principal (s). As the board monitors managers on behalf of principal, an independent board (comprising majority of outsiders) and separation of the post of chairman of the board and chief executive officer (CEO) would reduce agency cost, facilitating better performance.

Under the stewardship theory, objectives of both principals and agents are considered to be unidirectional, and hence, there is no conflict of interests. Managers are considered good stewards of resources entrusted to them (Donaldson, 1990; Donaldson and Davis, 1991, 1994). This theory considers managers trustworthy people (Donaldson and Preston, 1995). The agency cost will be minimal because, for fear of losing their reputation, managers will not act against interests of the shareholders (Donaldson and Davis, 1994). This theory indicates that to attain a superior performance by their corporations, CEOs should exercise complete authority over the corporation and that their role must be unambiguous and unchallenged (Donaldson and Davis, 1991). This situation is attained more readily if the CEO is also the chairman of the board. Hence, stewardship theory entails a better firm performance for companies with common role of CEO and chairperson of the board as a result of unidirectional strategic orientations provided by it.

The resource dependency theory provides a mechanism whereby firms have links to critical resources from the environment through affiliations of its directors and tends to emphasize on the economic nature of these resources (Barroso *et al.*, 2011). The board has a role in provision of resources that include providing legitimacy, administering advice and counselling, acting as a link to important stakeholders or other significant bodies, facilitating access to resources such as capital, building external relations, etc. (Barroso *et al.*, 2011). Board is a vital link between the company and the resources needed to maximize performance (Pfeffer and Salancik, 2003). Apart from this, the board itself is considered an important resource especially in relationship to its external environment as boards can manage environmental dependencies and would reflect the environmental needs (Hillman *et al.*, 2009). This enables the board to provide a sustainable competitive advantage over its competitors (Barney *et al.*, 2001). Thus, resource dependency theory would anticipate that board of directors with high level of external links would improve a company's access to various resources, thus improving firm performance (Jackling and Johl, 2009). The linkage between resources and performance provided by the board of directors would depend on the activity and busyness of directors. Hence, in line with the resource dependency theory, it can be assumed that size and diversity of the board, number of board meetings and association of directors with other companies either as directors or as committee members will have a positive association with the firm performance.

Primary function of board of directors in corporations is to ensure maximization of shareholder value through a mechanism that includes activities pertaining to hiring, firing, monitoring and compensating the managers (Shleifer and Vishny, 1997; Hermalin and Weisbach, 2001). Theoretically, the board is an effective corporate governance mechanism, but empirical results do not exactly support this. Some of the reasons for such results are as follows:

- Many a times, the board includes insiders whose monitoring is to be done by the board.
- Selection of outsiders on the board is decided or influenced by inside managers.
- Chairperson of the board is also the CEO of the firm.

Main issues highlighted in various empirical studies pertaining to the board have been certain specific variables and their impact on performance of the firm. These variables are size of the board, ratio of outside directors and inside directors, CEO duality, number of board meetings and internal and external busyness of directors.

3.1.1 Board composition. Board composition may affect corporate performance in two ways; one way is to have more number of outside directors that will lead to better evaluation and monitoring, whereas on the other hand, more number of internal directors will lead to better corporate performance because of alignment of interests (as per agency theorists). An optimal board composition depends upon the kind of firm and the environment in which it is operating (Mishra and Kapil, 2016). Coles *et al.* (2008) found that complex firms that have greater advising requirements than simple firms have larger boards with more outside directors.

Kamardin and Haron (2011), using factor analysis, extracted two dimensions of monitoring roles: management oversight and performance evaluation. Non-independent, non-executive directors and managerial ownership are positively related to both dimensions of monitoring roles, while multiple directorships of non-executive directors are negatively related to management oversight roles. Boards with a high representation of outside and foreign directors were associated with better performance compared to those boards that had a majority of insider executive and affiliated non-executive directors (Ameer *et al.*, 2010).

Petra (2006) explained that a dispersed nature of shareholding pattern results into a situation where an individual shareholder does not have either potential or incentive to monitor the behaviour of management directly. In such a situation, board of directors are entrusted to monitor the behaviour of management on behalf of shareholders. Majority of outside independent directors in the board would reduce conflict of interest and increase its monitoring potential. Reforms brought out in different countries indicate towards providing more independence to the board. As per Aguilera (2005), corporate governance reforms are increasingly focusing on non-executive directors/independent outside directors with a hope that they will bring greater transparency, accountability and efficiency to corporate governance.

In India, Clause 149(4), Chapter XI of Companies Act 2013, states that every listed public company shall have at least one-third of the total number of directors as independent directors, and the Central Government may prescribe minimum number of independent directors in case of any class or classes of public companies. Every company existing on or before the date of commencement of this Act (1 April 2014) shall, within one year, comply with the requirements of the provisions.

3.1.2 Chief executive officer duality. There are two different views on board leadership structure. Agency theorists argue that roles of CEO and chairperson combined into a single person (i.e. CEO duality) will lead to domination of board by that person making the board ineffective in monitoring managerial opportunism (Jensen, 1993). As a result, CEO duality enhances CEO entrenchment and reduces board independence (Rhoades *et al.*, 2001). Separating these two roles is desired so that the CEO is responsible for executing company's policies and running the company, and chairperson of the board is responsible for running the board and monitoring and evaluating managerial activities (Yan Lam and Kam Lee, 2008). Higgs (2003) recommends that separating these two roles, "avoids concentration of authority and power in one individual and differentiates leadership of the board from running of the business". The board is also responsible for the process of hiring, firing, evaluating and compensating the CEO, and thus, the chairperson should preferably not be the same person whose performance is being assessed (Jensen, 1993). CEO duality is expected to lower the performance because CEOs would gain much power to further their own interests rather than the interests of shareholders (Weisbach, 1988). On the other hand, steward theorists accept that managers are good stewards of company resources (Davis *et al.*, 1997). The supporters of stewardship theory advocate that there is no conflict of interest between the mangers and shareholders; hence, CEO duality would promote a unified and strong leadership with a clear sense of strategic direction.

3.1.3 Board size. Literature suggests that an increased board size has two competing effects: greater monitoring versus more rigid decision-making (Harford *et al.*, 2012). Impact of board size on corporate performance is a trade-off between two competing aspects; first, a large board leads to wide experience and more linkages to external environment (which may help in access to resources and stakeholders) and second, a large board slows down the decision-making process. Yermack (1996) found an inverse relationship between board size and firm value. In contrast, Harris and Raviv's (2008) model of boards trades off additional monitoring services with free-riding predicting larger boards to provide optimal monitoring when managers' opportunities to consume private benefits are high. Abor and Biekpe (2007) found that board size has significant positive impact on profitability. Empirical results indicate that board size is positively related to the ROA, earnings per share and market-to-book ratio. (Ahmed Sheikh *et al.*, 2013). Geraldes Alves (2011) predicted a non-linear relationship between board size and earnings management. Kumar and Singh (2013) found a negative relationship between board size and firm value in the Indian context. Kota and Tomar (2010) found that small boards are more effective in enhancing firm value.

Regarding board size in India, Clause 149(1), Chapter XI of Companies Act 2013, says that every company shall have a board of directors consisting of individuals as directors and shall have:

- a minimum number of three directors in the case of a public company, two directors in the case of a private company and one director in the case of a one-person company; and
- a maximum of 15 directors; a company may appoint more than 15 directors after passing a special resolution.

3.1.4 Board committees. Eberhart (2012) reported a significant increase in firm valuation (measured by Tobin's Q) for companies that adopted an alternative of the Anglo-American type committee system. This finding was attributed to "signal sending", as companies that adopted this system signal a choice towards transparency via monitoring by outsiders, suggesting a reduction of asymmetric agency costs. The above-mentioned paper finds that the committee corporate governance system produces higher corporate value than the traditional auditor governance, citing evidence that it is the signal provided by the adoption of the credible system, not the financial performance variables that account for this difference. Veronica and Bachtiar (2014) found that audit committee has a significant negative relation with discretionary accruals indicating effectiveness of audit committee in constraining the level of earnings management. Further, they found that proportion of independent directors on board and existence of audit committee increases the positive relationship between discretionary accruals and stock return, thereby indicating that earnings management conducted by firms have higher proportion of independent directors, and firms having audit committee will be valued higher by the market. Raja and Kumar (2007) found that committee component has statistically significant relationship with firm performance.

3.1.5 Board meetings and participation of directors. Directors on board discharge their responsibilities of monitoring and providing resource linkage through their active participation in the board meetings. Board effectiveness is dependent on behaviour of directors in board meetings. Active directors' behaviour – i.e. challenging, questioning, informing, encouraging, etc. – is an important driver of board effectiveness (Roberts *et al.*, 2005). Board members' commitment are far more important than board demographics for predicting board task performance (Minichilli *et al.*, 2009). The commitment of board members will depend upon their involvement in the meeting, which refers to their effort during discussions and in the follow-up of decisions taken during the board meetings (Judge and Zeithaml, 1992). Involvement also includes board members' willingness and ability to advance useful questions and to intervene constructively in the board decision-making process. Additionally, for increasing their involvement, the board members must be prepared for the board meeting, which refers to their willingness and ability to participate in board meetings with a deep knowledge of the topics to be discussed to actively contribute to the decision-making process. Preparation is related to the degree to which board members examine information prior to the meetings and take initiatives to collect further information (Forbes and Milliken, 1999). Hence, number of board meetings and an effective participation of directors in these meetings are expected to impact firm performance positively.

3.1.6 Outside busyness of directors. Number of directorship/chairmanship or committee positions in other companies held by directors of a company indicates degree of linkage with external environment and resources. Fama (1980) and Fama and Jensen (1983) note that the market for outside directorships provides an important source of incentives for outside directors to develop reputation as monitoring specialists. This reputation hypothesis tells that by sitting on many boards, an executive learns about different management styles or strategies used in other firms (Perry and Peyer, 2005). Because of their competence and extensive experience, they are more likely to serve on a larger number of board committees than those not holding multiple directorships. This hypothesis, thus, predicts a positive relation between the number of board seats and the number of board committees (Jiraporn *et al.*, 2009).

Ferris *et al.* (2003) has termed directors holding directorship position in multiple companies in terms of *busyness hypothesis*. Multiple directorships permit a firm to use its directors to form or solidify advantageous contracting relations with other firms, such as important suppliers or customers (Ferris *et al.*, 2003). However, individuals holding more outside board seats have less time to spend serving on board committees. At the cost of shareholders, executives may seek outside directorship because it improves their visibility and enhances their status. Large number of appointments can make directors over committed and consequently compromise their ability to monitor company management effectively on behalf of shareholders and adversely affect firm value (Fich and Shivdasani, 2006).

3.2 Uniqueness of Indian corporate governance system

Indian corporate governance system is unique because of certain specific issues as compared to much researched corporate governance system of developed economies. Although Indian corporate governance codes and systems are largely modelled on the developed economies, it is substantially different in terms of sources of corporate governance ills and structures to deal with those ills.

Corporate governance approach in developed economies is hinged on disciplining the management and making them accountable to the owners who are usually dispersed shareholders, whereas in India, it is the stronghold of the majority or dominant shareholder(s) who may use the majority of company resources to serve their own interests. Hence, the "agency cost", which arises out of difference in the interests of managers and shareholders in developed economies, arises out of difference in the interests of majority or dominant shareholders and minority shareholders in India. This applies across the Indian companies with dominant shareholders – public-sector undertakings (government as dominant shareholder), multinational companies (parent company incorporated abroad as dominant shareholder) and private-sector companies (family or business groups and sometimes non-listed holding companies as dominant shareholder).

Apart from this, there is one additional issue in the form of promoter-controlled companies. Promoter(s) in general is(are) person(s) who is(are) involved in incorporation and organization of a corporation. Promoters constitute an important part of companies in Indian context, as most of the companies are of family origin. Promoters (even though may not be the majority shareholders in many cases) are usually present on the board of Indian companies and exercise powers disproportionate to their shareholding.

In the case of developed economies, redressal of the corporate governance issues is addressed through boards and their committees, independent directors, managing CEO succession and the disclosures. In the Indian corporate culture, boards are not as empowered as their counterparts from developed economies, and often, functioning of the boards is fully controlled by the majority or dominant shareholders.

In India, corporate governance reforms started in 1990s with the formation of SEBI in 1992 and subsequent committees (K M Birla committee in 1999, Naresh Chandra Committee in 2002 and Narayan Murthty committee in 2003). Reforms recommended by these committees culminated into insertion of Clause 49 into the listing agreement in 2000 and subsequent insertion of penalty clause in 2004. These reforms called for prominence of independent directors and formation and functions of different board committees as measures to improve corporate governance.

Significant difference also exists in enforcement of corporate governance systems in India and developed economies. Chakrabarti *et al.* (2008) have noted that while on paper, the framework of the country's legal system provides some of the best investor protection in the world, enforcement is a major problem in view of the slow functioning of over-burdened courts and the widespread prevalence of corruption.

The following section considers the above unique aspects of Indian corporate governance system in understanding the hypothesized relationship between board structure and firm performance.

4. Hypotheses development

Impact of board composition on firm performance varies across different studies depending upon the theoretical bases considered by these studies. Agency theory, which is based on the inherent conflict between the firm's owners and its management (Fama and Jensen, 1983), indicates that a greater proportion of outside independent directors help boards to efficiently monitor in the situation of conflict.

Independent directors are invited on the board to oversee management on behalf of shareholders (Baysinger and Butler, 1985). Higher proportion of independent directors on the board may lead to superior financial performance (Baysinger and Butler, 1985) and greater firm value (Mak and Kusnadi, 2005). Hutchinson *et al.* (2008) found that board independence is associated with lower performance-adjusted discretionary accruals, a commonly used measure of earnings management. Outside directors were found impacting firm value positively (Black and Kim, 2012). Kumar and Singh (2012) found that independent director's proportion has an insignificant positive effect on firm value for Indian companies.

Ehikioya (2009) found no evidence to support the impact of board composition on performance. Yammeesri and Kanthi Herath (2010) reported that neither independent directors nor grey directors are significant determinants of firm value. Gill (2013), in an analysis of the central public-sector enterprises in India, has shown that non-compliance with the corporate governance provisions with regard to required number of independent directors on the board did not have any concomitant effect on their performance. Certain studies even indicate that outside directors are negatively related to ROA, earnings per share and market-to-book ratio (Ahmed Sheikh *et al.*, 2013). Kota and Tomar (2010) found that non-executive independent directors fail in their monitoring role.

Significant development has taken place in India for empowering boards through the introduction of Clause 49 of listing agreement in which independence of board has been emphasized. Companies Act 2013 also has provisions for specified number of independent directors ensuring independence of the board. However, true independence of the boards in India is yet to be fully ensured in spirit. This is because of two things, first, supply side constraint for qualified independent directors and second, appointment of directors based on kinship and social and family ties in India (Khanna and Rivkin, 2001).

In this study, monitoring role of the board has been considered of prominence. Agency theory has been taken as a base to analyze the monitoring role of the board and its impact on firm performance. Monitoring by independent directors is supposed to be efficient as it will not involve the clash of interest. Independent directors, because of their experience and to maintain their reputation, do better scrutiny of managerial behaviour, hence ensuring all shareholders' interests. This leads to better firm performance. Considering the above, we propose following hypothesis:

H1. Board independence is positively related to firm performance.

Prior studies have indicated that the leadership structure of the board, particularly role of the CEO, may influence the firm performance. This relationship is contingent upon the ability of a CEO to influence decisions (Adams *et al.*, 2005), which in fact is based on the power a CEO has (Finkelstein, 1992). Corporate governance reforms worldwide advocated separation of the role of CEO and chairman of the board. This was based on the premise that the one of the important tasks of the board is to evaluate and control the behaviour of top management including that of the CEO. In that case, if CEO himself/herself is the leader of the group responsible for evaluating and taking decisions in this regard, the process may get biased impacting firm performance negatively. Agency theory predicts that the separation of the chairman and CEO roles leads to a greater scrutiny of managerial behaviour, which further leads to a better performance (Lorsch and MacIver, 1989). On the other hand, stewardship theory predicts that decision-making under the unified leadership (having both the roles chairman and CEO) leads to better performance (Donaldson and Davis, 1991).

Empirical evidence suggests that the relationship between CEO duality and accounting performance is contingent on the presence of family control factor. CEO duality is good for non-family firms, and while non-duality is good for family-controlled firms. CEO duality has significant positive impacts on profitability (Abor and Biekpe, 2007). CEO duality is positively related to earnings per share (Ahmed Sheikh *et al.*, 2013; Kamal Hassan and Saadi Halbouni, 2013).

On the contrary, Ehikioya (2009) reported that there is significant evidence to support that CEO duality adversely impacts firm performance. CEO duality leads to a higher incidence of bad news disclosure, suggesting increased scrutiny works (Collett and Dedman, 2010). This may lead to lower market valuation and increased cost. Considering the Indian corporate scene with dominance of promoters and business groups having family-related CEOs possessing disproportionate power in the board, we arrive at our next hypothesis:

H2. Chief executive officer duality is negatively related to firm performance.

Prior studies have studied the relationship between board size and firm performance from two different theoretical perspectives; resource dependency theory and theory of group cohesiveness. Resource dependency theory predicted that a board of directors with high level of links to the external environment would improve company's access to various resources, thus improving corporate governance and firm performance (Jackling and Johl, 2009). However, theory of group cohesiveness indicates that with increased size, board faces problems of poor coordination and slow decision-making. Jensen (1993) indicated that when the board size is more than seven or eight, the board is less likely to function effectively.

There is an inverse relationship between board size and firm performance measured by Tobin's Q (Yermack, 1996; Eisenberg *et al.*, 1998), because of lack of coordination and communication associated with a large board. It becomes more difficult for all directors to express their ideas and opinions in limited time available when a board has more than ten members (Lipton and Lorsch, 1992). On the other hand, small boards augment monitoring capabilities (Yermack, 1996; Khanchel, 2007) and are more efficient (Garg, 2007).

As indicated in various studies, there is an optimum size of the board for maximum performance, so below the optimum size, it is expected that board size will have a positive relationship with performance, whereas above optimum size, board size will have a negative relationship. This is in line with earlier studies, for example, Cormier *et al.* (2010), Golden and Zajac (2001) and Vafeas (1999). Larger boards are likely to have higher coordination costs, which reduces their ability to effectively monitor management (Fauzi and Locke, 2012). Differences in findings of the relationship between board size and firm performance may be also due to firm-specific factors such as firm size and firm age (Bennedsen *et al.*, 2008).

In the Indian context, prominence of promoter-based and family-based companies generally restrict director's position to kinship and family members. So, more number of directors is expected to add more resource capability in line with resource dependency theory. However, inducting directors beyond kinship may not add value. First, because of lack of adequately qualified outside directors in sufficient numbers and second, the directors outside kinship may not gel with the internal directors leading to slow decision-making, resulting into inferior performance. Companies Act 2013 also specifies minimum and maximum number of directors, indicating that increasing the number of directors may not have a monotonically increasing effect on firm performance. This leads to following hypotheses:

H3. Board size is negatively related to firm performance.

H3a. Relation between board size and firm performance is different for smaller companies in comparison to larger companies.

H3b. Relation between board size and firm performance is different for smaller board companies in comparison to larger board companies.

Board of directors achieve monitoring through board meetings; hence, number of board meetings is a good proxy for the monitoring effects of directors (Vafeas, 1999). Vafeas (1999) demonstrated that boards meet more often during periods of turmoil, and that a board meeting more often shows improved financial performance. A board that meets more often should be able to devote more time to issues such as earnings management. A board that seldom meets may not focus on these issues and may perhaps only approve the management decisions. Lipton and Lorsch (1992) suggested that the greater frequency of meetings is likely to result in a superior performance. Hence, the following hypothesis is presented:

H4. Number of board meeting is positively related to firm performance.

Monitoring function and resource providing function of board would be established through board meetings. As indicated in various prior studies (Jackling and Johl, 2009; Minichilli *et al.*, 2009; Forbes and Milliken, 1999), the effectiveness of the board and subsequent firm performance depends on number of times the meeting happens and the "quality of meetings". When the directors attend at least 75 per cent of the meetings, it leads to an enhanced firm valuation (Brown and Caylor, 2004). Board activity has been found to positively impact firm value (Brick and Chidambaran, 2010). In the present study, internal busyness of directors has been measured in terms of average participation of board meetings, which is in line with earlier studies done in the Indian context (Mishra and Mohanty, 2014). This leads to our next hypothesis:

H5. Directors' internal busyness is positively related to firm performance.

Busyness hypothesis has been propounded to reflect the number of positions that directors accept on different company boards (Ferris *et al.*, 2003). In this paper, external busyness of directors has been measured in terms of average number of directorship and committee positions held in other companies by the directors of the company. Studies have found that directors with multiple appointments have a positive impact on firm performance (Harris and Shimizu, 2004; Ferris *et al.*, 2003). This is based on the presumption that they have networks and corporations and would benefit by accessing these resources (Booth and Deli, 1996).

In this regard, some studies (Fich and Shivdasani, 2006) view that a large number of appointments make directors over committed, which leads to a compromise over monitoring function affecting firm value adversely. In the studies done in the Indian context, it has been pointed out that multiple directorship is also because of supply constraint in directors market owing to lack of industrial leadership and adequacy of experience (Jackling and Johl, 2009). Family control of business groups leads to directorship position held under kinship and social ties (Khanna and Rivkin, 2001). Hence, outside directorship may not have a positive association with firm value, and this leads to our last hypothesis:

H6. Directors' external busyness is negatively related to firm performance.

5. Data, model and methodology

5.1 Data
